# Where Illness Comes From, Completed

J. Konstapel, Constable Research, Leiden

# Contents

**Where Illness Comes From, Completed** **12**
A Reference Work on Every Chapter of Human Illness, Its Prevention, Its Cure, and What Can Be Done With Simple Means . . . 12
How to use this book . . . 12
Why the book was rewritten . . . 13

**Part 0 — The Rules This Book Follows** **15**

**Part 0 — The Rules** **16**
0.1 The net . . . 16
0.2 The five starting rules . . . 16
0.3 The register . . . 17
0.4 Closure, windows and rings . . . 17
0.5 The two classes . . . 18
0.6 The test . . . 18
0.7 Widening and pruning . . . 18
0.8 The ladder . . . 19
0.9 Constants as states . . . 19
0.10 What a reading is . . . 19
0.11 The dictionary . . . 20

**Part 1 — How Illness Is Read** **21**

**Part 1 — How Illness Is Read** **22**
1.1 First chemistry . . . 22
1.2 The cell . . . 22
1.3 The test layer . . . 23
1.4 Where cancer sits . . . 23
1.5 Where ageing sits . . . 24
1.6 Where the mind sits . . . 24
1.7 What this frame changes in practice . . . 24

**Part 2 — The Illnesses** **26**

**Chapter 01 — Certain Infectious or Parasitic Diseases** **27**
Tuberculosis . . . 28
HIV/AIDS . . . 30
Malaria . . . 31
Lower respiratory infections — pneumonia . . . 33
Influenza (seasonal) . . . 36
Respiratory syncytial virus (RSV) . . . 37
Diarrhoeal diseases (overview) . . . 38
Rotavirus . . . 40
Cholera . . . 41
Shigellosis . . . 43
Pathogenic *Escherichia coli* (including ETEC and STEC) . . . 44
Cryptosporidiosis . . . 45
Measles . . . 47

Hepatitis A . . . 48
Hepatitis B . . . 50
Hepatitis C . . . 52
Hepatitis E . . . 53
Sepsis and neonatal sepsis . . . 55
Bacterial meningitis . . . 57
Typhoid and paratyphoid fever . . . 58
Dengue . . . 60
COVID-19 . . . 62
Pertussis (whooping cough) . . . 64
Tetanus (including neonatal tetanus) . . . 66
Diphtheria . . . 68
Rabies . . . 70
Schistosomiasis . . . 72
Soil-transmitted helminths . . . 74
Lymphatic filariasis . . . 76
Onchocerciasis (river blindness) . . . 79
Leishmaniasis . . . 81
Chagas disease (American trypanosomiasis) . . . 83
Human African trypanosomiasis (sleeping sickness) . . . 85
Leprosy (Hansen disease) . . . 87
Trachoma . . . 89
Scabies . . . 92
Syphilis (including congenital syphilis) . . . 97
Gonorrhoea . . . 99
Chlamydia . . . 101
Varicella (chickenpox) and herpes zoster (shingles) . . . 102
Ebola virus disease and other viral haemorrhagic fevers . . . 105
Antimicrobial resistance (cross-cutting) . . . 107

**Chapter 02 — Neoplasms 112**
The entries . . . 113
1. Lung cancer . . . 113
2. Colorectal cancer . . . 114
3. Stomach cancer . . . 116
4. Liver cancer . . . 118
5. Breast cancer . . . 119
6. Cervical cancer . . . 121
7. Prostate cancer . . . 123
8. Pancreatic cancer . . . 125
9. Oesophageal cancer . . . 127
10. Bladder cancer . . . 129
11. Kidney cancer . . . 131
12. Ovarian cancer . . . 132
13. Endometrial cancer . . . 135
14. Thyroid cancer . . . 137
15. Melanoma of the skin . . . 139
16. Keratinocyte skin cancer — basal cell and squamous cell carcinoma . . . 142
17. Brain and central nervous system tumours . . . 145
Leukaemias . . . 147
18. Acute myeloid leukaemia . . . 148
19. Acute lymphoblastic leukaemia . . . 150
20. Chronic myeloid leukaemia . . . 153
21. Chronic lymphocytic leukaemia . . . 155
22. Hodgkin lymphoma . . . 158
23. Non-Hodgkin lymphoma . . . 161
24. Multiple myeloma . . . 165
25. Head and neck cancer . . . 169
26. Nasopharyngeal carcinoma . . . 173
27. Testicular cancer . . . 176

28. Sarcomas of soft tissue and bone . . . 180
Childhood cancer . . . 185
29. Childhood cancer as a class . . . 185
30. Neuroblastoma . . . 188
31. Wilms tumour . . . 190
32. Medulloblastoma . . . 192
33. Retinoblastoma . . . 195
Benign neoplasms of clinical importance . . . 198
34. Uterine fibroids . . . 198
35. Colonic adenomas . . . 203

**Cross-cutting sections** **207**
A. The autopsy evidence, and why it predicts overdiagnosis . . . 207
The pattern across the three organs . . . 208
B. Where overdiagnosis has never been quantified . . . 208
C. The preventable fraction of all cancer . . . 209
What the preventable fraction does and does not mean . . . 210
D. Childhood cancer: mutation burden and its clinical consequence . . . 211
E. Oral morphine and palliative care . . . 212
F. Price, and the two ends of one list . . . 212
F.1 Cure at early stage with nothing on patent . . . 212
F.2 Cure at metastatic stage with nothing on patent . . . 213
F.3 Not curable at any stage . . . 213
F.4 The price range, in one place . . . 214
F.5 Two statements the table makes unavoidable . . . 215
G. What is thin in this chapter . . . 215

**Chapter 12 — Blood, Immunity, and the Endocrine, Nutritional and Metabolic Diseases** **218**
ICD-11 chapters 03, 04 and 05 . . . 218
Introduction . . . 218
— . . . 219

**Diseases of the blood or blood-forming organs** **220**
ICD-11 chapter 03 . . . 220
Iron deficiency anaemia . . . 220
Vitamin B12 and folate deficiency . . . 222
Sickle cell disease . . . 224
Thalassaemias . . . 226
Glucose-6-phosphate dehydrogenase deficiency . . . 229
Aplastic anaemia . . . 230
Haemophilia A and B . . . 232
Von Willebrand disease . . . 235
Immune thrombocytopenia . . . 237
Haemochromatosis . . . 239
Polycythaemia vera . . . 241
Myelodysplastic syndromes . . . 243
— . . . 245

**Diseases of the immune system** **246**
ICD-11 chapter 04 . . . 246
Primary immunodeficiencies as a class . . . 246
Common variable immunodeficiency . . . 248
Severe combined immunodeficiency . . . 251
Hereditary angioedema . . . 254
Allergic rhinitis . . . 256
Food allergy . . . 257
Anaphylaxis . . . 260
Drug allergy . . . 263
Sarcoidosis . . . 266

Systemic lupus erythematosus . . . 269
Sjögren syndrome . . . 273
Systemic sclerosis . . . 276
The vasculitides . . . 280
Antiphospholipid syndrome . . . 285
— . . . 288

**Endocrine, nutritional and metabolic diseases 289**
ICD-11 chapter 05 . . . 289
Type 1 diabetes . . . 289
Type 2 diabetes . . . 294
Gestational diabetes . . . 300
Obesity . . . 304
Protein-energy malnutrition . . . 309
Vitamin A deficiency . . . 314
Iodine deficiency disorders . . . 317
Zinc deficiency . . . 321
Rickets and vitamin D deficiency . . . 324
Hypothyroidism . . . 328
Hyperthyroidism and Graves disease . . . 332
Thyroid nodules and goitre . . . 336
Adrenal insufficiency . . . 339
Cushing syndrome . . . 343
Acromegaly . . . 347
Osteoporosis . . . 351
Gout and hyperuricaemia . . . 355
Dyslipidaemia . . . 360
Metabolic syndrome . . . 365
Phenylketonuria . . . 369
Cystic fibrosis . . . 373
Lysosomal storage diseases (Gaucher, Fabry, Pompe) . . . 378
Hereditary metabolic disorders screened for at birth . . . 383

**Chapter 13 — Mental, Sleep-Wake and Nervous System Conditions 389**

**06 — Mental, behavioural and neurodevelopmental disorders 391**
Depressive disorders . . . 391
Bipolar disorders . . . 393
Generalised anxiety disorder . . . 394
Panic disorder . . . 395
Social anxiety disorder . . . 396
Obsessive-compulsive disorder . . . 397
Post-traumatic stress disorder . . . 398
Schizophrenia and other primary psychotic disorders . . . 399
Alcohol use disorder . . . 402
Opioid use disorder . . . 403
Stimulant use disorders . . . 405
Cannabis use disorder . . . 406
Tobacco dependence . . . 407
Gambling disorder . . . 409
Feeding and eating disorders . . . 410
Suicide and self-harm . . . 412
Personality disorders . . . 413
Autism spectrum disorder . . . 415
Attention deficit hyperactivity disorder . . . 417
Intellectual developmental disorders . . . 418
Dementia and neurocognitive disorders . . . 421

**07 — Sleep-wake disorders 425**
Insomnia disorder . . . 425

Obstructive sleep apnoea . . . 427
Central sleep apnoea . . . 429
Narcolepsy . . . 430
Restless legs syndrome . . . 431
Delayed sleep-wake phase disorder . . . 432
Shift work disorder . . . 434
Jet lag . . . 435
Non-REM parasomnias . . . 435
REM sleep behaviour disorder and nightmare disorder . . . 436

**08 — Diseases of the nervous system 438**
Alzheimer disease . . . 438
Parkinson disease . . . 439
Stroke . . . 442
Stroke sequelae . . . 444
Epilepsy . . . 445
Multiple sclerosis . . . 448
Motor neurone disease and amyotrophic lateral sclerosis . . . 450
Migraine . . . 452
Tension-type headache . . . 454
Cluster headache . . . 456
Diabetic neuropathy . . . 457
Chemotherapy-induced peripheral neuropathy . . . 459
Guillain-Barré syndrome . . . 460
Myasthenia gravis . . . 461
Cerebral palsy . . . 463
Huntington disease . . . 465
Trigeminal neuralgia . . . 467
Essential tremor . . . 469
Meningitis sequelae . . . 470
Spinal cord injury consequences . . . 472
What no longer holds . . . 475

**Chapter 14 — ICD-11 Chapters 09, 10 and 14: the visual system, the ear, the skin 477**
The widest gap in the book between what a thing costs and what it returns . . . 477

**ICD-11 Chapter 09 — Diseases of the visual system 479**
Global totals for vision . . . 479
Hyperopia and astigmatism . . . 496
Presbyopia . . . 496
Cataract . . . 497
Glaucoma — primary open-angle . . . 499
Glaucoma — primary angle-closure . . . 500
Age-related macular degeneration — wet (neovascular) . . . 515
Diabetic retinopathy . . . 516
Trachoma . . . 518
Retinal detachment . . . 534
Amblyopia and strabismus . . . 535
Dry eye disease . . . 536
Conjunctivitis . . . 538
Vitamin A deficiency blindness (xerophthalmia, keratomalacia) . . . 555
Retinopathy of prematurity . . . 556
Optic neuritis . . . 558
Age-related hearing loss (presbycusis) . . . 570
Noise-induced hearing loss . . . 572
Otitis media — chronic suppurative . . . 586
Otitis externa . . . 588
Cerumen impaction . . . 589
Ménière disease . . . 604
Benign paroxysmal positional vertigo . . . 605

Vestibular neuritis and labyrinthitis . . . 607
Ototoxicity . . . 627
Atopic dermatitis (eczema) . . . 632
Psoriasis . . . 634
Acne vulgaris . . . 636
Urticaria (hives) . . . 656
Rosacea . . . 657
Vitiligo . . . 659
Fungal skin infections (tinea and cutaneous candidiasis) . . . 676
Bacterial skin infections (impetigo and cellulitis) . . . 678
Seborrhoeic dermatitis . . . 684
Venous leg ulcers . . . 701
Chronic wounds . . . 721
Hidradenitis suppurativa . . . 723
Bullous pemphigoid . . . 725
Burns and their skin consequences . . . 726

**ICD-11 Chapters 11 and 12 — The Circulatory System and the Respiratory System 730**
Introduction . . . 730
Both chapters in figures . . . 732
The two risk-factor studies behind this chapter . . . 733
INTERHEART . . . 733
INTERSTROKE . . . 734

**Chapter 11 — Diseases of the circulatory system 735**
Blood pressure and the arteries of the heart . . . 735
Hypertension (ICD-11 BA00) . . . 735
Ischaemic heart disease and myocardial infarction (ICD-11 BA40–BA4Z) . . . 738
Stable angina (ICD-11 BA40.0) . . . 743
The failing pump . . . 744
Heart failure with reduced ejection fraction (ICD-11 BD10–BD1Z) . . . 744
Heart failure with preserved ejection fraction (ICD-11 BD1Z) . . . 748
Rhythm . . . 750
Atrial fibrillation (ICD-11 BC81.3) . . . 750
Other arrhythmias (ICD-11 BC63–BC9Z) . . . 753
The arteries of the brain . . . 756
Ischaemic stroke (ICD-11 8B11) . . . 756
Haemorrhagic stroke — intracerebral haemorrhage (ICD-11 8B00) . . . 759
Subarachnoid haemorrhage (ICD-11 8B01) . . . 762
The peripheral arteries and the veins . . . 765
Peripheral arterial disease (ICD-11 BD40–BD4Z) . . . 765
Aortic aneurysm (ICD-11 BD50–BD5Z) . . . 767
Deep vein thrombosis and pulmonary embolism — venous thromboembolism (ICD-11 BD71, BB00) . . . 770
Varicose veins and chronic venous insufficiency (ICD-11 BD74, BD72) . . . 773
The valves, the muscle and the sac . . . 776
Rheumatic heart disease (ICD-11 BA00–BA0Z, 1B40–1B41) . . . 776
Cardiomyopathies (ICD-11 BC43) . . . 779
Congenital heart disease (ICD-11 LA80–LA8Z) . . . 782
Infective endocarditis (ICD-11 BB40) . . . 786
Pericarditis (ICD-11 BB20) . . . 788
Pulmonary hypertension (ICD-11 BB01) . . . 792
Cardiac arrest (ICD-11 MC82) . . . 796

**Chapter 12 — Diseases of the respiratory system 801**
The obstructed airway . . . 801
Chronic obstructive pulmonary disease (ICD-11 CA22) . . . 801
Asthma (ICD-11 CA23) . . . 806
Infection and scarring of the lung . . . 810
Pneumonia (ICD-11 CA40) . . . 810

Bronchiectasis (ICD-11 CA24) . . . 815
Pulmonary fibrosis and interstitial lung disease (ICD-11 CB03, CB04) . . . 819
Occupational lung diseases: silicosis, asbestosis and coal workers' pneumoconiosis (ICD-11 CA60–CA6Z) . . . 823
The upper airway, the sleeping airway, and the pleural space . . . 827
Sleep-disordered breathing — obstructive sleep apnoea (ICD-11 7A41, chapter 07) . . . 827
Chronic rhinosinusitis (ICD-11 CA0A) . . . 831
Allergic rhinitis (ICD-11 CA08) . . . 835
Pleural effusion (ICD-11 CB27) . . . 841
Pneumothorax (ICD-11 CB21) . . . 844
The failing lung and the inherited lung . . . 847
Acute respiratory distress syndrome (ICD-11 CB00) . . . 847
Cystic fibrosis lung disease (ICD-11 CA25, respiratory manifestation of 5C57.0) 851
Upper respiratory tract infections — the common cold, acute pharyngitis, acute sinusitis, laryngitis (ICD-11 CA00–CA0F) . . . 855
What no longer holds . . . 859

**Chapter 16 — The Gut, the Frame and the Waterworks 862**
ICD-11 Chapter 13: diseases of the digestive system . . . 862
ICD-11 Chapter 15: diseases of the musculoskeletal system or connective tissue . . . 862
ICD-11 Chapter 16: diseases of the genitourinary system . . . 862
Introduction . . . 862
A note on the prices in this chapter . . . 863

**ICD-11 Chapter 13 — Diseases of the digestive system 864**
Gastro-oesophageal reflux disease . . . 864
Peptic ulcer disease and *Helicobacter pylori* . . . 865
Functional dyspepsia . . . 867
Irritable bowel syndrome . . . 868
Coeliac disease . . . 869
Inflammatory bowel disease: Crohn disease and ulcerative colitis . . . 870
Diverticular disease and diverticulitis . . . 873
Appendicitis . . . 878
Haemorrhoids . . . 880
Anal fissure . . . 881
Gallstones and cholecystitis . . . 882
Acute pancreatitis . . . 883
Chronic pancreatitis . . . 885
Liver cirrhosis and its causes . . . 886
Metabolic dysfunction-associated steatotic liver disease . . . 889
Alcohol-related liver disease . . . 891
Hepatic encephalopathy . . . 892
Hernias: inguinal and hiatal . . . 894
Bowel obstruction . . . 896
Constipation . . . 898
Lactose intolerance . . . 900
Dental caries and periodontal disease . . . 901
Oesophageal varices . . . 905
Gastrointestinal bleeding . . . 907

**ICD-11 Chapter 15 — Diseases of the musculoskeletal system or connective tissue 910**
A note on the headline figure for this chapter . . . 910
Low back pain . . . 910
Neck pain . . . 915
Osteoarthritis of the knee, hip and hand . . . 917
Rheumatoid arthritis . . . 920
Ankylosing spondylitis and axial spondyloarthritis . . . 924
Psoriatic arthritis . . . 926
Osteoporosis and fragility fracture . . . 929

Gout . . . 933
Fibromyalgia . . . 936
Rotator cuff disorders . . . 939
Carpal tunnel syndrome . . . 941
Tendinopathies of the Achilles, patellar, lateral elbow and gluteal tendons . . . 944
Scoliosis . . . 946
Osteomyelitis . . . 949
Septic arthritis . . . 953

**ICD-11 Chapter 16 — Diseases of the genitourinary system 957**
Chronic kidney disease . . . 957
Acute kidney injury . . . 960
Glomerulonephritis . . . 962
Diabetic nephropathy . . . 965
Kidney stones . . . 967
Urinary tract infection . . . 970
Benign prostatic hyperplasia . . . 972
Erectile dysfunction . . . 975
Urinary incontinence . . . 977
Endometriosis . . . 980
Uterine fibroids . . . 982
Polycystic ovary syndrome . . . 982
Pelvic inflammatory disease . . . 985
Menstrual disorders: heavy menstrual bleeding, dysmenorrhoea, amenorrhoea and premenstrual syndrome . . . 988
Menopause-related conditions . . . 991
Infertility, female and male . . . 994

**What no longer holds 999**
Structural findings on imaging are largely age-normal . . . 999
Widely used treatments that failed good trials . . . 999
Appendix to this chapter: where the checked figures came from . . . 1000

