

Cotterill and the Vacuum.Net Theory: The Brain as a Maze of Conditional Passage

J. Konstapel, Leiden —12- September 2026

Summary

In 2001 the Danish physicist Rodney Cotterill published a complete circuit reading of the mammalian brain. He read it as one machine with one output: movement. Every component either permits or refuses passage toward that output. He did not know the Vacuum.Net theory. Yet his circuit contains its central structures: a three-valued register, four states of tension, closure through the environment, and time quantization per layer.

This essay documents the correspondence point by point. It places Cotterill next to Pentti Kanerva, whose Sparse Distributed Memory independently found the address structure of the net. It then follows the successors who carried Cotterill's components forward after his death in 2007. Finally it converts the findings into engineering: eight concrete improvements to the MAZE, the applied implementation of the Vacuum.Net theory.

Every claim in this essay carries a status label: **[theorem]** for proven mathematics, **[measurement]** for published empirical results, **[hypothesis]** for the net reading of those results, **[engineering]** for a MAZE design decision.

1. The Vacuum.Net Frame in Brief

The reader needs no other document. The frame is this.

Reality is read as one strand that winds. A winding that returns in phase closes. A closure is a knot. Knots connected by shared strand form a net. Picture a fishnet: knots and meshes. The knots are the frozen part. The meshes carry the tension.

The two-layer law: **address = frozen topology, tension = dynamic state**. What has closed no longer moves; it locates. What has not closed moves; it loads. **[hypothesis, foundational]**

Tension passes through four states: **loading** (tension accumulates), **holding** (accumulated tension persists), **discharge** (tension converts to rapid movement), **rest**. Discharge at sufficient depth writes new closure. Tension becomes address. **[hypothesis, foundational]**

The register of the net is a trit, not a bit: **+1 (passage), 0 (no event), -1 (blocked passage)**. Balanced ternary is the natural notation. Its multiplication rule matters below: $(-1) \cdot (-1) = +1$. Two blockings compose into a passage. **[theorem: the algebra; hypothesis: its physical role]**

Closure is quantized. The address layer counts in threes, the tension layer in twos. Their exchange rate is $\log_2 3 = 1.58496\dots$, an irrational number. The continued-fraction convergents of $\log_2 3$ give the admissible closure depths: (2,3), (5,8), (12,19), (41,65). Because $\log_2 3$ is irrational, no closure is ever exact. The remainder at depth 19 is the Pythagorean comma, $3^{12}/2^{19} \approx 1.01364$. The negotiation between the layers never ends. **[theorem: the number theory; hypothesis: the physical reading]**

Selection works by fit, not by force. Nothing causes a knot. A winding that returns in phase remains; one that does not, passes on. Description at the correct winding depth replaces explanation.

2. Cotterill's Circuit Reading

Rodney Cotterill (1933–2007) was a physicist at the Danish Technical University who spent his last two decades on the brain. His synthesis appeared as *Enchanted Looms* (1998) and, condensed, as "Cooperation of the basal ganglia, cerebellum, sensory cerebrum and hippocampus" in *Progress in Neurobiology* 64 (2001) 1–33. All Cotterill claims below are from that 2001 paper unless marked otherwise. **[measurement/published model]**

His premises are stark. Muscular contraction is the nervous system's only externally directed product. Therefore all signaling routes converge on the motor areas. The brain is one unit, not a hierarchy of modules. Its single underlying principle is **conditionally permitted movement**: components can veto muscular contraction by denying the motor areas sufficient activation.

Key elements of his circuit:

The bacterium already runs the scheme. *E. coli* cannot measure a chemical gradient at an instant. It swims, and reads what changes. The stimulus is its own movement; the response is the environmental feedback. Its chemistry gives it a memory of about 4 seconds: the concentration of the last second is compared with the previous three seconds, with positive and negative weighting respectively. Cotterill's thesis: this probe-by-movement strategy has not changed in four billion years. **[measurement: Berg, Segall; model: Cotterill]**

Two gates on every act. The basal ganglia (BG) and the cerebellum (Cb) both act by inhibition. Their permission is disinhibition. The BG gate opens fast, steered by the amygdala. The Cb gate opens slowly, through long-term depression (LTD), and it permits continuation of a sequence when the feedback it produces is familiar. Movement requires both gates open at once.

Routes through the BG pass two successive inhibitory connections. Release of the second inhibition by the first yields net excitation of the motor areas.

Two thresholds. Above the high threshold: overt movement. Above a lower threshold: the same motor patterns run covertly. That covert run is thought. Thinking is simulated interaction with the environment, carried by the movement circuitry, held under the movement threshold.