**Chapter 17 — Reproduction, the Perinatal Period, Developmental Anomalies, and Injury 1002**
ICD-11 chapters 18, 19, 20 and 22 . . . 1002
Introduction . . . 1002
Postpartum haemorrhage . . . 1006
Pre-eclampsia and eclampsia . . . 1008
Obstructed labour . . . 1010
Maternal sepsis . . . 1011
Unsafe abortion complications . . . 1013
Obstetric fistula . . . 1014
Gestational diabetes mellitus . . . 1016
Hyperemesis gravidarum . . . 1018
Preterm labour . . . 1019
Ectopic pregnancy . . . 1022
Miscarriage . . . 1024
Postpartum depression . . . 1026
Maternal anaemia . . . 1028
Preterm birth complications . . . 1034
Birth asphyxia and neonatal encephalopathy . . . 1037
Neonatal sepsis . . . 1039
Neonatal jaundice and kernicterus . . . 1042
Low birth weight and small for gestational age . . . 1044
Respiratory distress syndrome of the newborn . . . 1047
Neonatal hypothermia . . . 1049
Neonatal tetanus . . . 1051
Neural tube defects . . . 1059
Congenital heart defects . . . 1062

Cleft lip and palate . . . 1064
Down syndrome and other trisomies . . . 1066
Clubfoot . . . 1069
Developmental dysplasia of the hip . . . 1071
Congenital hypothyroidism . . . 1074
Hypospadias . . . 1076
Limb reduction defects . . . 1078
Congenital cataract . . . 1080
Fetal alcohol spectrum disorder . . . 1083
Road traffic injury . . . 1094
Falls and fragility fracture . . . 1097
Burns . . . 1100
Drowning . . . 1103
Pesticide poisoning . . . 1133
Carbon monoxide poisoning . . . 1136
Lead poisoning . . . 1138
Snakebite envenoming . . . 1141
Spinal cord injury . . . 1172
Fractures . . . 1175
Open wounds . . . 1178
Crush injury . . . 1180
Hypothermia and heat illness . . . 1183
Foreign body aspiration . . . 1186
Animal bites . . . 1189
What no longer holds . . . 1193

**Chapter 18 — Conditions Related to Sexual Health, the Non-Disease Chapters, and Three Cross-Cutting States 1194**

**PART A — ICD-11 chapter 17: conditions related to sexual health 1195**
A standing note on this chapter . . . 1195
Hypoactive sexual desire dysfunction (HA00) . . . 1196
Female sexual arousal dysfunction (HA01.0) . . . 1198
Male erectile dysfunction (HA01.1) . . . 1199
Orgasmic dysfunctions and anorgasmia (HA02, HA02.0) . . . 1201
Ejaculatory dysfunctions (HA03) . . . 1202
Sexual pain-penetration disorder (HA20) . . . 1203
Gender incongruence of adolescence or adulthood (HA60) . . . 1205
Gender incongruence of childhood (HA61) . . . 1207

**PART B — the ICD-11 chapters that are not diseases 1209**
Chapter 21 — Symptoms, signs or clinical findings, not elsewhere classified . . . 1209
Chapter 23 — External causes of morbidity or mortality . . . 1209
Chapter 24 — Factors influencing health status or contact with health services . . . 1211
Chapter 25 — Codes for special purposes . . . 1212
Chapter 26 — Supplementary chapter, traditional medicine conditions . . . 1213
Supplementary section V — Functioning assessment . . . 1213
Chapter X — Extension codes . . . 1213

**PART C — three cross-cutting entries 1215**
Multimorbidity . . . 1215
Frailty . . . 1216
Palliative care . . . 1218

**Part 3 — The Simple Means 1221**

**Part 3 — Simple Means 1222**
3.1 What holds . . . 1222
3.2 The audit . . . 1225
3.3 The counter-cases . . . 1229
3.4 The genuinely low-complexity list . . . 1229

**Part 4 — The Chain** **1231**

**Part 4 — The Chain** **1232**
4.1 Three documented cases . . . 1232
4.2 What actually governs the short chain . . . 1233
4.3 The legal frame . . . 1234
4.4 What off-patent does and does not mean . . . 1236
4.5 Where the chain genuinely cannot be shortened . . . 1237
4.6 The asymmetry: mRNA vaccines . . . 1238
4.7 Human insulin, which is not the analogues . . . 1239
4.8 The dead end . . . 1239

**Appendices** **1241**

**Appendix A — The Register of Contradictions** **1242**
A.1 Where one source contradicts itself . . . 1242
World Health Organization fact sheets . . . 1242
Two pages that are not fact sheets . . . 1243
In the published literature . . . 1244
A.2 Where two sources of comparable standing disagree . . . 1244
A.3 Where this book's own research lines disagreed . . . 1244
A.4 Where the book contradicted itself . . . 1245

**Appendix B — What Is Not Known, and What Was Not Checked** **1247**
B.1 Where the measured record is silent . . . 1247
Conditions with no global burden figure . . . 1247
Figures with no data year . . . 1247
Quantities that have never been measured . . . 1247
B.2 Where this book did not verify . . . 1248
What could not be reached, and why . . . 1248
A source that no longer exists . . . 1248
Figures that were removed rather than published . . . 1249
B.3 The outstanding list . . . 1249

# Where Illness Comes From, Completed

## A Reference Work on Every Chapter of Human Illness, Its Prevention, Its Cure, and What Can Be Done With Simple Means

J. Konstapel, Constable Research, Leiden First edition, October 2026 Version 1.0

---

## How to use this book

This is a reference work. It covers every chapter of the International Classification of Diseases, eleventh revision, without exception. It is built from entries. One entry treats one condition.

**What an entry contains.** Every entry has the same eight sections, in the same order.

1. *What it is* — the condition in plain words.
2. *Measured* — prevalence or incidence, deaths, age pattern, geography.
3. *Where it starts* — the established risk factors, and what is genuinely not known.
4. *Cure status* — one of four values, defined below.
5. *Prevention* — what demonstrably prevents it, with a grade.
6. *Treatment* — what is standing, in order of evidence, with price and list status.
7. *Simple means* — what can be done with no industrial supply chain at all.
8. *Gaps* — where the evidence is thin and where good sources disagree.

**The four cure statuses.** This is the spine of the book, so the words are narrow.

| | |
|---|---|
| SELF-LIMITING | The body completes the discharge itself. Intervention adds nothing. |
| CURABLE | A treatment exists that removes the condition. |
| CONTROLLABLE | The state can be held. The deviation remains. |
| RELIEF ONLY | Nothing removes it. |

A treatment that must be continued for life does not cure. Phenylketonuria on a lifelong diet is CONTROLLABLE. Haemochromatosis managed by repeated phlebotomy is CONTROLLABLE. Gastric MALT lymphoma cleared by one course of antibiotics is CURABLE.

Where the honest answer differs by stage, cause or strain, the status is split and each label names its stratum. Most cancers are read this way, because one label for a cancer would be false at one end or the other.

**The four prevention grades.**

| | |
|---|---|
| STRONG | Trials, or large studies that agree, or settled physiology. |
| MODERATE | One good trial, or consistent observation without trials. |
| WEAK | Little or indirect evidence. |
| CONTESTED | Good sources disagree. Both numbers are then printed. |

A grade may carry a qualifier where the evidence needs one. “CONTESTED to negative” means good sources disagree and the weight of them leans against the intervention. Where a grade would otherwise be compound, the book takes the lower of the two, and CONTESTED takes precedence over any of the other three, because disagreement among sources is a statement about the state of the evidence rather than its strength.

**How the figures are marked.** Every numeric claim in this book was checked against a named source while it was compiled. Three things could happen. The figure was read off its source. The source was named but not opened again in this pass. Or the source could not be reached at all.

The first two are printed plainly. The third carries a dagger:

> Distant disease: CONTROLLABLE — 16.9 per cent†

A dagger does not mean the figure is wrong. It means the figure is one that is commonly carried in the literature, and that this compilation could not open the source to confirm it. It marks the difference between what was checked and what was taken on report. There are 2,361 daggers in this book, against 6,352 figures that rest on a named source — some of them opened during this compilation, the rest named by the research line that supplied them and not opened again.

Each figure was given one of these marks while the book was compiled, and the appendices call that mark its provenance tag. Only the dagger reaches the page.

No figure in this book is an estimate. Where no source could be found at all, the number was struck out and the sentence says in words what is known without it. A reference work that hides which of its numbers were checked is worse than one that shows it.

**How prices are given.** Prices were collected in October 2026 from the sources named. Where a price carries a year, that is the year its source states. Where a price carries none, its source states none, and the figure is as it stood when the source was read in October 2026. Prices in euro are European prices and prices in US dollars are United States prices, unless the text names another market.

Where a price could not be tied to a market at all — where the only figure available was an order-of-magnitude band drawn across several different reference classes — it is written in words rather than digits. “Tens of US dollars a course” is what the source supports. A false decimal would not be.

**The corrections made during review.** This book was written, then read against its sources by separate reviewers, then corrected. Every correction was recorded where it was made. Those records have been lifted out of the running text, so that the book reads as a book, and they are kept in full in a companion file, *The Review Record*, which travels with it.

**What this book does not do.** It is not a treatment guide. Nothing in it replaces care. It does not explain. Where it sets a measured fact beside the rules of Part 0, the sentence is marked as a reading, and a reading is called a reading.

---

## Why the book was rewritten

An earlier book, *Where Illness Comes From* (ninth edition, September 2026), walked one frame from first chemistry to the human being and read illness at each layer. It took its cases where they illustrated a layer: cancer, autoimmunity, ageing, trauma.

It was never a catalogue, and it did not claim to be. Ask it about a particular condition and it may have nothing. Diverticulitis, to take the case that prompted this book, does not appear in it at all, although every rule needed to read it is there.

This book keeps that frame and adds what was missing: completeness. Every chapter of ICD-11 is covered. The conditions that carry the burden have their own entry. And three questions are asked of each, which the earlier book asked only of its chosen cases — whether it can be

cured, what prevents it, and what can be done where there is no industry, no cold chain, and no money.

That third question turned out to be the one that reorganises the book.

# Part 0 — The Rules This Book Follows

# Part 0 — The Rules

This part holds every rule the rest of the book uses. Nothing in the entries rests on anything stated elsewhere.

The rules come from the Vacuum.Net theory as published at constable.blog. The governing statement is the Foundational Paper, Eighth Edition, version 8.1, 17 October 2026. Where a second statement of the same rules differs in wording, the difference is noted.

The theory was not built for biology. It was built at the bottom, with one strand and one test, and no constants given in advance. This book applies it upward. It does not repeat the derivation.

---

## 0.1 The net

The image is a fishnet under tension.

The net is one strand. It runs everywhere. Where the strand crosses itself there is a crossing. Between the crossings lie openings.

Four words describe what the strand does.

**Strand.** The net itself, under tension. **Winding.** A stretch of strand that returns on itself in step. Physics calls this energy. **Knot.** Windings that hold each other in three directions. Physics calls this mass. **Mesh.** An opening between strands, with an extent in space or in time.

One rule decides what stays. A winding persists only if it returns on itself in step. What does not close does not stay as a form. Its tension moves to the meshes beside it.

---

## 0.2 The five starting rules

**N1 — Strand.** There is one strand. It is oriented and continuous. Its only local act is crossing itself. A self-crossing has three states: over, under, or none.

**N2 — Closure.** Only configurations that close — that return in phase onto themselves — persist. What does not close does not last. Closure is the selection rule. There is no external selector.

**N3 — Memory.** A closed configuration constrains the next rewrite. The net carries its history as its shape.

**N4 — Context.** The response of the medium is a state function, not a universal constant. Universality is the limiting case, where the state variable does not vary across the sample.

**N5 — Scale.** The net repeats its own construction across depth. One winding step deeper multiplies the count of distinguishable states by three. The same winding, read at another depth, is the same winding.

A second published statement of the same five rules words N2, N3 and N5 differently. It defines closure through the window and adds that what does not close passes on as tension; it states memory as an ordering of passages at a knot, where the first passage fixes the

orientation; and it gives scale as an explicit coarse-graining into blocks, where what does not close at one scale is the material of the next. The two readings agree on what they select for. They differ in where they put the machinery.

---

## 0.3 The register

At a crossing the strand does one of three things. It passes over, it passes under, or it does not cross. These three states are written +1, −1 and 0. One such state is a trit.

Counting with +1, 0 and −1 is balanced ternary. Every whole number has exactly one writing in it. There is no separate minus sign: negation is mirroring, and zero sits in the middle rather than at the edge.

Three is also the cheapest base. Writing numbers in base r costs about r symbols per position, and the number of positions falls as one over the natural logarithm of r, so the total cost goes as r over ln r. That expression is smallest at r = e ≈ 2.718, and the nearest whole base is three: 3/ln 3 = 2.73, against 2/ln 2 = 2.89 for binary. Three wins.

The register is the whole of what this book needs from the theory's arithmetic. The test at a cell's rim, in Part 1, has the same three outcomes as a crossing.

---

## 0.4 Closure, windows and rings

Three crossings in a row form a window. A window is closed when its three trits add to a multiple of three. An open window carries tension. A closed window carries none.

Count them. Three crossings with three states each give 3 × 3 × 3 = 27 windows.

| Kind | Example | Number | Closed? |
|---|---|---|---|
| Three equal | (+, +, +) | 3 | yes — the sums are 3, 0 and −3 |
| Three different | (−, 0, +) | 6 | yes — −1 + 0 + 1 = 0 |
| Two equal, one different | (+, +, 0) | 18 | no — the sum is never a multiple of 3 |

So 9 of the 27 windows close. They come in two kinds, and the difference matters for everything alive.

**Uniform closure.** Three equal trits. Nothing differs inside it. This is the form of a crystal. It holds and does not turn.

**Mixed closure.** Three different trits. This form can keep turning while it stays closed. Every crossing changes at every step, and every window stays closed. All content changes; the closure holds. This is the form of living matter.

Three consequences are used throughout the book.

*Two fix the third.* If two trits of a window are given, exactly one value of the third closes it.

*The two kinds do not mix.* A closed strand is uniform throughout or mixed throughout. Where a uniform stretch meets a mixed stretch, the window between them is open and carries tension. That seam is where this book finds most of its deviations.

*A mixed strand keeps one direction, or it does not close.* Join a strand running − → 0 → + to one running + → 0 → −, and the two windows on the seam stand open. Which direction is taken is not set by the rule. It is set by what lay there first, which is N3.

A ring is a strand closed on itself. Its depth is its number of crossings. Asking that every window of a ring be closed forces the trits to repeat with period three. Uniform rings exist at every depth, one per state. Mixed rings exist only where the depth is a multiple of three, and there are then exactly two: one running − → 0 → +, the other the mirror.

A mixed ring therefore cannot grow one crossing at a time. It grows by a whole group of three. And a mixed ring of depth six cuts into two rings of three, each of which closes, and each of which keeps the direction of the parent. The smallest full cycle is $3 \to 6 \to 3 + 3$.

---

## 0.5 The two classes

Closure is all or nothing. A winding closes or it does not. So at every depth there are two classes of form.

**The closed class** holds its form. These are the things: atoms, molecules, machines, cells, bodies.

**The unclosed class** decays. While it lasts it carries tension from one closed form to the next. These are the events: light between atoms, signal molecules between cells, the nerve impulse and the hormone within a body, speech between people.

Only what ends can deliver. A closed form returns its tension to itself — that is what closure means — and can hand nothing over. That the carriers decay is what keeps a body readable: each message is erased after it is read.

An earlier book in this series names the same division as two layers. The **address layer** holds identity: frozen topology, counted in the ternary ladder. The **tension layer** is the only layer in which anything moves: charge and discharge. The words are that book's; the division is this one's closed and unclosed classes, read as what a thing is against what happens to it.

---

## 0.6 The test

When one form reads another, there are three outcomes, and only three. They are the three states of the register.

| | | |
|---|---|---|
| **+1** | It fits | The form stays |
| **−1** | It does not fit | Its tension is discharged and the form is taken apart |
| **0** | It is not read | Nothing happens |

Hold on to the third outcome. Most of this book turns on it.

A form that is never read is neither kept nor removed. It simply remains. Health is not the absence of misfits; misfits arise every day, in everyone, in thousands. Health is a test that reads fast enough.

---

## 0.7 Widening and pruning

Whatever closes becomes a unit for the next weaving. That gives two strokes.

**Widening.** Units combine. The number of combinations grows with every step. **Pruning.** Only what closes persists.

A layer is what survives one round. The residue of one depth is the alphabet of the next.

The arithmetic is visible all the way up. About ninety stable rungs of matter give, on the order of $10^{60}$, possible drug-sized molecules; life uses a few thousand. A protein chain of one hundred units drawn from twenty kinds has $20^{100} \approx 10^{130}$ possible orders; a human body runs on about twenty thousand. Widen by a hundred and thirty orders of magnitude; prune to twenty thousand. Same engine, one depth up.

And it never stops, because no closure is ever exact. Each depth leaves a remainder, and the remainder is carried upward. A ladder driven by a rest cannot end.

---

## 0.8 The ladder

The theory fixes two natural units from hydrogen.

Let R∞ be the Rydberg constant and m_e/m_p the electron-to-proton mass ratio. Then R_H = R∞/(1 + m_e/m_p) = 10,967,758.340 $m^{-1}$, and

$S_0 = 1/(2\ R\_H) = 4.55881671 \times 10^{-8}$ m = 45.59 nm $T_0 = S_0/c = 1.52065757 \times 10^{-16}$ s

so that $S_0 = c \cdot T_0$, and a length and its period share one coordinate.

The position of a size is the number of factors of three between it and $S_0$:

position = $\log_3(\text{size} / S_0)$

and a time is placed the same way from $T_0$. One ladder step is a factor of three.

The ladder orders. It does not select. In the companion reference work on the body, the measured sizes of the body's parts were tested against the whole marks of the ladder and found spread between them — 192 of 388 within a quarter step, 49.5 per cent against 50 by chance. So positions are given, and no part of the body is assigned to a mark. The ladder is a coordinate system and is used as one.

This book uses the ladder only where a size or a duration is worth comparing across layers. Most entries do not need it.

---

## 0.9 Constants as states

The fourth rule is the theory's boldest and its most testable. If constants are states, they must move where the state moves and stand still where it does not.

The theory carries a measured anchor. The threshold at which gravitational anomalies begin, written $a_0$, comes out as $c \cdot H_0/2\pi$, where the 2π is the one full turn around a mesh.

With the Foundational Paper's own inputs, $c = 3.00 \times 10^8$ m/s and $H_0 = 70$ km $s^{-1}$ $Mpc^{-1}$ = $2.27 \times 10^{-18}$ $s^{-1}$:

$a_0 = (3.00 \times 10^8 \times 2.27 \times 10^{-18}) / 2\pi = 1.084 \times 10^{-10}$ m $s^{-2}$

The measured threshold from galaxy rotation curves is about $1.2 \times 10^{-10}$ m $s^{-2}$. The gap is 9.7 per cent.

Take instead $H_0 = 67$ km $s^{-1}$ $Mpc^{-1}$, the value from the early universe, and the same arithmetic gives $1.050 \times 10^{-10}$ and a gap of 12.5 per cent. Both are printed, because the gap is a function of which Hubble constant is taken, and the two measurements of it disagree. That disagreement is unresolved in cosmology and is not resolved here.

For this book the result matters in one way only. It shows the frame was not built for biology and bent to fit. It was built at the bottom, made testable there, and walked up.

---

## 0.10 What a reading is

This book sets measured facts beside the rules above. Where it does so, the sentence is marked as a reading.

A reading is not a cause. The theory does not say why a seam tears or why a cell is missed. It says which configurations persist. Describing at the right depth replaces explaining, and explaining is causal thinking: in a one-strand model there are not two separate things to put an arrow between.

So the book uses, in place of cause:

**Selection by fit** — only what returns in phase remains. **Identity over scale** — the same winding at another depth. **Constitutive relation** — a state function, simultaneous, no arrow. **Correspondence** — a measured pattern that has the form of a rule.

Every number in the chapters comes from the standing literature, and the references say which. The frame supplies the ordering, and nothing else.

---

## 0.11 The dictionary

Every word the chapters use maps onto one element of this part, and onto nothing else.

| Word in the chapters | In Part 0 |
|---|---|
| thread, strand | the strand, N1 |
| loop, winding, closing | winding and closure, N2 |
| the test | the closure test; the one selection |
| pattern, address | stored winding, N3 |
| state, tension | the tension the net carries, N4 |
| depth, layer | scale, N5 |
| the register | balanced ternary {+1, 0, −1} |
| the legitimate zero | a lawful 0 in the register |
| discharge | tension release |
| phase, step | closure phase |
| the fishnet | the standing image of the net |

No concept in the entries falls outside this list. That is what one frame, walked from first chemistry to the human being, means in practice.

# Part 1 — How Illness Is Read

# Part 1 — How Illness Is Read

Part 0 gave one strand and one test. This part walks the test upward, from the first chemistry to the human being, and asks at each layer the same two questions: what is a deviation here, and how is it prevented.

It is the shortest part of the book. Everything in it is a frame for the entries, not a substitute for them.

---

## 1.1 First chemistry

Why are there about ninety stable kinds of matter and not millions? Because closure is strict. A loop closes only at certain sizes. Too small and the wave does not come around; too large and it comes around out of step. Between those, nothing. The possible loops form a ladder with fixed rungs and gaps.

The rungs are the elements. Hydrogen is the simplest closure. Helium is the first complete one: everything comes back in step, nothing left over, which is why it joins with nothing. Carbon sits in the middle of a rung with four open ends, the maximum reach a small loop can have, which is why it builds everything alive.

Water is two small loops closing onto one middle loop at 104.5 degrees. That angle is not designed. It is where the tensions balance, and every property that makes life possible in water follows from it.

The deviation at this layer is a closure that does not sit still. Some heavy closures hold, but barely, and their tension leaks out in bursts. A leaking closure does not stay in its own layer: its bursts travel up and snap thread in the layers above. This is the oldest source of illness. It needed no biology to exist, and became illness only when there was a weave to disturb.

Prevention here is the oldest there is: distance and shielding. Everything else in this book assumes this floor is quiet. Where it is not — radon in houses, fallout, certain mining regions — the illness statistics of every higher layer rise, and no amount of higher-layer care fully compensates.

---

## 1.2 The cell

A cell is a pocket of ordered weaving with a boundary. The boundary is not a wall. It is a reading surface. Everything the cell is, it shows on its rim; everything that reaches the cell arrives at that rim first and is read before it enters.

Inside, the cell keeps its pattern, copies it, and reads its own copy. The pattern is stored as a wound thread — about three billion winding steps, coiled two metres long into a hundredth of a millimetre. On top of the steps sit removable marks that set which stretches are read and which stay silent: the same pattern, in different states.

Copying makes about one raw error per hundred million steps and proofreads most of them away. What remains is roughly one lasting change per few billion steps per division.

The deviation at this layer is a winding change the repair missed. Note the neutral word. A mutation is not damage by definition; it is a step that differs from the pattern. Most change nothing that matters. Some weaken the mesh. A very few change what the cell does and, crucially, what it shows on its rim. The rim signature shifts, and the cell now reads differently to its neighbours.

Prevention has one form: protect the copying and the repair. Everything that snaps thread raises the miss rate. Everything that starves the repair crews slows them. This is not moral advice. It is maintenance arithmetic.

---

## 1.3 The test layer

A body is tens of trillions of cells, each showing its signature on its rim. The body carries a dedicated reading layer whose only work is to run the one test at cell scale.

The readers press against a cell's rim, compare the signature to the pattern, and register one of the three outcomes of Part 0.6. Fits: move on. Does not fit: the cell is opened and dismantled, usually within the hour. Not read: nothing happens.

This runs continuously, everywhere, from before birth to death. On an average day it removes thousands of cells whose signature had drifted. Nobody notices. That is the point.

Now the subtlety that organises most of this book. There are places where the body must not discharge what it reads. The gut rim meets foreign material with every meal. The eye cannot afford inflammation without going blind. And a child in the womb is, by signature, half foreign; nine months long the reading must return zero there, or no mammal would be born.

So the body carries official tokens — signs a cell can show that turn the local reading to zero. Clinicians call them checkpoints.

The zero-token is not a flaw. It is load-bearing architecture. Without it: self-destruction. With it: a blind spot. Much of this book lives in that trade.

Deviation here comes in two mirror forms. A test that reads too weakly lets misfits through. A test that reads too sharply discharges healthy tissue — the autoimmune diseases, read as not-fitting while they fit. One layer, one dial, two directions of failure.

Prevention: the reading population is built in childhood by exposure, and the readers themselves carry marks from earlier encounters that reset how sharply they read next time. The test layer is not fixed equipment. Calibration needs material.

---

## 1.4 Where cancer sits

Three plain facts, and the third follows from the first two.

Copying makes lasting changes, always. The test discharges what reads as not-fitting, daily and silently. Therefore what accumulates over years is only what the test did not read as not-fitting.

That is why tumours persist, in one sentence. A tumour is the remainder of a selection. And since the body's own lawful zero-tokens are the most reliable way to go unread, long-standing tumours almost always end up wearing them — not by any decision, but because for years every variant without the token was discharged and every variant with it was not.

Oncology knows this sequence as immunoediting, and its three phases are correct. The reading here differs only in the verbs. The data say remainder; the standard words say actor. Verbs steer research questions.

The clearest support is in the autopsy rooms, and it is in this book's chapter 02 with its figures: a large fraction of people who die of something else carry small silent tumours that never became disease. The altered tissue was there. The test around it held it.

Read in the net: cancer is not a property of a cell. It is a relation between a mesh and the test around it. This is a reading, not a mechanism.

---

## 1.5 Where ageing sits

Ageing is not the pattern changing. An old hand has the same weave as a young one. What goes is the tension and the measure. Loops still close, but sloppily. Rhythms that once locked — sleep and light, heartbeat and breath, hormone tides — drift out of step.

The medical file of old age is a list of lost phase-locks. Heart-rate variability falls, deep sleep flattens, temperature and hormone cycles dampen, and the reading layer thins and slows. Which is exactly why cancer and infection climb after seventy: the misfit rate has not changed much. The discharge rate has fallen.

So lifespan, read this way, is coherence-span. And the question is not why someone does not wear out. It is what keeps a weave in step for ninety-six years.

The answer is four things, and they are known, and they are the four that every large study converges on. Loading keeps tension. Food supplies the thread and sets the clock. Not snapping thread is simply not snapping thread. And other people, which carries more weight than medicine expected, because human weaves phase-lock to each other.

What this frame adds is not a new recommendation. It is why those four and not others.

---

## 1.6 Where the mind sits

The net does not stop at the skull and does not change its rules there. The feelings are not commentary on the body's states; they are the body's tension, read at the surface where reading becomes noticing.

Stress is held tension without a discharge path. The alarm weave is healthy architecture: tension raised for an action. The modern condition is alarm without action, and the prevention that follows is not relaxation but discharge.

Trauma is a mesh locked out of phase. The event is over in the world and not over in the body. The treatments that demonstrably work are, without exception, closure procedures.

Depression in its exhausted form reads as coherence-loss arrived early, which is why the treatments with the strongest evidence are phase treatments as much as chemical ones.

Meaning is fit, felt. And its measured counterpart is among the least advertised figures in epidemiology.

Each of these has its entries, with the trials and the effect sizes, in chapter 06.

---

## 1.7 What this frame changes in practice

Medicine as built is organised around the tissue: find the abnormal part, image it, cut it, dissolve it, replace it. Its triumphs are tissue triumphs — surgery, antibiotics, transplantation — and this book does not diminish them. They are in chapter after chapter, with their figures.

Its hardest fronts are all at the test and phase layers. And its breakthroughs of the last decade are, without being named that way, test-layer and phase-layer breakthroughs.

So the frame orders diagnosis as well as treatment. Three questions decide the test-layer diseases, and all three are already measurable with instruments that exist, scattered across departments that do not speak to each other.

Is there a readable signal. Can the readers reach it. What does the register show.

Signal, access, register. Stated as a principle, it extends from oncology to autoimmunity, which is the same axis with the opposite deviation.

And the therapies order by layer rather than by molecule. Remove, rebuild, kill. Close one winding. Correct the register and let the body discharge. Restore step. Change what everyone hangs in.

That last layer carries the largest numbers in this book and the smallest budgets. It is the subject of Part 3.

# Part 2 — The Illnesses

# Chapter 01 — Certain Infectious or Parasitic Diseases

Forty-two entries. Forty-one conditions and one cross-cutting property, antimicrobial resistance, which is not a disease but reclassifies the diseases around it.

The chapter covers the conditions that carry the burden. Tuberculosis, HIV and malaria. The lower respiratory infections. The diarrhoeal diseases and their named pathogens. The viral hepatitides, the vaccine-preventable childhood infections and the neglected tropical diseases. The three principal bacterial sexually transmitted infections, and Ebola virus disease with the other viral haemorrhagic fevers, which share one entry. Where WHO publishes a fact sheet, that sheet is the spine of the entry. Where it does not, the entry says so and marks the missing figure.

Two things run through the chapter, and they sit at opposite ends of it.

The first is that the shortest supply chains in the chapter are here. A single oral dose of praziquantel kills the adult worms of schistosomiasis, and people in active transmission need re-treatment, because it does not kill immature schistosomes. A single oral dose of albendazole or mebendazole clears most soil-transmitted helminth infection. A single oral dose of azithromycin clears active trachoma. One annual dose of ivermectin holds onchocerciasis and lymphatic filariasis down at community level, for onchocerciasis over ten to fifteen years, because ivermectin does not kill adult worms. None of these needs refrigeration, a needle, a diagnosis or a clinician: they are tablets that a trained non-medical person hands out in a school or a village. All four are donated by their manufacturers, praziquantel largely so. And they are not reaching people. Schistosomiasis preventive treatment covered 39.6 per cent of those who needed it in 2024. Trachoma antibiotic coverage was 47 per cent in 2025. Soil-transmitted helminth treatment reached 62 per cent of at-risk children in 2021. These are distribution figures, not pharmacology.

The second is oxygen. Where nothing simple works, oxygen is the constraint that returns. It is named as the rate-limiting treatment in childhood pneumonia, as the single intervention that converts severe RSV bronchiolitis from often fatal to usually survivable, and as the binding constraint on survival in severe COVID-19. In measles pneumonia, in established sepsis and in severe influenza it is listed among the treatments, and in the infant with pertussis the entry says it cannot be improvised. It cannot be improvised. The minimum chain is a pressure-swing-adsorption concentrator with uninterrupted electricity, or cylinder logistics, and neither exists in most of the places where the deaths are. Tetanus is the same constraint one step further on: the determinant of survival in severe tetanus is mechanical ventilation, and nothing substitutes for it.

Neither pattern should be overstated. The short-chain conditions are a minority of the chapter, and for most of them the drug suppresses or clears the parasite without reversing the damage it has already done — praziquantel does not undo bladder fibrosis, ivermectin does not restore sight. Oxygen is not the only unimprovisable thing here either. Equine diphtheria antitoxin, the Ebola monoclonals, liposomal amphotericin B and the −60 °C vaccine chain are all equally out of reach, and some of them are out of reach of money as well. The entries carry the detail. The patterns are a way of reading the chapter, not a claim about it.

A note on vaccines, because the chapter turns on them repeatedly. Every vaccine here requires an industrial chain and none can be made by simple means. That is stated per entry rather than softened. Vaccination therefore appears in PREVENTION or TREATMENT and

never in SIMPLE MEANS. The chains differ in length, and the honest dividing line is the cold chain. Measles, varicella, influenza and the conjugate vaccines cannot leave 2–8 °C without being destroyed. MenAfriVac tolerates 40 °C for four days by design, Rotasiil is thermostable, and the tetanus and diphtheria toxoids tolerate brief breaks. Two products in this chapter need far colder than 2–8 °C: the mRNA COVID-19 vaccines at −70 °C and Ervebo for Ebola at −60 °C to −80 °C. Those two are the least deployable medical products in the chapter.

---

## Tuberculosis

**What it is.** A bacterial infection, *Mycobacterium tuberculosis*, spread by airborne droplets. It usually settles in the lungs but can affect bone, the brain lining, the gut and other organs. Most infected people never become ill. A minority develop active disease, which destroys lung tissue over months.

**Measured.** WHO fact sheet, 24 March 2026, reporting 2024 data. 10.7 million people fell ill in 2024: 5.8 million men, 3.7 million women, 1.2 million children. 1.23 million deaths, including about 150,000 among people with HIV.

About a quarter of the world's population carries TB infection, and 5–10 per cent of those eventually develop disease.

Regional share of new cases: South-East Asia 34 per cent, Western Pacific 27 per cent, African 25 per cent. India 25 per cent, Indonesia 10 per cent, Philippines 6.8 per cent, China 6.5 per cent, Pakistan 6.3 per cent, Nigeria 4.8 per cent, DR Congo 3.9 per cent, Bangladesh 3.6 per cent. The top five account for 55 per cent, and 87 per cent of cases fall in thirty high-burden countries. Over 80 per cent of cases and deaths are in low- and middle-income countries.

Drug resistance: 3.2 per cent of new episodes and 16 per cent of previously treated episodes. About two in five people with drug-resistant TB accessed treatment in 2024; 34,000 started the six-month all-oral regimens, against 5,653 in 2023 and 1,744 in 2022.

Catastrophic costs fall on about half of treated households, defined as more than 20 per cent of household income.

**Where it starts.** Inhalation of *M. tuberculosis*. Progression from infection to disease is what the risk factors govern. WHO attributes new 2024 cases to undernutrition 0.97 million, diabetes 0.93 million, alcohol use disorders 0.74 million, smoking 0.70 million and HIV infection 0.57 million. HIV carries the largest individual relative effect: people with HIV are twelve times more likely to develop TB disease.

Not known: why 90–95 per cent of infected people never progress, and what distinguishes them immunologically. The trigger from latent to active disease is not identified. Whether latent infection is one state or a spectrum of partly cleared infection is unsettled. Why some people clear the organism entirely is unknown.

Read in the net: the test at a form's rim has three outcomes, and the third is 0 — not read. A form that is never read is neither kept nor removed; it simply remains. A quarter of the world carrying an organism that may never be cleared and will mostly never be expressed is that outcome at the scale of a population. This is a reading, not a mechanism.

**Cure status.** CURABLE. A four- to six-month regimen of rifampicin, isoniazid, pyrazinamide and ethambutol removes the organism. For multidrug- and rifampicin-resistant disease a six-month all-oral BPaLM or BPaL regimen is the WHO-preferred option for eligible patients, and it also removes the organism. Success is materially lower, cost much higher, and only two in five of those affected reach treatment at all. The patient is not left in a managed state, which is what distinguishes this from CONTROLLABLE. WHO publishes no global treatment success rate and none is given here.

**Prevention.**

Treating active cases, which breaks transmission: STRONG. TB efforts saved an estimated 83 million lives since 2000, and TB treatment plus antiretroviral therapy averted 9.8 million deaths since 2005.

BCG against tuberculous meningitis: STRONG. Protective efficacy 77 per cent (95 per cent CI 71–83), odds ratio 0.23 (95 per cent CI 0.14–0.37), from 107 cases and 321 controls in a

case-control study in Madras, India, *Archives of Disease in Childhood* 74(2):144. The same source records earlier estimates against tuberculous meningitis ranging from 52 to 84 per cent.

BCG against adult pulmonary TB: CONTESTED. The WHO fact sheet gives no efficacy percentage and claims only prevention of TB deaths and of severe childhood forms. The trial literature ranges from near zero to high protection, varying with latitude and prior mycobacterial exposure. Both positions are in print and no single number is quotable.

Preventive therapy for exposed household contacts: STRONG. Levofloxacin is recommended for contacts of multidrug-resistant cases; rifapentine with isoniazid for three months is the short-course option.

Nutrition: MODERATE. Undernutrition is the largest single attributable factor at 0.97 million cases, but that is an attribution calculation and not a trial of feeding as prophylaxis.

BCG production needs a long industrial chain: live attenuated bacterial culture, lyophilisation, sterile fill-finish and a maintained cold chain. It is a needle vaccine and cannot be made by simple means.

**Treatment.** Prices are Stop TB Partnership Global Drug Facility indicative ex-works prices, version Q3-2025, dated 22 September 2025, valid through December 2025. GDF publishes price per pack, not price per completed course, and no course cost is derivable from it.

| Regimen or drug | EML | Off-patent | GDF Q3-2025 pack price, USD |
|---|---|---|---|
| RHZE 150/75/400/275 fixed-dose combination, first line | Yes | Yes | 66.04 per 672 tablets |
| RHE 150/75/275 fixed-dose combination | Yes | Yes | 52.18 per 672, limited availability |
| Rifapentine/isoniazid 300/300, preventive | Yes | Yes | 9.97 per 36 tablets |
| Linezolid 600 mg | Yes | Yes | 16.00 per 100 tablets |
| Levofloxacin 500 mg | Yes | Yes | 4.61 per 100 tablets |
| Bedaquiline 100 mg | Yes | Patent contested and eroding | 44.44 per 100 blister; 122.20 per 188 HDPE |
| Pretomanid 200 mg | Yes | No, patented and licensed | 123.08 per 100 tablets |
| Delamanid 50 mg | Yes | No | 85.00 per 48 tablets |

Paediatric dispersible formulations, same source: rifampicin/isoniazid 75/50 mg at 4.75 per 84; RHZ 75/50/150 mg at 6.57 per 84; isoniazid 100 mg at 9.00 per 100.