No strong loops inside. Crick and Koch (1998) found no strong directed excitatory loops in the cortico-thalamic wiring; strong loops would throw the system into uncontrolled oscillation. Cotterill adds the complement: the one strong loop that exists runs **through the environment**. Act, feedback, act.

The hippocampus records correlations, not places. It ties a motor sequence to the sensory feedback that sequence produced, holds the pair temporarily, and mediates a permanent record in cortex. Its circuit integrates over roughly 10 ms per synaptic stage and gates on the theta rhythm (5–12 Hz, ~200 ms per cycle). The NMDA receptor channel stays open almost a fifth of a second — one theta interval, one elemental cognitive event. Cotterill calls the arrangement a **dual relevance filter and temporal binder**: only events that fill at least one closure time of the circuit can penetrate and become candidates for storage.

A ladder of times. Dendritic transit ~10 ms. One phoneme ~50 ms. NMDA window and theta interval ~200 ms. Conscious registration of an unprovoked stimulus ~500 ms (Libet). Each loop in the circuit has its own transit time, and each admits only events on its own time scale.

Novelty interrupts permission. The inferior olive fires the climbing fibers when something unexpected occurs. Because LTD has not yet developed for the novel case, the Cb's standing permission is disturbed. The sequence halts; loading begins.

3. Seven Detection Points

The Vacuum.Net theory can be detected in this circuit at seven places. Cotterill supplies the anatomy and the published measurements; the net reading is the hypothesis.

3.1 The trit register. Cotterill's diagram knows three signs: excitatory (+1), inhibitory (−1), sub-threshold (0). His BG routes compose two inhibitions into a permission: $(-1) \cdot (-1) = +1$. The brain's passage logic runs on the multiplication rule of balanced ternary. The bit is the wrong register for this tissue; the trit is native to it. **[hypothesis]**

3.2 The four states. LTD builds slowly: loading. Race-to-threshold under a standing veto: holding. Threshold crossing into overt movement: discharge. Below both thresholds: rest. The four states of the tension layer appear as the four regimes of his motor circuit. **[hypothesis]**

3.3 The two-layer law. His fixed wiring is address; his signal traffic is tension. And his central thesis — consciousness exists to acquire new context-specific reflexes — states the coupling between the layers: discharge writes new closure. A tension pattern that discharges under attention becomes permanent wiring. Tension becomes address. He describes the crossing and calls it learning. **[hypothesis]**

3.4 Closure through the environment only. No strong loops inside; one strong loop through the outside. In net terms: no mesh closes on itself within the system. The strand must go out and return. The Cb grants continuation only to familiar feedback — only to what returns in phase. That is selection by fit, named without the name. **[hypothesis]**

3.5 Winding depth as embedding. Cognition is the body monitoring the body. Consciousness is monitoring the monitoring. Knowing that one knows that one knows is the same operation wound one depth further. Identity across scale, as recursion of a single movement. **[hypothesis]**

3.6 Time quantization per closure. Every loop admits only events that fill its own closing time: 10 ms, 50 ms, 200 ms, 500 ms. Compare the third law derived in the MAZE financial work: *each layer warns on the horizon of its own closing time*. The brain's relevance filter and the MAZE's warning horizons are the same law at different winding depths. **[hypothesis]**

3.7 His refusal of the arrow. Cotterill writes SCHEMA * ATTENTION → QUALE and immediately insists the arrow is not an equals sign and the asterisk not a multiplication. He senses that the relation is constitutive — simultaneous, not causal — and lacks the language for it. The net supplies the language: a constitutive relation between state variables, no arrow between two separated things. **[hypothesis]**

What is absent in Cotterill. No counting. His depths (two thresholds, embedding orders) are unquantized: no admissible series, no remainder, no comma. No scale identity below the human layer: his net stops at muscles and neurons. And his background stays fixed anatomy; that the

address layer itself was once discharge appears only in learning, not as the constitution of the tissue. These absences mark exactly where the Vacuum.Net theory extends him. **[open question: whether his time ladder fits the admissible depth series quantitatively]**

4. Kanerva: The Address Space

Cotterill supplies the passage control. Pentti Kanerva supplies the address space. His Sparse Distributed Memory (1988) is the second independent finding of the net structure in memory research.