The resistance penalty, computed from those pack prices: first-line RHZE works out at 9.8 US cents a tablet at the GDF Q3-2025 ex-works pack price, pretomanid at US$1.23 a tablet — about 12.5 times as much per tablet, before the rest of the regimen is counted. GDF published no per-course BPaLM price in the Q3-2025 list. A 38 per cent price reduction for the BPaLM regimen was announced by GDF and relayed by EATG, but the per-course figure was not confirmed from the primary catalogue.

**Simple means.** Partial, and genuine as far as it goes. Ventilation and sunlight: airborne transmission falls with air exchange, which was the sanatorium rationale. Separating the coughing patient from children, especially where people sleep. Feeding the patient, since undernutrition is the largest attributable factor and food is not an industrial product. Case-finding by asking who has coughed for more than two weeks, which needs no instrument.

What cannot be done without a chain is cure. The drugs require multi-step pharmaceutical synthesis, and partial or interrupted treatment generates resistance, which is worse than no treatment. The minimum chain is multi-drug synthesis, plus an uninterrupted four- to six-month supply, plus some means of distinguishing drug-resistant disease.

**Gaps.** WHO publishes no global treatment success rate; it is not on the fact sheet, not on either Global Tuberculosis Report page, and sits only in the full report PDF, which did not render as text. BCG efficacy against adult pulmonary TB is genuinely contested and WHO declines to give a number. The widely cited figure of tens of US dollars for a first-line course could not be confirmed from the primary GDF document and is not asserted. The latent reservoir of a quarter of the global population rests on tuberculin and IGRA positivity, which measure immune memory rather than live organisms; the viable reservoir is unknown.

Neither the fact sheet nor the report pages carry an incidence rate per 100,000 or a total drug-resistant TB burden†.

---

## HIV/AIDS

**What it is.** A retrovirus that infects and destroys CD4 T-cells, the coordinating cells of the immune system. Untreated, immunity falls over years until ordinary organisms become lethal. Treatment suppresses the virus but does not remove it from the body.

**Measured.** WHO fact sheet, 27 July 2026, reporting 2025 data. 41.0 million people living with HIV at the end of 2025, 64 per cent of them in the WHO African Region. 1.2 million new infections in 2025. 570,000 HIV-related deaths. 44.2 million cumulative deaths to date.

Cascade 2025: 88 per cent knew their status; 89 per cent of those were on antiretroviral therapy; 95 per cent of those on therapy were virally suppressed. Multiplying the first two gives about 78 per cent of all people with HIV on treatment; that product is arithmetic performed here and is not a WHO-stated figure.

Advanced HIV disease is defined as CD4 below 200 cells/mm³ or WHO stage 3 or 4. All children under five with HIV are presumed to have it.

The fact sheet gives no age-specific breakdown of incidence or mortality.

**Where it starts.** Unprotected sexual contact, blood and blood products, shared injecting equipment, and transmission from mother to child in pregnancy, at birth or through breastfeeding. Syphilis roughly doubles the risk of acquiring HIV. Untreated HIV raises TB risk twelve-fold.

Not known: why a small number of people control the virus without treatment, and why a few appear resistant to infection beyond the known CCR5-delta32 mechanism. The persistence of the latent proviral reservoir is understood mechanically — integrated DNA in resting cells — and has no solution. Why post-treatment control occurs in rare individuals is unexplained.

**Cure status.** CONTROLLABLE. Antiretroviral therapy suppresses replication to undetectable levels and restores immunity, and 95 per cent of those treated achieve viral suppression. But the integrated proviral reservoir persists and stopping treatment leads to rebound, so treatment is lifelong. A handful of individual cures exist following allogeneic stem-cell transplant with CCR5-delta32 donors. These are case reports arising from cancer treatment, not a scalable cure, and they do not change the classification.

**Prevention.**

Antiretroviral therapy for the infected person, treatment as prevention: STRONG. An undetectable viral load effectively prevents sexual transmission, and 95 per cent of those treated are suppressed.

Lenacapavir, twice-yearly injectable pre-exposure prophylaxis: STRONG. PURPOSE 1, in South Africa and Uganda, recorded zero infections among 2,134 women in the lenacapavir arm. The Descovy arm of 2,136 had 39 infections, an incidence of 2.0 per cent, and the Truvada arm of 1,068 had 16, an incidence of 1.7 per cent†. Background incidence was 2.4 per cent. No confidence intervals were released at that point, and with zero events in the active arm efficacy is bounded below rather than point-estimated. UNAIDS, 24 September 2025, reports PURPOSE 2 as 96 to 100 per cent effective, citing the NEJM paper.

Oral pre-exposure prophylaxis: STRONG where taken. In PURPOSE 1, Descovy reduced incidence by about 16 per cent and Truvada by about 30 per cent against background — the trial's own comparison, which reflects adherence in young women rather than drug potency.

Prevention of mother-to-child transmission: STRONG. WHO recommends infant virological testing from birth or six weeks. Denmark was reported as the first EU country to eliminate mother-to-child transmission of HIV and syphilis, WHO news item, 27 February 2026.

Condoms: STRONG. The barrier blocks the transmission route.

Voluntary medical male circumcision: STRONG, from three randomised trials in Africa. The trial figures were not retrievable and no number is asserted.

No vaccine exists.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| TLD — tenofovir, lamivudine, dolutegravir — first line | Yes | Yes, generic under voluntary licence | Below US$45 per patient-year for low-income countries, via Global Fund agreements reported 2023/2024 |
| Lenacapavir, for prevention | Added for PrEP, 2025 update | No; patented, with voluntary licences to six manufacturers for 120 countries | US$40 per person-year generic target under the Dr Reddy's and Hetero agreements, plus up to US$17 for the oral lead-in; US list price for treatment US$28,000 per person-year; Lancet HIV estimates generic at US$35–46 per person-year at scale, falling to US$25 at high demand |
| Co-trimoxazole prophylaxis | Yes | Yes | Cents per day |

Co-trimoxazole is given to reduce opportunistic infection, including in HIV-infected children to reduce pneumonia risk. The US$40 per person-year lenacapavir figure, the generic target reported by UNAIDS in 2025 for the 120 countries under voluntary licence, is a commitment, not an observed market price.

**Simple means.** Condoms are a manufactured item, but they need no cold chain, no prescription and no clinician. Not sharing needles; using a fresh blade or needle where one exists. Boiling or sterilising any skin-piercing instrument. Breastfeeding decisions depend on maternal treatment status under WHO guidance and are therefore not supply-chain-free.

Nothing available without an industrial chain treats HIV or prevents it pharmacologically. The minimum chain for antiretroviral therapy is multi-step organic synthesis, formulation, and an uninterrupted lifelong supply; interruption causes resistance and rebound. There is no low-technology substitute.

**Gaps.** The fact sheet gives no age-disaggregated incidence or mortality, so no age pattern is reported. Lenacapavir confidence intervals were not retrievable. Whether the US$40 per person-year price, the 2025 generic target for the 120 licensed countries, will be realised at volume is unknown. Male circumcision trial effect sizes are well established in the literature but were not retrieved, and no number is asserted.

---

## Malaria

**What it is.** A parasitic disease caused by *Plasmodium* species, carried between people by *Anopheles* mosquitoes. The parasite multiplies in liver and red blood cells, causing cycles of fever. *P. falciparum* can obstruct brain and organ circulation and kill within days.

**Measured.** WHO fact sheet, 4 December 2025, drawing on the World Malaria Report 2025 and reporting 2024 data. About 282 million cases in 2024, up about 9 million or 3 per cent on 2023, in 80 countries. About 610,000 deaths, against 598,000 in 2023.

The WHO African Region carried about 95 per cent of cases, 265 million, and about 95 per cent of deaths, 579,000. Over half of African Region deaths fell in three countries: Nigeria 31.9 per cent, DR Congo 11.7 per cent, Niger 6.1 per cent. Eleven African countries account for about two thirds of global cases and deaths.

Children under five account for about 75 per cent of malaria deaths in the African Region. The fact sheet also prints 76 per cent, in an adjacent paragraph of the same section, and the two figures are not reconciled on the page. Both are recorded; the appendix of single-source contradictions carries this as item 1.

37 countries reported fewer than 1,000 indigenous cases in 2024, up from 13 in 2000, and 14 countries have been certified malaria-free since 2017.

Resistance and diagnostic failure: partial artemisinin resistance is confirmed in Eritrea, Rwanda, Uganda and Tanzania and suspected in Ethiopia, Namibia, Sudan and Zambia. HRP2/HRP3 gene deletions, which defeat the rapid diagnostic tests, are reported in 42 countries and exceed 15 per cent prevalence in Brazil, Djibouti, Eritrea, Ethiopia, Nicaragua and Peru. *Anopheles stephensi* has been detected in eight African countries.

**Where it starts.** Inoculation of *Plasmodium* sporozoites by an infected *Anopheles* mosquito, with symptoms beginning 10–15 days after the bite. The risk structure is proximity to vector breeding water, absence of a barrier at night since the vector bites nocturnally, and absence of prior immunity — which is why under-fives and pregnant women carry the mortality. Partial acquired immunity in endemic adults is well established and is why the same parasite load produces different disease at different ages.

Not known: what determines progression to severe and cerebral malaria in a given child, beyond parasite load and age. The mechanism of cerebral malaria is contested between mechanical obstruction and inflammatory models. Why some children develop severe anaemia and others cerebral disease is unexplained. The duration and decay of naturally acquired immunity are not well quantified.

**Cure status.** Split by species and regimen.

P. falciparum: CURABLE P. vivax and P. ovale, with radical cure added: CURABLE P. vivax and P. ovale, blood-stage treatment only: CONTROLLABLE

An artemisinin-based combination therapy clears the parasite and the person is well. The relapsing species carry dormant liver stages and need an added 8-aminoquinoline, primaquine or tafenoquine, for radical cure; without it the infection recurs from the liver, so blood-stage treatment alone holds the state rather than removing it. Emerging partial artemisinin resistance, confirmed in four African countries, threatens curability without yet having removed it.

**Prevention.**

Insecticide-treated nets: STRONG. Cochrane review CD000363, insecticide-treated nets against no nets:

- all-cause child mortality, rate ratio 0.83 (95 per cent CI 0.77–0.89), a 17 per cent reduction; 5 trials, 200,833 participants; high certainty
- severe malaria episodes, RR 0.56 (95 per cent CI 0.38–0.82), a 44 per cent reduction; 2 trials, 31,173; high certainty
- uncomplicated *P. falciparum*, RR 0.55 (95 per cent CI 0.48–0.64); 5 trials, 35,551; high certainty
- uncomplicated *P. vivax*, RR 0.61 (95 per cent CI 0.48–0.77); moderate certainty
- 5.6 fewer child deaths per 1,000 children protected per year (95 per cent CI 3.6–7.6)

Against *untreated* nets the picture is different and should not be collapsed into the first: child mortality RR 0.67 (95 per cent CI 0.36–1.23), an interval that includes 1, and 3.5 deaths averted per 1,000 (95 per cent CI −2.4 to 6.8), an interval that includes zero. The insecticide, not the net alone, carries the measured mortality benefit, and that specific comparison is uncertain.

R21/Matrix-M vaccine: STRONG. Phase 3 in 4,800 children in Burkina Faso, Kenya, Mali and Tanzania, as reported by the University of Oxford Nuffield Department of Medicine from the Lancet phase 3 paper:

- 12-month efficacy, seasonal sites: 75 per cent (95 per cent CI 71–79, $p<0.001$)
- 12-month efficacy, perennial sites with age-based dosing: 68 per cent (95 per cent CI 61–74, $p<0.001$)
- 18-month efficacy, seasonal sites, after a booster: 74 per cent (95 per cent CI 70–77, $p<0.001$)
- youngest group, aged 5–17 months: 79 per cent (CI 73–84) seasonal, 75 per cent (CI 65–83) standard

RTS,S/AS01 vaccine: STRONG. Phase 3 reduced cases by more than 50 per cent in the first year, and by about 75 per cent in combination with seasonal malaria chemoprevention in highly seasonal areas. The pilot programme in Ghana, Kenya and Malawi, 2019–2023, showed a vaccine-attributable 13 per cent reduction in all-cause mortality among age-eligible children. WHO publishes no confidence intervals on that page, and states that the two vaccines have not been compared head to head and that there is no evidence either performs better.

Both malaria vaccines need a long industrial chain. They are recombinant protein vaccines with saponin adjuvants — R21 uses Matrix-M, which requires *Quillaja* extract, and RTS,S

uses AS01, containing QS-21 and MPL. Production requires recombinant protein expression, adjuvant manufacture, sterile fill-finish and an unbroken 2–8 °C cold chain. Neither is producible by simple means.

Seasonal malaria chemoprevention: STRONG in the Sahel, including in combination with vaccination. Indoor residual spraying: STRONG by WHO recommendation, with no numerical effect size published. New-generation nets: MODERATE; WHO states they outperform pyrethroid-only nets and gives no numerical effect size.

**Treatment.** Artemisinin-based combination therapy is first line. The standing agents — artemether-lumefantrine, artesunate-amodiaquine, dihydroartemisinin-piperaquine — are all on the EML and off-patent. Injectable artesunate is the treatment for severe malaria, on the EML and off-patent. Primaquine and tafenoquine are used for radical cure of relapsing species; tafenoquine is not off-patent.

Neither the fact sheet nor the WHO vaccine question-and-answer page gives ACT course prices, and no primary-source price was confirmed. The frequently cited figure of cents to a dollar per paediatric ACT course is not asserted here. On vaccines, WHO states that R21 is currently less expensive than RTS,S and that many Gavi-supported countries pay as little as US$0.20 per dose, as their co-financed portion. No list price is published.

**Simple means.** A net over the sleeping place. A plain untreated net is a physical barrier against a night-biting vector; the Cochrane comparison above shows the insecticide carries most of the measured mortality benefit, so an untreated net is weaker and not equivalent — but it requires no chain. Draining or covering standing water near dwellings. Screening windows and doors, and closing openings at dusk. Sleeping away from breeding water, and siting dwellings accordingly. Smoke and plant repellents are traditional and widely used, with no reliable effect size.

Cure and vaccination are not achievable without a chain. The minimum chain for ACTs is *Artemisia annua* cultivation or semi-synthesis, extraction of artemisinin, synthesis of the partner drug, and co-formulation.

One simple means here is worse than none. Artemisinin monotherapy from home-brewed *Artemisia* tea is actively counter-productive: subtherapeutic monotherapy selects for exactly the partial resistance now confirmed in four African countries.

**Gaps.** The fact sheet contradicts itself on the under-five share of African deaths, 76 against 75 per cent in adjacent sentences; see the appendix, item 1. The page also prints 4 December 2025 while carrying a 2026 copyright notice and 2026 linked items; see the appendix, item 2. WHO publishes no numerical effect size for indoor residual spraying or for new-generation nets. No list price exists for either vaccine, only the Gavi co-financing figure. ACT course prices could not be sourced primarily. Cases rose 3 per cent in 2024, and whether that reflects true incidence, better detection or both is not resolved in the source. HRP2/HRP3 deletions above 15 per cent in six countries undermine the rapid tests that case counts depend on, so case figures from those countries are not comparable with others.

---

## Lower respiratory infections — pneumonia

**What it is.** Infection of the lung’s air sacs, which fill with fluid and pus so that breathing no longer oxygenates the blood. It is caused by bacteria, viruses or fungi. It is the common final pathway by which many infections kill children.

**Measured.** WHO fact sheet on pneumonia in children, 11 November 2022, reporting 2019 data. This is the oldest principal source used in this chapter, and no newer WHO pneumonia sheet exists.

740,180 children under five died of pneumonia in 2019. Pneumonia caused 14 per cent of all under-five deaths and 22 per cent of deaths in children aged one to five. Only one third of children with pneumonia receive the antibiotics they need. Deaths are highest in southern Asia and sub-Saharan Africa.

The dossiers disagree on the same quantity, and the disagreement stands. This chapter’s source gives the point figure 740,180 for 2019; the circulatory and respiratory chapter gives roughly 700,000 to 740,000 child deaths a year, about 14 per cent of all under-five deaths.

The range and the point figure are compatible. What is not compatible is scope: this entry carries no all-age lower respiratory infection death figure at all, while that chapter gives WHO 2.7 million against GBD 2023 2,501,300 and flags the roughly 200,000 gap between them. The two chapters are therefore not comparable on the burden of this disease. Both stand.

For orientation across the book: GBD 2023 ranks lower respiratory infections fourth among all causes of death and fourth among causes of DALYs, at 98.7 million DALYs (95 per cent UI 87.7–112). WHO's Global Health Estimates for 2023 give 2.7 million deaths and the same fourth rank. Age-standardised DALY rates for lower respiratory infections fell 25 per cent between 2010 and 2023.

Pathogen shares: *Streptococcus pneumoniae* is the most common bacterial cause, *Haemophilus influenzae* type b second, respiratory syncytial virus the most common viral cause, and *Pneumocystis jirovecii* causes at least a quarter of pneumonia deaths in HIV-infected infants.

**Where it starts.** The pathogens above, acquired by inhalation or aspiration. WHO names as risk factors the absence of exclusive breastfeeding in the first six months, undernutrition, indoor air pollution, crowding, parental smoking and HIV infection. Measles and pertussis predispose to pneumonia, which is why their vaccines appear as pneumonia prevention.

Not known: the true pathogen attribution per case. Sputum and blood cultures are insensitive in children, so pathogen-specific shares rest on vaccine-probe studies and modelling rather than direct measurement. What makes one child with a common virus develop bacterial superinfection is not established. The relative contribution of viral-bacterial co-infection is contested.

**Cure status.** Split by cause.

bacterial pneumonia: CURABLE viral pneumonia: SELF-LIMITING

Antibiotics clear the bacterial organism and the lung recovers; amoxicillin dispersible tablets are first line in children. For viral pneumonia no agent reliably removes most respiratory viruses, and most cases resolve with supportive care and, where needed, oxygen. For RSV and influenza specifically, see their own entries.

The classification turns on which pathogen is present, which is often not determinable at the point of care. That is the practical reason WHO recommends empirical antibiotics for children with fast breathing.

The circulatory and respiratory chapter declares a single CURABLE label for the same disease, calling it one of the clearest cures in medicine, with viral pneumonia demoted to a bullet inside its evidence. Both stand.

**Prevention.**

Pneumococcal conjugate vaccine: STRONG. The Gambian 9-valent PCV trial, Cutts and colleagues, *Lancet* 2005;365:1139–46, per-protocol:

- invasive pneumococcal disease, vaccine serotypes: 77 per cent (95 per cent CI 51–90)
- invasive pneumococcal disease, all serotypes: 50 per cent (95 per cent CI 21–69)
- radiological pneumonia: 37 per cent (95 per cent CI 27–45)
- all-cause admissions: 15 per cent (95 per cent CI 7–21)
- all-cause mortality: 16 per cent (95 per cent CI 3–28)

Intention-to-treat, same trial: vaccine-serotype invasive disease 71 per cent (95 per cent CI 46–86); all-serotype 45 per cent (95 per cent CI 19–62); radiological pneumonia 36 per cent (95 per cent CI 27–43); all-cause admissions 13 per cent (95 per cent CI 6–19); all-cause mortality 14 per cent (95 per cent CI 2–24).

The all-cause mortality figure is worth isolating: a vaccine reducing death from all causes, not merely from its target disease.

On the radiological pneumonia figure the dossiers disagree. The circulatory and respiratory chapter gives roughly 25 to 37 per cent from the Gambian and South African trials. The 37 per cent upper end agrees with the per-protocol figure above. The 25 per cent lower end appears in no other file, and its source is named but was not opened again. Both stand.

PCV needs a long industrial chain, among the longest in this chapter: bacterial polysaccharide culture, chemical conjugation to a carrier protein, purification, sterile fill-finish and an unbroken 2–8 °C cold chain. Coverage of the last PCV dose was 71 per cent globally in 2025.

Hib conjugate vaccine: STRONG. Hib is the second most common bacterial cause, and coverage for three doses was 78 per cent in 2025. Trial efficacy figures were not retrievable and are not asserted. The chain is as for PCV: long, cold.

Measles and pertussis vaccination: STRONG as pneumonia prevention, by removing the predisposing infections.

Exclusive breastfeeding for six months: STRONG by WHO recommendation. No effect size is published on the page.

Reducing indoor air pollution: MODERATE. WHO lists it as a risk factor; cookstove trials have given mixed results.

Co-trimoxazole prophylaxis in HIV-infected children: STRONG, with no figure given on the page.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Amoxicillin dispersible tablets, first line in children | Yes, 6.2.1 Access group, core | Yes | UNICEF indicative price US$0.54 per pack of ten 250 mg dispersible tablets, October 2026, or about 5.4 US cents per tablet |
| Oxygen | Yes, medical oxygen is listed | n/a | Variable; requires a concentrator or cylinder supply |
| Ampicillin with gentamicin, severe inpatient disease | Yes | Yes | Cents to low dollars per course |
| Ceftriaxone, second line | Yes | Yes | Low dollars per course |

The amoxicillin price is a UNICEF Supply Catalogue indicative price read on 19 October 2026. The catalogue returns different indicative prices for the same material number on different pages, so it is printed as indicative and dated, not as a price. For comparison, the NHS Drug Tariff for England and Wales, September 2026, Part VIIIA, gives amoxicillin 250 mg capsules at 76 for a pack of 15, about 5.1 per capsule. The retrieved text does not carry the column heading, so the unit is unconfirmed; NHS basic prices are conventionally pence.

Oxygen is the rate-limiting treatment for severe childhood pneumonia. It is a supply problem, not a drug-cost problem.

**Simple means.** Counting breaths. WHO’s case definition uses respiratory-rate thresholds by age, and a carer can count breaths for a minute with no instrument. That is the detection step, and it is free. Breastfeeding, exclusively for six months. Keeping cooking smoke out of the sleeping space, by cooking outdoors or venting it. Keeping the child warm and fed, and upright rather than flat. Handwashing by carers, which reduces transmission of the respiratory pathogens.

Two things cannot be done without a chain: cure of bacterial pneumonia, and oxygen for the hypoxic child. The minimum chain for amoxicillin is semi-synthetic penicillin fermentation plus formulation. For oxygen it is either a pressure-swing-adsorption concentrator with uninterrupted electricity, or cylinder logistics. Oxygen cannot be improvised.

**Gaps.** The WHO pneumonia fact sheet is dated 11 November 2022 and reports 2019 deaths; it is the oldest principal source in this chapter and no newer sheet was retrievable. Pathogen attribution rests on vaccine-probe and modelling methods, not direct measurement. The fact sheet gives no incidence figure, only deaths. GBD 2023 per-cause death counts could not be read off the published table, which truncates at the same point on every attempt, so the all-age figure here rests on WHO’s Global Health Estimates rather than on GBD’s own table. No effect size is published on WHO pages for breastfeeding or for air-pollution reduction against pneumonia.

## Influenza (seasonal)

**What it is.** A respiratory virus with surface proteins that change continually, so immunity from one year does not reliably protect the next. Most people recover in about a week. It kills mainly through pneumonia and through decompensation of existing heart and lung disease.

**Measured.** WHO fact sheet, 28 February 2025. About 1 billion cases a year, including 3 to 5 million cases of severe illness. 290,000 to 650,000 respiratory deaths a year.

In industrialised countries most influenza-associated deaths occur in people aged 65 and over. 99 per cent of deaths in children under five with influenza-related lower respiratory tract infection occur in developing countries.

Symptoms begin one to four days after infection, with an incubation of about two days, and usually last about a week; cough can persist two weeks or more.

**Where it starts.** Influenza A and B viruses, transmitted by droplets and aerosols. Risk factors for severe disease are age over 65, age under 5, pregnancy, chronic heart, lung, kidney, liver and metabolic disease, immunosuppression, and health-worker exposure. Antigenic drift and shift in the surface haemagglutinin are the established reason for annual recurrence and for pandemics.

Not known: the determinants of seasonality are not settled. Humidity, temperature, indoor crowding, vitamin D and host-immunity hypotheses all have support and none is established. Which strain will dominate a coming season cannot be predicted reliably, which is the structural limit on vaccine matching. Why some healthy young adults die of influenza while most do not is unexplained.

**Cure status.** Split by severity.

most cases: SELF-LIMITING severe cases: RELIEF ONLY

Most infections resolve unaided in about a week and intervention adds nothing for a healthy adult. No agent removes the virus. Antivirals shorten illness and reduce complications if started early, which is relief and risk reduction, not cure. For the severely ill, treatment is supportive. WHO recommends antivirals as soon as possible for high-risk people and for those with severe symptoms, including children under 59 months and people aged 65 and over.

**Prevention.**

Annual vaccination: MODERATE, varying by season and by age. The fact sheet gives no numerical efficacy figure. It states that the vaccine may be less effective in older people while still reducing severity, complications and death, and that safe and effective vaccines have been in use for over sixty years. Efficacy genuinely varies year to year with strain match, which is why a single figure is not quotable, and no confidence interval is asserted because WHO publishes none on the page.

Influenza vaccine needs a chain that repeats every year. Most seasonal vaccine is grown in fertilised hen’s eggs or in mammalian cell culture, then inactivated, split, formulated, sterile-filled and cold-chained at 2–8 °C — and the whole cycle is repeated annually against a new strain selection. It is among the least improvisable products in this chapter.

Hand hygiene and respiratory etiquette: MODERATE. Staying home when ill: MODERATE, by removing the source from circulation. Ventilation: MODERATE, on aerosol physics.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oseltamivir | Yes | Yes | Low; no primary price confirmed |
| Supportive care and oxygen | Yes, oxygen | n/a | Variable |
| Paracetamol, symptom relief | Yes | Yes | Cents per course |

The fact sheet gives no dosages, efficacy figures or prices for antivirals. Baloxavir is not off-patent. Zanamivir is off-patent but little used.

**Simple means.** Rest, fluids and time, which is the actual treatment for most cases. Isolating the ill person from the elderly and the chronically ill in the household — the people who die.

Ventilating rooms; opening windows. Handwashing and covering coughs. Paracetamol is manufactured but is a simple, cheap and widely available chemical.

These are adequate for the majority of cases, because the condition is self-limiting. What cannot be done without a chain is prevention, which means the annual vaccine, and treatment of the severely ill, which means antivirals, oxygen and ventilation.

**Gaps.** WHO publishes no vaccine efficacy percentage or confidence interval on the fact sheet, and genuine season-to-season variation makes any single figure misleading. The death range, 290,000 to 650,000, is wide, and influenza deaths are mostly statistically inferred from excess mortality rather than counted, because most are attributed to pneumonia or cardiac causes. The 1 billion annual case estimate is modelled. Burden in low-income countries is poorly measured, and the figure that 99 per cent of child deaths occur there implies the burden is concentrated exactly where surveillance is weakest. GBD 2023 influenza figures were not retrievable†.

---

## Respiratory syncytial virus (RSV)

**What it is.** A respiratory virus that infects nearly every child by the age of two. In most it causes a cold. In small infants it inflames the smallest airways — bronchiolitis — which can obstruct breathing. It also causes severe disease in the elderly.

**Measured.** WHO fact sheet, 19 December 2025. About 3.6 million RSV-associated hospitalisations a year in children under five worldwide. About 100,000 RSV-attributable deaths a year in children under five. About half of paediatric RSV deaths occur in infants under six months. 97 per cent of paediatric RSV deaths occur in low- and middle-income countries.

In United States adults over 65: up to 160,000 hospitalisations and up to 10,000 deaths a year. No global adult burden estimate is published, so the global elderly burden is unquantified here.

Almost all babies are infected by their second birthday, and maternal antibodies protect infants for about six months after birth. Temperate climates have seasonal epidemics, usually in late autumn and winter, with elevated circulation of about five months on average; subtropical and tropical countries have consistent high-circulation months without a clear seasonal pattern.

No global case count is published.

**Where it starts.** RSV, transmitted by droplets, hands and surfaces. Risk factors for severe disease are age under six months, prematurity, congenital heart and lung disease, immunodeficiency and crowding. The established protective mechanism is transplacental maternal antibody, which is the rationale for both maternal vaccination and monoclonal antibody prophylaxis.

Not known: why bronchiolitis severity varies so widely between infants with the same virus. The relationship between infant RSV bronchiolitis and later childhood asthma is genuinely unresolved — whether RSV causes the airway change or reveals a pre-existing predisposition is contested. The failure of the early formalin-inactivated RSV vaccine, which worsened disease, is explained after the fact but was not predicted, and vaccine-enhanced disease remains a design constraint.

**Cure status.** Split by severity.

most infections: SELF-LIMITING severe bronchiolitis: RELIEF ONLY

Most infections resolve unaided. For severe bronchiolitis nothing removes the virus, and management is oxygen, suction and feeding support. Bronchodilators and corticosteroids do not alter the course of RSV bronchiolitis in infants, a well-replicated negative finding. Ribavirin is not recommended for routine use.

**Prevention.**

Long-acting monoclonal antibody, nirsevimab: STRONG. WHO recommends it for infants entering their first RSV season and notes that countries could consider it for high-risk children up to 24 months entering a second season. WHO gives no efficacy figures and does not name the product. The MELODY and HARMONIE trial efficacy figures with confidence intervals

could not be retrieved: publisher sites were blocked and the search budget was exhausted. **Efficacy.** No efficacy number is asserted.

Nirsevimab needs a long chain. A monoclonal antibody requires mammalian cell culture, chromatographic purification, sterile fill-finish and an unbroken 2–8 °C cold chain. It is among the least improvisable interventions in this chapter.

Maternal vaccination in the third trimester: STRONG by WHO recommendation, from 28 weeks' gestation in most settings. **Efficacy:** — no figure is given on the WHO page and the MATISSE trial was not retrievable. The chain is a recombinant protein vaccine: long, with a 2–8 °C cold chain and a needle.

Handwashing and surface hygiene: MODERATE. RSV transmits readily by hands and fomites. Keeping small infants away from coughing children: MODERATE, on transmission grounds. Breastfeeding: MODERATE, on consistent observational association with reduced severity. Avoiding tobacco smoke exposure: MODERATE, on consistent observational evidence.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oxygen and supportive care | Yes, oxygen | n/a | Variable; the main requirement |
| Nasal suction, feeding support | n/a | n/a | Minimal |
| Nirsevimab, prophylaxis rather than treatment | Not confirmed on the 24th List | No, patented | High-income list prices in the hundreds of US dollars per dose; no verified low-income price |

There is no curative drug. Bronchodilators, corticosteroids and antibiotics do not help uncomplicated RSV bronchiolitis, and antibiotics are frequently given without benefit.

**Simple means.** Upright positioning, clearing the nose, small frequent feeds. For a wheezy infant that is most of the care. Saline drops and gentle suction, both improvisable. Handwashing before handling small infants. Keeping newborns out of crowds during local epidemics. Not smoking near the infant. Watching for the signs that matter — feeding failure, chest recession, apnoea, blue lips — all observable with no instrument.

What cannot be done without a chain is oxygen for the hypoxic infant, and both forms of prophylaxis. Oxygen is the single intervention that converts severe RSV bronchiolitis from often fatal to usually survivable, and it requires a concentrator plus electricity, or cylinders.

**Gaps. Nirsevimab efficacy and maternal vaccine efficacy** are the two interventions that define current practice, and neither figure is in this entry. WHO publishes none, and the trial papers — MELODY, NEJM 2022; HARMONIE, NEJM 2023; MATISSE, NEJM 2023 — could not be reached. This is the largest single data gap in the chapter. **Global case count. Global adult burden:** ; the only adult figures available are United States figures. The RSV-asthma causal question is genuinely contested. The 100,000 under-five deaths figure is modelled, since RSV is rarely laboratory-confirmed where most deaths occur.

---

## Diarrhoeal diseases (overview)

**What it is.** Passage of three or more loose or liquid stools a day, caused by many organisms acquired from contaminated water, food or hands. It kills by dehydration. The loss of water and salts, not the organism itself, is what stops the heart.

**Measured.** WHO fact sheet on diarrhoeal disease, 7 March 2024. Diarrhoea is the third leading cause of death in children aged 1 to 59 months. About 443,832 children under five die each year, plus 50,851 children aged five to nine. Nearly 1.7 billion cases of childhood diarrhoeal disease a year. In low-income countries, children under three average three episodes a year.

The page gives no data year anywhere for its mortality figures. Only the 2024 print date is available, and the 443,832 figure is stated to six significant figures for what is a modelled estimate.

780 million people lack access to improved drinking water and 2.5 billion lack improved sanitation. Those two figures are not dated on the page and appear to predate the sheet's 2024 revision.

Definitions, from the same source: diarrhoea is three or more loose stools a day; persistent diarrhoea is 14 days or longer.

For orientation across the book: GBD 2023 ranks diarrhoeal diseases tenth among causes of DALYs, at 56.5 million (95 per cent UI 43.8–72.7). Age-standardised diarrhoeal DALY rates roughly halved between 2010 and 2023. In low-income countries diarrhoeal diseases ranked fifth among all causes of death in 2023.

**Where it starts.** Faecal-oral transmission of viruses, bacteria and protozoa through water, food, hands and surfaces. Risk factors: absence of safe water, absence of sanitation, absence of handwashing, absence of exclusive breastfeeding, undernutrition — which is both cause and consequence — and measles.

Not known: the pathogen-specific attribution of deaths is uncertain, because most fatal cases are never cultured. The bidirectional relationship between diarrhoea and undernutrition, environmental enteric dysfunction, is recognised but not quantitatively resolved. Why some children develop persistent diarrhoea is not established.

**Cure status.** Split by cause.

most episodes, with rehydration: SELF-LIMITING shigella, typhoid, amoebiasis, giardiasis: CURABLE cholera, rotavirus, norovirus: SELF-LIMITING

Most episodes are self-limiting: the body clears the organism, and the intervention needed is replacement of water and salts, not removal of the pathogen. That is the central fact of the condition. The deaths are from dehydration, which is preventable with a solution of salt, sugar and water. Specific bacterial and protozoal causes are additionally curable with antibiotics. The viral causes have no curative agent and need none. Cholera is moved to the self-limiting row.

**Prevention.**

Handwashing with soap: STRONG. Cochrane review CD004265, handwashing promotion:

- child day-care centres and schools, high-income countries: incidence rate ratio 0.70 (95 per cent CI 0.58–0.85); 9 trials, 4,664 participants; high certainty
- communities, low- and middle-income countries: IRR 0.71 (95 per cent CI 0.62–0.81); 9 trials, 15,950; moderate certainty
- communities *with soap provided*: risk ratio 0.66 (95 per cent CI 0.58–0.75); 7 trials, 12,646
- communities, *education only, no soap*: RR 0.84 (95 per cent CI 0.67–1.05) — the interval includes 1; 2 trials, 3,304
- day-care and schools in low- and middle-income countries: IRR 0.66 (95 per cent CI 0.43–0.99); low certainty, interval barely excluding 1

Providing the soap, not telling people to wash, is what carries the effect.

Safe drinking water and sanitation: STRONG on settled transmission physiology; 780 million and 2.5 billion people respectively lack them. Exclusive breastfeeding for six months: STRONG by WHO recommendation. Rotavirus vaccination: STRONG, and see its own entry. Measles vaccination: STRONG as diarrhoea prevention, by removing a predisposing infection. Zinc supplementation: STRONG as a treatment adjunct, below.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oral rehydration salts | Yes | Yes | “A few cents per treatment”; UNICEF indicative US$4.80 per carton of 100 low-osmolarity sachets, October 2026, or about 4.8 US cents a sachet |
| Zinc, 10–14 day course | Yes | Yes | Cents per course |
| Intravenous Ringer’s lactate, severe dehydration only | Yes | Yes | Low dollars |
| Antibiotics, only for specific causes | Yes | Yes | See individual entries |

Zinc reduces episode duration by 25 per cent and is associated with a 30 per cent reduction in stool volume, over a recommended course of 10 to 14 days.

The fact sheet gives no numerical effectiveness figure for oral rehydration salts themselves, stating only that most people can be treated successfully with prompt rehydration. Antibiotics are not indicated for most diarrhoea and are widely misused in it, which drives resistance.

**Simple means.** This is the condition in this chapter where simple means do the most work.

Oral rehydration. The WHO-formula sachet is a manufactured item, but a home solution of salt, sugar and clean water replaces its essential function, and that alone addresses the mechanism of death. Continued feeding and breastfeeding during the illness rather than withholding food. Handwashing with soap — and soap is producible from fat and ash without an industrial chain. Water treatment: boiling, solar disinfection in clear bottles, sand and cloth filtration, settling and decanting. Separating faeces from water and hands, with latrines sited away from and below water sources, and covered. Assessing dehydration by hand: WHO's own three-level scale uses the skin pinch — returning slowly, at least two seconds, in severe dehydration — sunken eyes, and ability to drink, with no instrument required. Zinc is a manufactured tablet but a simple inorganic salt, not a complex synthesis.

Only intravenous rehydration for the child too shocked to drink requires a chain: sterile fluid, tubing and a cannula.

**Gaps.** The fact sheet reports no effectiveness figure for oral rehydration salts, despite its being the central intervention; the evidence predates modern trial reporting and is treated as settled. Pathogen-specific death attribution is uncertain. The water and sanitation figures are undated on the page. The under-five death figure is given to six significant figures, which overstates the precision of a modelled estimate, and no data year is printed for it at all. GBD 2023 per-cause diarrhoeal death counts could not be read off the published table; the DALY figure above is from the DALY table, which was legible.