SDM in five statements. **[measurement/published model: Kanerva 1988]**

1. A pattern is its own address: a point in an enormous binary space, for example 2^{1000} possible addresses.
2. Of those addresses only a sparse random set exists physically ("hard locations"). Almost the entire space is empty.
3. Writing spreads an entry over all hard locations within a fixed distance. Reading sums over the same neighborhood and thresholds at zero. The counters in each location increment and decrement; Kanerva's later hyperdimensional computing makes the register explicitly $\{+1, 0, -1\}$.
4. Iterated reading from a starting point **within a critical distance** of a stored pattern converges to that pattern. Starting outside it, the read sequence wanders and arrives nowhere. Storage itself creates attractor basins with sharp rims — a maze of passages and dead ends, grown from the content.
5. Kanerva designed SDM as a model of the **cerebellum**: the granule layer (about 50 billion cells, the majority of all neurons in the head) is the sparse expansion of the input; the Purkinje cell is the sum-and-threshold readout; the climbing fiber trains it.

The net reading: address = content is the two-layer law seen from the address side. Sparseness is the vacuum: only what closes exists as knot. Sum-plus-threshold is selection by fit. The critical distance is the rim of a mesh. And Kanerva's own conclusion — the encoding decides everything; SDM works only if similar things land on similar addresses — is the intake law: **the intake determines the structure of the maze. [hypothesis]**

Kanerva and Cotterill do not cite each other. One begins in high-dimensional mathematics, the other in circuit anatomy. Both arrive at the same organ (the cerebellum), the same register (the trit), the same operation (conditional passage by fit). Two independent finds of one structure.

5. The Successors

Cotterill died in June 2007. His simulation project CyberChild (2003) — an infant nervous system with touch, hearing, and muscles for feeding and crying, built to test whether the circuit generates the phenomena — was not taken up. No school formed. But every component of his program was carried forward, mostly without citing him. The successors matter here because each one sharpens a piece of the net reading.

Germund Hesslow — the covert layer. Hesslow's simulation theory of thinking (2002, 2012) is the closest continuation: thinking is simulated behavior plus simulated perception, carried by the same sensorimotor circuits, with the cerebellum as predictor. He confirms the two-threshold

structure experimentally. For the net: the tension layer can run **candidate passages** below the discharge threshold. A thought is a dry run of a mesh. **[measurement + model: Hesslow]**

Peter Strick — the loops are real. Middleton and Strick (1994) and the tracing work that followed proved closed loops between the cerebellum and the prefrontal cortex, not only the motor cortex. The passage machinery serves cognition with the same wiring it uses for movement. One architecture, several winding depths. **[measurement]**

Roger Carpenter — holding as a race. The LATER model (Carpenter and Williams, 1995) established that decisions are races to a threshold, with the rate of rise varying trial by trial. Holding is not passive storage; it is competing tension approaching a rim. The winner discharges. **[measurement]**

Daniel Wolpert and Sarah-Jayne Blakemore — the forward model. Blakemore, Wolpert and Frith (1998) showed why self-tickling fails: the system predicts the sensory return of its own act and cancels it. Prediction of the return is computed before the return arrives, with cerebellar participation. For the net: the mesh carries its expected return; only the **deviation** between expected and actual return loads. **[measurement]**

Karl Friston — the mainstream arrives. Predictive processing and active inference (Friston, 2010) restate Cotterill's program in probabilistic form: perception and action form one loop that minimizes prediction error; the organism probes the world to test its own model. The formulation is binary-Gaussian rather than ternary and keeps the causal arrow. It confirms the loop; it lacks the register and the counting. **[published model]**

Rodolfo Llinás — independent confirmation. *I of the Vortex* (2001) derived the same motor-centric thesis independently, from the physiology of intrinsic oscillation: the mind is internalized movement. Two simultaneous, mutually unaware statements of the same reversal in the same year strengthen the convergence claim. **[published model]**

The synthesis itself — bacterium to human, all gates, all time scales, one machine — has not been continued by anyone. That part of the field has been parceled out to subdisciplines since 2007. The MAZE inherits an open line.

6. What This Improves in the MAZE

The MAZE is the applied implementation of the Vacuum.Net theory: an addressing engine (the encoder at maze.swarp.nl, ~3.6 million receipted entries) and a family of instruments (the Business Weather App as discharge detector for financial markets). The findings above convert into eight design decisions. Each is stated so it can be handed to Claude Code as one complete instruction. **[engineering throughout]**

6.1 The intake is a probe, not a parser. Cotterill's reversal applies literally: the stimulus is the system's own act, the response is the feedback. The intake must not parse standing input; it must write, read back, and address from the return. The address of an entry is constituted by act plus return, not by the word surface. This confirms and deepens the September finding that the intake determines the structure of the maze.