---

## Rotavirus

**What it is.** A virus that infects the gut lining of young children, causing vomiting and watery diarrhoea. Before vaccination it infected essentially every child worldwide. It kills by dehydration.

**Measured.** Rotavirus is the leading single cause of severe childhood diarrhoea and is subsumed in the diarrhoeal totals of the overview entry: 443,832 under-five diarrhoeal deaths a year. The WHO diarrhoeal fact sheet lists rotavirus vaccination as a prevention measure but gives no rotavirus-specific case or death figures. A rotavirus-specific global death estimate could not be sourced primarily and is not asserted.

Vaccine coverage was 61 per cent globally in 2025 — the lowest coverage of the major childhood vaccines except the hepatitis B birth dose.

**Where it starts.** Rotavirus, faecal-oral. Incidence is notably *not* strongly reduced by water and sanitation improvement. Rotavirus spreads efficiently regardless of sanitation, which is why it remained universal in high-income countries until vaccination. This distinguishes it from the bacterial diarrhoeas.

Not known: why vaccine efficacy is so much lower in high-mortality settings. Candidate explanations include maternal antibody interference, gut microbiome differences, environmental enteric dysfunction, concurrent infections and oral polio vaccine interference. None is established. This is one of the clearest unexplained efficacy gradients in vaccinology.

**Cure status.** SELF-LIMITING. The body clears the virus. No antiviral exists or is needed. The intervention that matters is rehydration, which prevents death without removing the organism. Deaths occur from dehydration, not from failure to eliminate the virus.

**Prevention.**

Rotavirus vaccination: STRONG, with a large and unexplained setting gradient. Cochrane review CD008521, prevention of severe rotavirus diarrhoea. The Cochrane plain-language summary reports point estimates without confidence intervals; the absence of intervals is a limitation of the accessible summary, not of the review.

| Vaccine | Age period | Low-mortality countries | High-mortality countries |
|---|---|---|---|
| Rotarix | first year | 93 per cent; 14,976 participants, 4 trials, high certainty | 58 per cent; 15,882, 4 trials, high certainty |
| Rotarix | second year | 90 per cent; 18,145, 6 trials, high certainty | 35 per cent; 13,768, 2 trials, moderate certainty |
| RotaTeq | first year | 97 per cent; 5,442, 2 trials, high certainty | 57 per cent; 6,775, 2 trials, high certainty |
| RotaTeq | second year | 96 per cent; 5,442, 2 trials, high certainty | 44 per cent; 6,744, 2 trials, high certainty |

The vaccine works best where the disease kills least. In high-mortality settings second-year protection falls to 35–44 per cent.

The chain is long but shorter than for the conjugates, and the difference is instructive. Live attenuated oral rotavirus vaccines require cell-culture propagation in Vero cells, formulation and a cold chain — but no needles and no sterile injection, and oral administration needs no trained injector. Rotavac, made in India, and Rotasiil, which is thermostable and therefore reduces cold-chain dependence, have lowered both cost and chain burden. Thermostability here is a design achievement, not a property of the platform.

Exclusive breastfeeding: MODERATE. Water and sanitation: WEAK for rotavirus specifically, in contrast to bacterial diarrhoea — a well-documented exception.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oral rehydration salts | Yes | Yes | “A few cents per treatment”; UNICEF indicative about 4.8 US cents a sachet, October 2026 |
| Zinc, 10–14 days | Yes | Yes | Cents per course |
| Intravenous fluids if shocked | Yes | Yes | Low dollars |

No antiviral. Antibiotics are useless and harmful here.

**Simple means.** Fully effective for survival without any industrial chain. Oral rehydration with salt, sugar and clean water, which is the whole treatment for the overwhelming majority. Continued breastfeeding and feeding through the illness. Assessing dehydration by skin pinch, eyes, thirst and urine output. Handwashing, though it reduces rotavirus less than it reduces bacterial diarrhoea.

Prevention by vaccine requires a chain — cell culture, cold chain — but survival does not require any chain at all. This is one of the few conditions in the chapter where simple means address mortality almost completely.

**Gaps.** Cochrane reports point estimates without confidence intervals in the accessible summary; the full review contains them. **No rotavirus-specific global death figure is asserted** because none could be sourced primarily and WHO’s diarrhoeal sheet omits it. The efficacy gradient between low- and high-mortality settings is unexplained and is the single most important open question for this condition. Intussusception risk with the vaccines is small, real and differently quantified across studies; no figure is asserted.

---

## Cholera

**What it is.** *Vibrio cholerae* produces a toxin that makes the small intestine pour out water and salts. A healthy adult can lose litres an hour and die of dehydration within hours. It follows contaminated water, so it follows collapsed sanitation, war and displacement.

**Measured.** WHO fact sheet, 29 September 2026. Researchers’ annual global estimate is 1.3 to 4.0 million cases and 21,000 to 143,000 deaths. That range carries no data year at all on the page; the cited source is 2015.

Reported to WHO in 2025: 451,499 cases and 7,870 deaths across 47 countries. WHO states those were the highest reported deaths since 1999, and that reported figures fall below researchers’ estimates. Dividing gives a case fatality of about 1.7 per cent; that division is arithmetic performed here and is not a WHO-stated figure. WHO publishes no observed

case fatality rate, only the benchmark that case fatality in treatment centres should remain below 1 per cent.

Symptoms appear 12 hours to 5 days after infection, and asymptomatic people shed bacteria for 1 to 10 days. Only serogroups O1 and O139 cause outbreaks, and O1 has caused all recent ones. The seventh pandemic began in south Asia in 1961.

**Where it starts.** Ingestion of *V. cholerae* O1, or O139, in water or food. The risk structure is absence of safe water and sanitation, displacement and camp settings, and population movement. The determinant of mortality is not the organism but the speed of fluid replacement.

Not known: the environmental reservoir dynamics between outbreaks. The role of copepods, algal blooms, estuarine persistence and climate drivers is partly characterised and not predictive. Why some infected people develop catastrophic purging while most are mild or asymptomatic is not explained; blood group O is a recognised severity risk factor without a settled mechanism. Outbreak timing is not predictable.

**Cure status.** SELF-LIMITING. The body clears the organism within days. Rehydration prevents the deaths, which come from dehydration, and does not remove the organism. Antibiotics shorten shedding and illness duration but are adjunctive. WHO states that most people can be treated successfully with prompt oral rehydration, and that case fatality in treatment centres should remain below 1 per cent — against an untreated severe-case fatality that historically reached 50 per cent or higher†. The patient returns to health and the organism does not persist.

**Prevention.**

Safe water and sanitation: STRONG. Settled transmission physiology; cholera does not occur where water is clean.

Oral cholera vaccine: MODERATE, with supply as the binding constraint. WHO gives no efficacy percentage. It states that two doses are needed for full adult protection, lasting at least three years; that one dose of Euvichol-Plus or Euvichol-S gives good but shorter-term protection; and that the vaccine is usable from the age of one. Since October 2022 only one-dose regimens have been used, because of shortage. Global production rose from about 30 million doses in 2022 to about 80 million in 2025, and in February 2026 20 million doses were allocated for preventive campaigns. Trial efficacy figures with confidence intervals could not be retrieved and are not asserted.

This is the least chain-dependent vaccine in the chapter, and it is worth being precise about why. Oral cholera vaccine is a killed whole-cell oral product: bacterial fermentation, inactivation, formulation, oral delivery. No needles, no sterile injection, no injector training, and less cold-chain sensitivity than live or conjugate vaccines. Bacterial fermentation is achievable at a far lower technological level than mammalian cell culture. The current limit on supply is manufacturer investment, not technical feasibility. It still cannot be made by simple means.

Case isolation and safe handling of the dead: MODERATE in outbreak settings. Treating cases promptly, which reduces both deaths and transmission: STRONG.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oral rehydration salts, the primary treatment | Yes | Yes | “A few cents per treatment”; UNICEF indicative about 4.8 US cents a sachet, October 2026 |
| Ringer’s lactate intravenously, for shocked patients | Yes | Yes | Low dollars per patient |
| Doxycycline, single dose, adjunct | Yes | Yes | Cents per course |
| Azithromycin, for children and in pregnancy | Yes, 6.2.2 Watch group, first choice for cholera | Yes | UNICEF indicative US$0.56 per pack of six 250 mg tablets, October 2026, about 9.3 US cents a tablet |

WHO maintains six cholera kits; each treatment kit treats 100 patients.

**Simple means.** Cholera is the clearest case in the chapter where simple means are decisive.

Oral rehydration with salt, sugar and clean water, given continuously and in volume. This converts a 50-per-cent-fatal illness into a survivable one. Rice water or cereal-based rehy-

dration, which works and uses local staples. Boiling or chlorinating drinking water; solar disinfection; filtration. Siting latrines away from and below water sources; burying faeces. Handwashing with soap, which is producible from fat and ash. Isolating the patient's stool and soiled cloth, and safe burial practice. A cholera cot — a simple bed with a hole and a bucket — allows output to be measured with no instrument.

What requires a chain: intravenous fluids for the patient too collapsed to drink, which means sterile fluid, tubing and a cannula; antibiotics; and vaccine. But the great majority of cholera deaths are preventable with salt, sugar, clean water and someone willing to keep giving it.

**Gaps.** WHO publishes no oral cholera vaccine efficacy figure; the trial literature does, and it was not retrievable. The gap between reported cases, 451,499, and estimated burden, 1.3 to 4.0 million, is a factor of three to nine, and the estimate range itself spans a factor of seven for deaths, so the true mortality is genuinely poorly known. The Key Facts burden range carries no data year. Reporting is politically sensitive and some countries do not report cholera as cholera, so reported figures are a floor. WHO's statement that reported deaths were the highest since 1999 sits against a long-term downward trend in case fatality; both are true and the source does not reconcile them.

---

## Shigellosis

**What it is.** *Shigella* bacteria invade the lining of the large bowel, causing bloody, painful diarrhoea with fever. A very small dose causes infection, so it spreads directly from person to person. It is the classic cause of epidemic dysentery.

**Measured.** Shigella is subsumed in the diarrhoeal totals of the overview entry. WHO publishes no standalone *Shigella* fact sheet, and the 19 October 2026 retrieval pass confirmed none exists at the expected address.

**Global cases. Global deaths.** No shigellosis-specific global figure was retrievable and none is asserted. What exists: *Shigella* is consistently identified in pathogen-attribution studies as a leading bacterial cause of moderate-to-severe diarrhoea and of diarrhoeal death in children over one year, and WHO lists fluoroquinolone- resistant *Shigella* among its priority resistant pathogens. The age pattern falls disproportionately on children aged one to four and above, rather than on infants.

**Where it starts.** *Shigella* species — *S. flexneri*, *S. sonnei*, *S. dysenteriae*, *S. boydii* — faecal-oral. The distinguishing feature is an infectious dose as low as 10 to 100 organisms, which permits direct person-to-person and hand-to-mouth transmission with no contaminated water vehicle. Risk factors: crowding, camps, childcare settings, absence of handwashing, and malnutrition.

Not known: why *S. sonnei* has displaced *S. flexneri* as economies develop is observed but not mechanistically explained. There is no licensed vaccine despite decades of effort, and the correlates of protective immunity are not established — which is the central reason no vaccine exists. The contribution of asymptomatic carriage to transmission is not well quantified.

**Cure status.** CURABLE. Antibiotics shorten illness, clear the organism and reduce transmission, and unlike most diarrhoea, antibiotics are genuinely indicated for *Shigella* dysentery. Resistance is advancing: WHO lists fluoroquinolone-resistant *Shigella* as a priority pathogen, and extensively drug-resistant *S. sonnei* has spread internationally. Where resistance defeats available agents the condition shifts toward supportive care only. Untreated, most cases are self-limiting over about a week, but in malnourished children shigellosis carries substantial mortality and causes lasting nutritional damage.

**Prevention.**

Handwashing with soap: STRONG, and especially effective here because the low infectious dose makes hand transmission dominant. Cochrane CD004265: communities with soap provided, RR 0.66 (95 per cent CI 0.58–0.75); education only, RR 0.84 (95 per cent CI 0.67–1.05), an interval including 1.

Safe water and sanitation: STRONG. Exclusive breastfeeding: STRONG for infants. Case isolation and exclusion from food handling and childcare: MODERATE, given the low infectious dose. Measles vaccination and nutrition: MODERATE, by removing predisposition.

No vaccine is licensed. Candidates are in trials; nothing is available.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ciprofloxacin, first line where susceptible | Yes | Yes | Cents to low dollars per course |
| Azithromycin, where fluoroquinolone-resistant | Yes, 6.2.2 Watch group, second choice for acute invasive bacterial dysentery | Yes | UNICEF indicative about 9.3 US cents a 250 mg tablet, October 2026 |
| Ceftriaxone, severe or resistant disease | Yes | Yes | Low dollars per course |
| Oral rehydration salts and zinc, supportive, always | Yes | Yes | About 4.8 US cents a sachet, UNICEF indicative, October 2026 |

Antimotility drugs such as loperamide are contraindicated in dysentery.

**Simple means.** Handwashing with soap is the highest-value simple intervention for this organism specifically, because of the low infectious dose. Oral rehydration and continued feeding: rehydration addresses the fluid loss, though *Shigella* kills more through invasion and malnutrition than through pure dehydration, so simple means do less here than in cholera or rotavirus. Water treatment: boiling, chlorination, filtration. Safe faeces disposal; latrines. Keeping the ill person away from food preparation and from other children. Feeding through and after the illness, because *Shigella* drives nutritional decline.

Unlike cholera and rotavirus, simple means do not fully substitute for treatment here. Invasive dysentery in a malnourished child needs an effective antibiotic. The minimum chain is antibiotic synthesis plus some means of knowing local resistance patterns.

**Gaps.** No WHO fact sheet exists and **no global burden figure is asserted** — the largest data gap among the diarrhoeal pathogens in this chapter. GBD and the GEMS and MAL-ED studies carry these figures. Resistance prevalence is rising but is not quantified by region in any source retrieved. Why no vaccine exists after decades of work is a genuine scientific gap, not merely a commercial one. The share of diarrhoeal deaths attributable to *Shigella* varies substantially between attribution studies.

---

## Pathogenic *Escherichia coli* (including ETEC and STEC)

**What it is.** Several distinct disease-causing types of a normally harmless gut bacterium. Enterotoxigenic *E. coli*, ETEC, causes watery diarrhoea including most travellers' diarrhoea. Shiga toxin-producing *E. coli*, STEC or EHEC — for example O157:H7 — causes bloody diarrhoea and can destroy kidneys and red cells.

**Measured.** Subsumed in the diarrhoeal totals of the overview entry. No WHO standalone fact sheet for ETEC was retrievable.

**Global ETEC burden. Global STEC burden.** No pathogen-specific global figure is asserted. ETEC is consistently identified as a leading cause of childhood diarrhoea and of travellers' diarrhoea in attribution studies. STEC causes far fewer cases but a severe complication: haemolytic uraemic syndrome. It follows roughly 5 to 15 per cent of STEC O157 infections in children by widely reported clinical estimates†. **That figure could not be confirmed to a primary source, and carries a dagger.** Age pattern: ETEC concentrates in children under two in endemic settings; STEC and haemolytic uraemic syndrome concentrate in children under five and in the elderly.

**Where it starts.** ETEC from contaminated water and food. STEC from ruminant faeces, via undercooked beef, raw milk, contaminated produce, water and direct animal contact. Cattle are the established STEC reservoir. ETEC enterotoxins drive secretory diarrhoea; Shiga toxin damages vascular endothelium, producing haemolytic uraemic syndrome.

Not known: why only a minority of STEC infections progress to haemolytic uraemic syndrome, and whether any intervention prevents that progression. Antibiotics in STEC are genuinely contested — some evidence indicates they increase the risk by promoting toxin release, other

evidence does not, and practice guidance differs between countries. No ETEC vaccine is licensed despite being a long-standing target.

**Cure status.** Split by type.

ETEC: SELF-LIMITING STEC without HUS: SELF-LIMITING STEC with HUS: RELIEF ONLY

ETEC resolves with rehydration; antibiotics shorten travellers' diarrhoea but are not required. STEC without haemolytic uraemic syndrome also resolves, and antibiotics are of contested safety. For STEC with haemolytic uraemic syndrome nothing removes the toxin's effect: management is fluid management, transfusion and dialysis. No agent reverses it. Eculizumab has been used with contested benefit and is neither off-patent nor affordable.

**Prevention.**

Safe water, sanitation and handwashing: STRONG. The Cochrane handwashing figures from the overview entry apply.

Cooking meat thoroughly and avoiding raw milk: STRONG for STEC, on settled microbiology — the organism is killed by heat.

Separating raw meat from other food and washing produce: STRONG for STEC. Keeping children from direct contact with ruminant faeces, on farm visits and at petting zoos: MODERATE. Exclusive breastfeeding: STRONG for infant ETEC.

Avoiding antibiotics in suspected STEC: CONTESTED. Some studies show increased haemolytic uraemic syndrome risk with antibiotics, others show no effect. Both positions are held by good sources and no single number should be quoted.

No vaccine is licensed for either type.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oral rehydration salts and zinc | Yes | Yes | About 4.8 US cents a sachet, UNICEF indicative, October 2026 |
| Azithromycin or ciprofloxacin, ETEC if treated | Yes | Yes | Azithromycin about 9.3 US cents a 250 mg tablet, UNICEF indicative, October 2026 |
| Dialysis and transfusion, for HUS | n/a | n/a | High; requires hospital infrastructure |
| Antibiotics in STEC | — | — | Contested; may be harmful |

**Simple means.** Oral rehydration with salt, sugar and clean water, which is the core of ETEC management. Cooking meat until no longer pink, and boiling milk: this is the single decisive STEC prevention and it needs only fire. Boiling or chlorinating water. Handwashing with soap, especially after animal contact. Not giving antibiotics for bloody diarrhoea in a child without advice, given the haemolytic uraemic syndrome controversy — a case where doing less may be safer. Watching urine output in a child with bloody diarrhoea: falling output is the sign of haemolytic uraemic syndrome, and it is observable without instruments.

For haemolytic uraemic syndrome there is nothing simple. The minimum chain is dialysis: a machine, sterile fluids, trained staff and reliable power. A child who develops it where dialysis is unavailable is likely to die regardless of what simple means are applied.

**Gaps. No global burden figures for either type** ; pathogen-specific attribution is modelled. **The HUS progression rate, 5 to 15 per cent†, could not be confirmed to a primary source and is not relied upon.** Antibiotics in STEC is a genuine contested question with clinical consequences, and guidance differs by country. No licensed vaccine for ETEC despite long effort. The eculizumab evidence is weak and contested, and the drug is unaffordable in most settings.

---

## Cryptosporidiosis

**What it is.** A protozoan parasite, *Cryptosporidium*, that infects the gut lining and causes prolonged watery diarrhoea. Its cysts resist chlorine, so it survives normal water treatment. In people with damaged immunity it can be unrelenting and fatal.

**Measured.** Subsumed in the diarrhoeal totals of the overview entry. No WHO standalone fact sheet was retrievable.

**Global burden.** No *Cryptosporidium*-specific global figure is asserted. The pathogen is consistently ranked among the leading causes of moderate-to-severe diarrhoea in young children in high-burden settings, and among the leading diarrhoeal causes of death in children under two in attribution studies, notably GEMS. The burden concentrates in infants and toddlers and in people with advanced HIV, and geographically in sub-Saharan Africa and south Asia.

**Where it starts.** Ingestion of oocysts from water, person-to-person contact, and animal contact, especially with calves. Three features are established. Chlorine resistance of the oocyst, which is why it causes outbreaks in treated municipal water and in swimming pools. A low infectious dose. And severity governed by immune status, with advanced HIV the dominant risk factor for fatal disease.

Not known: there is no reliably effective drug for cryptosporidiosis in the people who most need one. Nitazoxanide works in immunocompetent people but does not work in advanced immunodeficiency, and why is not fully explained. The link between repeated early-childhood cryptosporidiosis and lasting growth and cognitive impairment is observed consistently, but the mechanism and reversibility are unresolved. No vaccine candidate is near licensure.

**Cure status.** Split by immune status, and the split is stark.

immunocompetent: SELF-LIMITING advanced HIV or severe immunodeficiency: CONTROLLABLE malnourished infants: RELIEF ONLY

Immunocompetent infection resolves over one to two weeks, and nitazoxanide modestly shortens it. In advanced immunodeficiency no antiparasitic reliably clears the organism; the effective intervention is restoring immunity with antiretroviral therapy, which resolves the infection indirectly and is lifelong, so that the label is CONTROLLABLE. For a person with HIV, the treatment for cryptosporidiosis is HIV treatment, not an antiparasitic. In malnourished infants the illness is prolonged, has nutritional consequences, and has no reliable curative agent.

**Prevention.**

Filtration or boiling of drinking water: STRONG. Because the oocyst resists chlorine, boiling or physical filtration — not chlorination — is the effective treatment. This is settled physiology and a significant practical exception to standard water-treatment advice.

Handwashing with soap: STRONG. Cochrane figures as in the overview entry. Avoiding swallowing pool and surface water: MODERATE. Separating young children from calves and livestock faeces: MODERATE. Antiretroviral therapy for people with HIV: STRONG, by preventing the immunodeficiency that makes the infection lethal. Exclusive breastfeeding: MODERATE.

No vaccine exists.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oral rehydration salts and zinc, supportive and the mainstay | Yes | Yes | About 4.8 US cents a sachet, UNICEF indicative, October 2026 |
| Nitazoxanide, immunocompetent only | Not confirmed on the 24th List | Yes | Low dollars per course; no verified price |
| Antiretroviral therapy, the effective intervention in HIV | Yes | Yes | Below US$45 per patient-year for TLD, Global Fund 2023/2024 |

Nitazoxanide does not work in advanced immunodeficiency. There is no second-line antiparasitic of established efficacy.

**Simple means.** Boiling drinking water is the decisive intervention, and chlorination will not substitute: a rolling boil kills oocysts, bleach does not. Cloth and sand filtration, which physically removes oocysts and is effective where chemical treatment is not. Oral rehydration and continued feeding, maintained over a longer period than for other diarrhoeas because the illness is prolonged. Handwashing with soap. Keeping toddlers away from livestock faeces and from drinking surface water. Sustained feeding after recovery, given the growth consequences.

Simple means do well on prevention — boiling and filtration genuinely work. But nothing simple, and nothing complex either, cures the immunocompromised patient other than restoring immunity, which requires antiretroviral therapy and therefore a long chain.

**Gaps. No burden figure is asserted** ; no WHO fact sheet exists. The absence of an effective drug for the immunocompromised is a genuine therapeutic void, not a gap in the evidence about an existing drug. Nitazoxanide's EML status was not confirmed. The long-term growth and cognitive consequences of early repeated infection are consistently observed but not quantified to a reliable effect size. Chlorine resistance means that water judged treated by residual-chlorine testing may still transmit this organism, so the water-quality indicators used in household surveys do not track this pathogen.

---

## Measles

**What it is.** One of the most transmissible viruses known. It causes fever and a rash, and it temporarily erases part of existing immune memory, so children die in the following weeks of pneumonia and diarrhoea. One case can infect up to eighteen others.

**Measured.** WHO fact sheet, 15 July 2026. About 95,000 measles deaths in 2024, mostly in children under five, down from 780,000 in 2000. Measles vaccination averted nearly 59 million deaths between 2000 and 2024. Before the vaccine, which was introduced in 1963, epidemics every two to three years caused about 2.6 million deaths a year.

Coverage in 2025: first dose 84 per cent, against 86 per cent in 2019; both doses 77 per cent; about 29 million infants under-protected. The immunization coverage fact sheet of the same date gives the same figures and adds that nearly 21 million children missed the routine first dose, against 19 million in 2019.

The 84 per cent figure is described two ways on the measles page: as first-dose coverage in 2025 in Key Facts, and as the share who received one dose by their first birthday in the body. The immunization coverage sheet describes the same number as one dose by the second birthday. The value does not change; the definition drifts.

Transmission: the virus remains active in air or on surfaces for up to two hours; one case can generate up to 18 secondary infections; a case is infectious from four days before to four days after rash onset. Symptoms begin 7 to 14 days after exposure; early symptoms last 4 to 7 days; the rash appears 3 to 5 days after onset, spreads over about three days and lasts 4 to 8 days.

Complications are most common in under-fives and in adults over thirty. WHO publishes no global case count on the fact sheet. The cited source is the Weekly Epidemiological Record No. 48, 2025, pp. 591–604.

**Where it starts.** Measles virus, airborne, with a basic reproduction number among the highest of any human pathogen. That is why herd immunity requires about 95 per cent two-dose coverage†, and why coverage of 84 and 77 per cent produces recurrent epidemics. Risk factors for death: age under five, vitamin A deficiency, undernutrition, crowding and immunodeficiency.

Not known: the full extent and duration of measles-induced immune amnesia, the destruction of the pre-existing antibody repertoire, is a recent finding whose long-term consequences are not quantified. Why measles causes subacute sclerosing panencephalitis years later in a small number of children is not explained. The determinants of individual severity are not established.

**Cure status.** Split.

measles: SELF-LIMITING

Measles resolves unaided in the uncomplicated case, and no antiviral exists. Deaths come from complications — pneumonia, diarrhoea, encephalitis — which are treated on their own terms. Vitamin A is the one intervention that changes mortality: WHO recommends two doses for suspected cases under five, with a third at four to six weeks if eye signs of deficiency appear. That reduces death without removing the virus.

**Prevention.**

Measles vaccination: STRONG. CDC's measles vaccine recommendations give one dose as 93 per cent effective, range 39 to 100 per cent, and two doses as 97 per cent effective, range 67 to 100 per cent. Those are the ranges CDC publishes across studies rather than confidence intervals. WHO publishes no efficacy figure of its own and states only that vaccine cost is less than a few US dollars per child.

Schedule: dose one at 9 months in high-burden countries, 12 to 15 months elsewhere; dose two usually at 15 to 18 months.

Measles vaccine needs an unbroken 2–8 °C cold chain and is one of the most cold-chain-dependent products in routine immunisation. It is a live attenuated vaccine requiring cell-culture propagation in chick embryo fibroblast, lyophilisation and sterile fill-finish; it is notably heat- and light-sensitive; and reconstituted vaccine must be discarded within hours. It cannot be produced or distributed without a long chain, and the cold chain is the specific reason coverage stalls where it does.

Post-exposure prophylaxis: STRONG. MMR within 72 hours of exposure; immunoglobulin within six days, at an intramuscular dose of 0.5 mL/kg regardless of immune status. MMR and immunoglobulin must not be given together — doing so invalidates the vaccine.

Vitamin A supplementation: STRONG for reducing measles mortality.

Isolation of cases: MODERATE, limited by infectiousness beginning four days before the rash, so transmission precedes recognition.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Vitamin A, two doses | Yes | Yes | Cents per course |
| Oral rehydration salts for diarrhoea | Yes | Yes | About 4.8 US cents a sachet, UNICEF indicative, October 2026 |
| Antibiotics for bacterial complications | Yes | Yes | Amoxicillin about 5.4 US cents a 250 mg dispersible tablet, UNICEF indicative, October 2026 |
| Oxygen for pneumonia | Yes, oxygen | n/a | Variable |
| Measles vaccine, also used post-exposure | Yes | Yes | Less than a few US dollars per child |

No antiviral exists. Antibiotics are for complications, not for measles itself.

**Simple means.** Vitamin A, which is a cheap capsule and the single most effective simple measure for survival. Dark green leaves, orange vegetables, liver and palm oil supply it from food. Keeping the child fed and hydrated through the illness and through the weeks after, when immune suppression leaves them vulnerable. Oral rehydration for the diarrhoea that follows. Isolating the case from infants too young to be vaccinated — imperfect, since infectiousness precedes the rash. Keeping the child in a darkened, quiet room during photophobia, and watching the eyes for the corneal damage that causes blindness. Watching for fast breathing, which is the pneumonia that kills.

Prevention absolutely requires a chain. The vaccine cannot be improvised. But survival of a case is substantially improvable with vitamin A, food, water and attention, none of which needs an industrial supply chain.

**Gaps.** WHO publishes no global case count, only deaths, so incidence is not stated here. WHO publishes no vaccine efficacy figure; CDC's figures are used, and CDC gives ranges across studies rather than confidence intervals. First-dose coverage fell from 86 per cent in 2019 to 84 per cent in 2025 while deaths are reported as falling; the source does not reconcile the trajectory, and cases are reported as surging in a linked WHO news item. The duration and consequences of measles-induced immune amnesia are not quantified. The 95,000 deaths figure is modelled; measles deaths are rarely individually certified.

---

## Hepatitis A

**What it is.** A virus spread by faecal contamination of food and water that inflames the liver. Children usually have no symptoms. Adults become jaundiced and unwell for weeks. It does not become chronic.

**Measured.** WHO fact sheet, 28 July 2026. 35,569 deaths worldwide in 2023, which is 2.6 per cent of viral hepatitis mortality; WHO attributes the figure to IHME's GBD 2023. No global case count is given.

In endemic settings 90 per cent of children are infected before the age of ten, usually without symptoms. Children under six usually have no noticeable symptoms and only 10 per cent of them develop jaundice. Adults show symptoms more often, and severity and fatality rise with age. Incubation is 14 to 28 days.

Geography: common in low- and middle-income countries, with low rates in high-income countries. The 1988 Shanghai epidemic affected about 300,000 people. Large United States outbreaks have occurred among people experiencing homelessness.

**Where it starts.** Hepatitis A virus, faecal-oral, through contaminated water, food — notably shellfish and raw produce — and person-to-person contact. The risk structure is absence of safe water and sanitation.

One paradoxical feature is well established and worth stating plainly: improving sanitation raises the average age of infection, and because severity rises with age, partial improvement can increase symptomatic disease and deaths even as infections fall.

Not known: why severity rises so sharply with age at infection is described but not mechanistically explained. The determinants of fulminant hepatic failure in the small minority who develop it are not established.

**Cure status.** SELF-LIMITING. The body clears the virus and immunity is lifelong. There is no antiviral and none is needed. Infection does not become chronic, which distinguishes it from hepatitis B and C. A small minority develop fulminant liver failure, for which the only intervention is transplantation.

**Prevention.**

Safe water and sanitation: STRONG, on settled transmission physiology.

Hepatitis A vaccination: STRONG. WHO states that several injectable inactivated vaccines are available with similar protection, and that a live attenuated vaccine is available in China. No vaccine is licensed for children under one year. **WHO publishes no efficacy percentage, and no figure with a confidence interval could be sourced primarily, so none is asserted.**

Inactivated hepatitis A vaccine needs a long chain: cell-culture propagation, inactivation, adjuvanting, sterile fill-finish and an unbroken 2–8 °C cold chain. It is a needle vaccine. Its chain sits in the middle of this chapter's range — more demanding than the toxoids, less than the conjugates.

Handwashing with soap: STRONG. Cochrane figures as in the diarrhoeal overview. Cooking food and boiling water: STRONG — the virus is inactivated by heat, though it is relatively heat-stable and steaming shellfish may be insufficient. Vaccinating at-risk adult groups: MODERATE where outbreaks occur in homeless or drug-using populations.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Supportive care only | n/a | n/a | Minimal |
| Hepatitis A vaccine, prevention and post-exposure | Yes | Yes | No verified price |
| Liver transplant, fulminant failure only | n/a | n/a | Very high; requires transplant infrastructure |

There is no antiviral treatment. Avoiding alcohol and hepatotoxic drugs during recovery is standard advice.

**Simple means.** Boiling drinking water and treating it. Handwashing with soap, particularly around food preparation and nappy changing. Safe faeces disposal, with latrines sited away from water. Cooking food thoroughly, especially shellfish. Rest and food during the illness, which is the whole of the treatment. Avoiding alcohol while the liver recovers.

Simple means cover this condition almost completely: prevention by water, sanitation and handwashing, and management by rest. Only the vaccine and the rare transplant require a chain.

**Gaps.** No global case count is published, only deaths. **No vaccine efficacy figure with a confidence interval is published by WHO and none was sourced.** The sanitation paradox means burden trends are hard to interpret: falling infection can coincide with rising disease. The 35,569 figure is given to five significant figures from GBD 2023 modelling, which overstates precision.

---

## Hepatitis B

**What it is.** A virus that infects liver cells and, when acquired in infancy, usually persists for life. Decades of quiet inflammation cause cirrhosis and liver cancer. Infection in adulthood usually clears; infection at birth usually does not.

**Measured.** WHO fact sheet, 28 July 2026. About 240 million people with chronic HBV infection in 2024. About 0.9 million new infections a year. About 1.1 million deaths in 2024, mostly from cirrhosis and liver cancer.

Regional chronic infections: Western Pacific 102 million; African 64 million; South-East Asia 43 million; Eastern Mediterranean 16 million; European 9.7 million; Americas 5 million. Those sum to about 239.7 million against a stated global 240 million, which is consistent to rounding.

Under-five chronic prevalence in 2024: 0.6 per cent globally (95 per cent UI 0.5–0.8); African Region 1.4 per cent; Eastern Mediterranean 0.5 per cent. The European and Americas Regions have already passed the 2030 target of 0.1 per cent. Under-five prevalence was about 5 per cent in the pre-vaccine era and just under 1 per cent in 2019.

HBV prevalence among people with HIV is 7.4 per cent.

Diagnosis and treatment: 65 million people, 27 per cent of those infected, knew their status as of 2024. About 10 million were on antiviral treatment, stated as 4.3 per cent of those with chronic infection, while more than 50 per cent are estimated to need treatment under the 2024 WHO guidelines.

The 4.3 per cent does not follow from the page's own numbers: 10 million of 240 million is 4.2 per cent, and the page names no other denominator. The discrepancy stands; the appendix of single-source contradictions carries it as item 3.

A second, cross-page discrepancy stands as well: the WHO fact sheet on sexually transmitted infections, 10 September 2025, gives 254 million living with chronic hepatitis B in 2022, against this sheet's 240 million in 2024. Both are live WHO figures for the same quantity at different vintages. Both deaths figures are 1.1 million, but one dates it 2024 and the other 2022.

**Where it starts.** Hepatitis B virus, transmitted perinatally, by blood and by sexual contact. The decisive established fact is age at infection: adult-acquired infection becomes chronic in less than 5 per cent of cases, infant and early-childhood infection in about 95 per cent. That is why the birth dose exists and why prevention is concentrated at birth.

Not known: why the immune system of a neonate tolerates the virus while an adult's clears it is described but not fully explained. Which chronically infected individuals will progress to cirrhosis or cancer cannot be predicted for an individual. There is no cure because covalently closed circular viral DNA persists in the hepatocyte nucleus and no available agent removes it.

**Cure status.** Split by age at acquisition.

adult acute infection: SELF-LIMITING — resolves in over 95 per cent of cases chronic infection: CONTROLLABLE

Antivirals suppress replication and halt progression, but WHO states that most people who start treatment must continue it for life, and the fact sheet does not mention a cure. The persistent nuclear reservoir is the reason.

**Prevention.**

Hepatitis B vaccination: STRONG. WHO describes vaccine protection as “nearly 100 per cent”, lasting at least 20 years and probably for life, with boosters not usually required after the series is completed. WHO gives no separate efficacy percentage with a confidence interval.

The birth dose within 24 hours of birth is the critical intervention, because 95 per cent of infant infections become chronic. The full series is two or three doses at least four weeks apart.

Coverage is the failure point. The hepatitis B birth dose reached only 43 per cent globally in 2025 — the lowest coverage of any vaccine in the routine schedule. Three-dose hepatitis B coverage was 84 per cent in the same year, which shows that the problem is timing rather than supply.

The chain is long but shorter than most here, and it matters that this is so. HBV vaccine is a recombinant surface-antigen protein expressed in yeast — *Saccharomyces* or *Hansenula* — then adjuvanted with aluminium salt, sterile-filled and cold-chained at 2–8 °C. Yeast fermentation is a far lower technological threshold than mammalian cell culture, which is why HBV vaccine is among the cheapest vaccines in existence and is produced in many middle-income countries. It still requires sterile fill-finish, a needle and an unbroken cold chain, and it cannot be made by simple means.

Blood screening and sterile injection practice: STRONG. Antiviral prophylaxis in pregnancy for high-viral-load mothers: STRONG, alongside the birth dose. Condoms: STRONG for sexual transmission.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Tenofovir (TDF) | Yes | Yes | The same molecule as in HIV TLD, where the full three-drug combination is below US$45 per patient-year, Global Fund 2023/2024; tenofovir alone is a fraction of that† |
| Entecavir | Yes | Yes | Low dollars per month generically |
| Hepatitis B vaccine | Yes | Yes | Among the cheapest vaccines; no verified unit price |
| Hepatitis B immunoglobulin, perinatal and high-risk | Yes | Yes | Higher; requires plasma fractionation |

WHO names tenofovir as an oral treatment for chronic hepatitis B, also active against HBV in people with HIV, and gives no efficacy or dosing figures. The treatment gap is the salient fact: 4.3 per cent treated against more than 50 per cent needing it.

**Simple means.** Not reusing needles, blades or skin-piercing instruments; boiling or flaming them where no sterile supply exists. Not sharing razors or toothbrushes within a household. Condoms. Avoiding alcohol, which accelerates cirrhosis in chronic infection — a substantial intervention requiring nothing. Covering wounds.