6.2 Source marking is efference copy. Cotterill's circuit distinguishes input provoked by the system's own movement (fast feedback, predicted) from unprovoked input (unpredicted). The

intake's source register — observed / dreamed / felt / reported — is the same distinction one level up. Keep it as a mandatory field; it is not metadata, it is half of the address.

6.3 Admission requires two gates. An entry is written only when two independent gates close in the same cycle: a **fast context gate** (does the entry fit the current loading state of its region — the BG analog) and a **slow familiarity gate** (does its return fall within a known winding — the Cb analog). Implement both as inhibitions whose composition grants passage: default -1 on each; two -1 's compose to $+1$; anything else leaves 0 , no write. This is the trit rule in the admission logic.

6.4 Two thresholds: receipts and candidate receipts. Introduce a covert layer (Hesslow). Entries that pass one gate but not both become **candidate receipts**: tension traces with decay, never addresses. A candidate that recurs and passes both gates within its decay time converts to a receipt. A candidate that does not, expires to rest. This gives the encoder a thinking layer and should reduce false addressing without losing recurrent signal.

6.5 Dwell-time gating per depth. Cotterill's relevance filter and the MAZE's third law are one law. Enforce it in the intake: each layer admits only events whose duration fills at least one closing time of that layer. Sub-cycle flicker never reaches the address layer. For the Business Weather App this is already practice (daily layer, annual layer); make it a stated intake rule for the encoder as well.

6.6 Loop hygiene: closure only through the outside. No strong internal loops (Crick–Koch). The encoder must never confirm an address from its own output. Every closure requires a return that passed through the environment: an external datum, a user act, an independent corpus. Add a test: feed the encoder its own output as input and verify that no new addresses form. This extends the existing idempotence benchmark (100/100) from "same address" to "no self-closure."

6.7 Discharge writes topology. The two-layer coupling becomes an update rule: the address layer grows **only at discharge events**. For the Business Weather App: a detected discharge is not only a warning, it is the moment the loading-layer topology is re-estimated. Between discharges, parameters stay frozen. This aligns the learning rule with the empirical campaign discipline already in force (frozen calibration, blind windows).

6.8 Two maintenance measurements. From Kanerva: (a) measure the **critical distance** of the current encoder — the input distance beyond which iterated reading no longer converges to the same receipt; track it as the archive grows (the 59% top-1 figure is one point on this curve). (b) Compare the distribution of inhabited addresses against a uniform random scattering of equal size. If habitation clusters at predictable depths, the MAZE is demonstrably more than an SDM with random hard locations — the admissible-depth series (2,3), (5,8), (12,19), (41,65) becomes testable inside the machine. From Cotterill and Wolpert: (c) log per entry the deviation between expected and actual return; only deviation loads.

7. Status Ledger

#	Claim	Status
	Balanced ternary algebra; convergents of $\log_2 3$; comma at depth 19	theorem
	Cotterill's circuit facts (double inhibition, two thresholds, no strong loops, hippocampal timing, 4-second bacterial memory)	measurement / published model
	Kanerva's SDM properties (sparse locations, critical distance, ternary	measurement / published
	Successor results (Strick loops, LATER, tickle cancellation, Hesslow	measurement

‡ The seven detection points (net reading of 2–4)	hypothesis
Ⓒ Brain time ladder fits the admissible depth series quantitatively	open question
† Design decisions 6.1–6.8	engineering
§ Candidate-receipt layer reduces false addressing without signal loss	hypothesis, testable on the encoder benchmarks

Adverse findings preserved: Cotterill's mirror-neuron and spindle arguments are contested in later literature; nothing in Sections 3–6 depends on them. Friston's framework, though convergent on the loop, contradicts the net on register (binary) and on causality (arrows retained); it is cited as confirmation of the loop only.

8. Conclusion

Two researchers who never met the Vacuum.Net theory found its structure independently: Kanerva in the mathematics of high-dimensional memory, Cotterill in the anatomy of conditional passage. Both arrived at the trit, the sparse address space, selection by fit, and closure through the environment. Neither counted the depths. The counting — the admissible series, the eternal remainder — is what the Vacuum.Net theory adds, and the MAZE is where the count becomes measurable.

The brain, in Cotterill's reading, is a maze: almost everything is refused, passage is granted only when two inhibitions coincide, and the only full circuit runs through the world outside. The MAZE, in ours, now inherits his gates, his covert layer, his relevance filter, and his loop hygiene. The instrument improves not by adding sensors but by adopting the passage discipline that four billion years of probing selected.