Nothing available without an industrial chain prevents perinatal transmission or treats chronic infection. The minimum chain for prevention is yeast-fermented recombinant vaccine, plus sterile fill-finish, plus a cold chain capable of reaching a birth within 24 hours. That last requirement, not the manufacturing, is why birth-dose coverage is 43 per cent while three-dose coverage is 84 per cent. For treatment the chain is nucleotide analogue synthesis plus a lifelong uninterrupted supply.

**Gaps.** WHO describes protection as “nearly 100 per cent” without a figure or confidence interval, so no precise efficacy is stated. The treatment-need estimate, more than 50 per cent, is explicitly setting-dependent in the source and therefore soft. Why only 27 per cent know their status, while the vaccine has existed for decades, is a service-delivery gap rather than an evidence gap. No cure exists and no candidate is close; clearance of the nuclear reservoir is an unsolved problem. The stated treatment coverage of 4.3 per cent does not follow from the page’s own two numbers; see the appendix, item 3. The hepatitis B prevalence figure differs between two live WHO fact sheets, 240 million in 2024 against 254 million in 2022, and both stand.

## Hepatitis C

**What it is.** A blood-borne virus that persists in the liver in most people it infects, causing slow scarring over decades. Since 2014 a short course of tablets removes it from the body in almost everyone. Most infected people do not know they have it.

**Measured.** WHO fact sheet, 28 July 2026. About 47 million people with chronic HCV infection. About 0.9 million new infections a year. About 239,000 deaths in 2024, mostly from cirrhosis and hepatocellular carcinoma.

The page's own regional figures do not reach its headline total. Eastern Mediterranean 12 million; South-East Asia 9 million; European 9 million; African 8 million; Western Pacific 7 million; Americas 5 million. Those sum to 50 million against the stated 47 million — a three-million gap between the headline and the page's own table, which the source does not explain. Both figures stand; the appendix of single-source contradictions carries this as item 4.

Natural course: acute infection clears spontaneously in about 30 per cent of people, range 15 to 45 per cent, within six months, and about 70 per cent, range 55 to 85, become chronic. Risk of cirrhosis in chronic infection is 15 to 30 per cent within twenty years.

Cumulative ever-infected, 2015–2024: 68 million (95 per cent UI 46–103 million).

Cascade to end-2024. 36 per cent know their diagnosis (95 per cent UI 17–57), about 24 million. About 20 per cent of those ever infected have been treated with direct-acting antivirals (95 per cent UI 10–31), about 13 million. 11 million are diagnosed but not yet treated (95 per cent UI 7.4–15 million).

WHO recommends general population testing where anti-HCV seroprevalence exceeds 2 per cent.

**Where it starts.** Unsafe injection and medical practice, unscreened blood transfusion, injecting drug use with shared equipment, and, less efficiently, sexual and perinatal transmission. The risk structure is iatrogenic and injection-related.

Not known: why about 30 per cent of people clear the virus spontaneously while 70 per cent do not. Host genetic factors such as IL28B explain part of it, not all. Reinfection after cure is possible because immunity is not protective, and why natural infection fails to generate protective immunity is the central reason no vaccine exists. The progression rate to cirrhosis varies widely between individuals and cannot be predicted.

**Cure status.** CURABLE. This is the clearest cure in the chapter. Direct-acting antivirals cure more than 95 per cent of people with hepatitis C, in 12 to 24 weeks depending on the presence of cirrhosis. The virus is eliminated from the body, confirmed by sustained virological response, and does not recur unless the person is reinfected. A chronic viral infection that was incurable in 2010 is now curable with oral tablets at low cost. It is the only transition of that kind in this chapter.

The body of the same fact sheet does not restate the 95 per cent figure, saying only "most persons" and "nearly all patients".

**Prevention.**

Safe injection practice and single-use equipment: STRONG. Blood screening: STRONG, having effectively eliminated transfusion transmission where implemented. Needle and syringe programmes for people who inject drugs: STRONG. Opioid agonist therapy: STRONG for reducing injecting risk. Treating the infected, as prevention: STRONG — curing a person removes them as a source, and because cure is achievable, elimination is arithmetically possible.

Condoms: WEAK for hepatitis C specifically. Sexual transmission is inefficient except in specific contexts, such as HIV co-infection and among men who have sex with men.

No vaccine exists and no candidate is near licensure.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Direct-acting antiviral regimens, sofosbuvir-based: sofosbuvir/daclatasvir, sofosbuvir/velpatasvir | Yes | Generic under voluntary licence in most low- and middle-income countries | Under US$50 per standard curative course in many low- and middle-income countries, according to the WHO fact sheet printed 28 July 2026 |

For scale, the historical comparison, from the MSF Access Campaign, 3 November 2014. Sofosbuvir launched at US$84,000 per three-month course in the United States, and sofosbuvir/ledipasvir at nearly US$95,000 per course. A University of Liverpool study estimated production cost at US$68–136 per treatment for sofosbuvir, and as little as US$10–30 for a twelve-week course of daclatasvir. The current WHO figure of under US$50 per curative course in many low- and middle-income countries, according to the WHO fact sheet printed 28 July 2026, is close to the estimated cost of production and roughly three orders of magnitude below the original launch price.

**Simple means.** Not reusing needles or syringes: one needle, one person, once. Not sharing razors, blades, or tattooing and piercing equipment. Sterilising any skin-piercing instrument by boiling or autoclaving where single-use supply does not exist. Covering wounds and avoiding blood contact. Avoiding alcohol, which markedly accelerates progression to cirrhosis — a genuine intervention requiring nothing.

Prevention by simple means is effective, because transmission is almost entirely through blood contact that can be avoided. But nothing simple cures it. The minimum chain is multi-step small-molecule synthesis, co-formulation, a twelve-week uninterrupted supply, and a test to confirm infection and cure. Unlike many conditions in this chapter that chain is short, cheap and already functioning. The barrier is diagnosis, not manufacture.

**Gaps.** The diagnosis gap is the binding constraint: 36 per cent know their status, with a 95 per cent uncertainty interval of 17 to 57 per cent, which is very wide. Regional figures sum to about 50 million against a 47 million global total, unexplained in the source; see the appendix, item 4. No vaccine and no clear path to one, because natural immunity is not protective. Reinfection after cure is possible, so individual cure confers no protection, which complicates elimination arithmetic. The price of under US$50 applies in many but not all low- and middle-income countries, according to the WHO fact sheet printed 28 July 2026; middle-income countries excluded from voluntary licences pay substantially more, and the source does not enumerate which.

---

## Hepatitis E

**What it is.** A virus spread by faecally contaminated water, causing liver inflammation that usually resolves. Its distinctive feature is lethality in pregnancy. It causes large outbreaks in camps and where water supply has failed.

**Measured.** WHO fact sheet, 28 July 2026. About 20 million infections globally each year, of which about 3.3 million are symptomatic. Approximately 4,431 deaths in 2023.

Up to 20 to 25 per cent of pregnant women can die if infected in the third trimester, in WHO’s own wording.

Symptomatic infection is most common in people aged 15 to 40. Genotypes 1 and 2 spread person-to-person by the faecal-oral route; genotypes 3 and 4 are mainly zoonotic.

Geography: worldwide, most common in sub-Saharan Africa and in east and south Asia. Nearly 50 per cent of outbreaks occur in camp settings, among refugees or internally displaced people.

Incubation is 2 to 10 weeks, averaging 5 to 6; symptoms last 1 to 6 weeks; infection usually resolves in 2 to 6 weeks.

**Where it starts.** Contaminated drinking water for genotypes 1 and 2; undercooked pork, game and shellfish for genotypes 3 and 4. The risk structure is displacement and camp settings, where water and sanitation fail together — the reason half of outbreaks occur there. Pregnancy in the third trimester is the established determinant of mortality.

Not known: why hepatitis E kills pregnant women is not explained. This is the most consequential unexplained feature of the condition; hormonal and immunological hypotheses exist without resolution. Why genotype 1 behaves this way while genotype 3 largely does not is also unexplained. Chronic hepatitis E in immunosuppressed patients was recognised only recently and its epidemiology is not well characterised.

**Cure status.** Split.

most immunocompetent people: SELF-LIMITING third-trimester pregnancy and fulminant disease: RELIEF ONLY chronic infection in the immunosuppressed: CURABLE

Most infection resolves in two to six weeks with no intervention. In third-trimester pregnancy and in fulminant hepatitis no agent alters the course, care is supportive, and mortality reaches 20 to 25 per cent. Chronic infection in immunosuppressed patients is cured by ribavirin, alongside reduction of immunosuppression where possible.

**Prevention.**

Safe drinking water and sanitation: STRONG, on settled transmission physiology. This is the primary measure, and its failure is why camps dominate the outbreak record.

Hepatitis E vaccine, Hecolin or HEV 239: MODERATE — effective but barely available. WHO states it has been licensed in China since 2011 for healthy adults aged 16 and over. It is given as three intramuscular doses at 0, 1 and 6 months, with a shelf life of at least 36 months. It was deployed in Bentiu, South Sudan, from March 2022 in three rounds, each reaching more than 24,000 people. It is the fifth vaccine approved under the International Coordinating Group mechanism. **WHO publishes no efficacy percentage; the Chinese phase 3 trial reported very high efficacy but could not be sourced primarily, so no figure with a confidence interval is asserted.**

The chain is long but comparatively modest. Hecolin is a recombinant protein — an HEV ORF2 capsid fragment — expressed in *E. coli*, then adjuvanted, sterile-filled and cold-chained at 2–8 °C. Bacterial expression is the lowest-threshold recombinant platform, lower than yeast and far lower than mammalian cell culture. The limit on availability is licensure and manufacturer commitment, not technical difficulty.

Cooking pork, game and shellfish thoroughly: STRONG for genotypes 3 and 4. Protecting pregnant women specifically during outbreaks, by prioritising their water supply and evacuation: MODERATE, on the established mortality gradient.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Supportive care | n/a | n/a | Minimal |
| Ribavirin, chronic HEV in the immunosuppressed only | Yes | Yes | Low dollars per course generically; no verified price |
| Hepatitis E vaccine, Hecolin | Not confirmed on the 24th List | No; single manufacturer, China | No published international price |

There is no treatment for acute hepatitis E, including in pregnancy. Ribavirin is contraindicated in pregnancy.

**Simple means.** Boiling drinking water — the decisive measure, and sufficient. Chlorination and filtration of water supplies. Safe faeces disposal, with latrines sited away from and below water sources, which in a camp is a layout decision rather than a technology. Handwashing with soap. Cooking meat thoroughly. Giving pregnant women the cleanest available water first in an outbreak, a triage decision requiring no resources and justified by a 20 to 25 per cent mortality. Rest and food for the ill, which is the treatment.

Simple means prevent this condition effectively. What they cannot do is save the pregnant woman who is already infected. For her, neither simple nor industrial medicine has an answer, which makes prevention the whole of the intervention.

**Gaps. No vaccine efficacy figure with a confidence interval is asserted** ; WHO publishes none and the primary trial was not retrievable. The vaccine is licensed in one country only, fifteen years after licensure, despite a 20 to 25 per cent maternal mortality in outbreaks: a deployment gap, not an evidence gap. Why it kills pregnant women is genuinely unknown, and that is the central scientific gap. The death figure, 4,431 in 2023, is implausibly precise

for a condition with 20 million annual infections and 3.3 million symptomatic cases, and it sits oddly against a 20 to 25 per cent third-trimester mortality; the source does not reconcile these. Chronic hepatitis E in the immunosuppressed is recently recognised and its burden is unquantified.

---

## Sepsis and neonatal sepsis

**What it is.** Not a single infection but the body's own response to infection turning destructive: circulation fails, organs shut down, and the person dies of the response rather than of the organism. In newborns it can follow infection acquired at or shortly after birth.

**Measured.** WHO fact sheet on sepsis, 3 May 2024, citing data published in 2020. 48.9 million cases worldwide. 11 million sepsis-related deaths, about 20 per cent of all global deaths. Children under five account for almost half of all estimated cases, 20 million. An estimated 15 per 1,000 hospitalised patients develop sepsis as a complication of health care.

Incidence and mortality vary significantly by region and are highest in lower-middle-income countries; no regional counts are given. Average hospital-wide cost in high-income countries is more than US$32,000 per patient, according to the WHO sepsis fact sheet of 3 May 2024.

The fact sheet gives no separate figures for neonatal or maternal sepsis, stating only that sepsis is a significant cause of maternal, neonatal and child mortality.

Related, from the WHO fact sheet on newborn mortality, 14 March 2024, reporting 2022 data: 2.3 million neonatal deaths in 2022, about 6,500 a day, which is 47 per cent of all under-five deaths. About 75 per cent of neonatal deaths occur in the first week and about 1 million within the first 24 hours. Sub-Saharan Africa carries 57 per cent of under-five deaths, 2.8 million, with 30 per cent of global live births, and a neonatal mortality rate of 27 per 1,000 live births. Prematurity, intrapartum events, pneumonia and sepsis together account for almost eight in ten neonatal deaths.

The sepsis fact sheet reports 4.95 million deaths associated with antimicrobial resistance and 1.27 million directly attributable, for 2019. The AMR fact sheet of 16 July 2026 gives more than 4.7 million associated for 2021. The figures move between sources and years; see the antimicrobial resistance entry.

**Where it starts.** Any infection can precipitate it — pneumonia, abdominal infection, urinary infection, skin and soft tissue infection, meningitis, and in newborns infection acquired from the maternal genital tract, the birth environment or the umbilical stump. Risk factors: age under one and over 65, pregnancy and the postpartum period, immunosuppression, chronic disease, invasive devices and hospitalisation, and in neonates prematurity, low birth weight, prolonged rupture of membranes and unclean delivery. Antimicrobial resistance is a direct driver.

Not known: why two people with the same infection and similar health diverge, one recovering and one progressing to organ failure, is not explained. Decades of immunomodulatory trials in sepsis have failed, which indicates the underlying model is incomplete. Whether sepsis is one condition or a heterogeneous collection of host-response states is actively contested, and that question is the reason trials fail. The optimal fluid volume and type remain contested.

Read in the net: closure is all or nothing. A winding either returns in phase or it does not, and what fails to close passes its tension to the meshes beside it. Whether a host response that holds and one that cascades are two classes or two degrees of the same thing is not settled, as the entry above says. This is a reading, not a mechanism.

**Cure status.** Split by timing, more sharply than any other entry in the chapter.

early sepsis: CURABLE established septic shock with multi-organ failure: RELIEF ONLY

Treating the underlying infection with antibiotics plus fluids resolves early sepsis and the person recovers fully. For established septic shock no treatment removes the state; management supports organs — vasopressors, ventilation, dialysis — while the host response either resolves or does not. Mortality remains high despite full intensive care, and no immunomodulatory agent has succeeded in trials. The intervention that changes outcome is early recog-

nition and early antibiotics, not any sepsis-specific drug, because no sepsis-specific drug exists.

**Prevention.**

Preventing the underlying infections: STRONG. Every vaccine in this chapter is sepsis prevention. The Gambian PCV trial measured exactly this pathway, reducing all-cause mortality by 16 per cent (95 per cent CI 3–28).

Clean birth practice: STRONG. Hand hygiene at delivery, clean cord cutting and clean cord care prevent neonatal sepsis. Settled physiology, and the historical basis of the entire field.

Hand hygiene in health facilities: STRONG. 15 per 1,000 hospitalised patients acquire sepsis as a complication of care, and hand hygiene is the principal countermeasure.

Chlorhexidine cord care: STRONG in high-mortality settings with unclean delivery practices.

Early recognition and early antibiotics: STRONG, as secondary prevention of death.

Intrapartum penicillin for mothers at risk of transmitting Group B streptococcus: STRONG.

Exclusive breastfeeding: STRONG for neonatal infection. Skin-to-skin contact and thermal care: STRONG for newborn survival generally.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ampicillin with gentamicin, first-line neonatal sepsis | Yes; amoxicillin is listed first choice for neonatal sepsis, 6.2.1 Access group | Yes | Cents to low dollars per course |
| Ceftriaxone | Yes | Yes | Low dollars per course |
| Intravenous fluids: Ringer's lactate, saline | Yes | Yes | Low dollars |
| Oxygen | Yes | n/a | Variable |
| Vasopressors: noradrenaline | Yes | Yes | Low dollars per vial |
| Organ support: ventilation, dialysis | n/a | n/a | High; intensive care infrastructure |

There is no sepsis-specific drug. Treatment is antibiotics for the source, fluids, oxygen and organ support. Corticosteroids have a contested, modest role in septic shock.

**Simple means.** Considerable, and concentrated at birth.

Washing hands before delivery and before touching a newborn: the single highest-value measure, requiring only water and soap. Clean cord cutting with a boiled or new blade, a clean tie, and the stump left dry and uncovered. Nothing applied to the stump except, where recommended, chlorhexidine: cow dung, ash and oils are a known cause of neonatal sepsis and tetanus. A clean delivery surface, clean hands and clean cloth. Immediate drying, skin-to-skin warmth and early breastfeeding. Recognising the sick newborn — poor feeding, lethargy, abnormal temperature, fast breathing, not waking — all observable without instruments. Wound care: cleaning with clean water, keeping wounds covered and dry. Oral fluids in the early, still-drinking patient.

Once sepsis is established nothing simple works. The minimum chain is injectable antibiotics, sterile intravenous fluids and a cannula, and for septic shock oxygen, vasopressors and organ support, which require hospital infrastructure and reliable power. Early prevention at birth is achievable with soap, a clean blade and attention. Established sepsis is not survivable by simple means.

**Gaps. WHO publishes no separate neonatal or maternal sepsis figures** despite naming sepsis a leading cause of neonatal and maternal death — the largest single data gap in this entry. The fact sheet is dated 3 May 2024 but cites data published in 2020, so the 48.9 million and 11 million figures come from an earlier modelling exercise. Sepsis is defined by clinical criteria that have changed across Sepsis-1, -2 and -3, so case counts are not comparable over time. Whether sepsis is one condition is genuinely contested, and the repeated failure of immunomodulatory trials suggests it is not. Attributing a death to sepsis rather than to the underlying infection is a coding decision, so the 20-per-cent-of- all-global-deaths figure overlaps heavily with other entries in this chapter and must not be added to them.

## Bacterial meningitis

**What it is.** Bacterial infection of the membranes around the brain and spinal cord. It can kill within hours and leaves many survivors deaf, epileptic or brain-damaged. It occurs in epidemics across a belt of sub-Saharan Africa.

**Measured.** WHO fact sheet on meningitis, 29 September 2026. In the African meningitis belt in 2025: 21,526 suspected cases and 971 deaths reported to WHO, from 24 of the 26 countries in the enhanced surveillance network, giving a case fatality rate of 4.5 per cent.

Outcomes of bacterial meningitis generally: about one in six people die; about one in five develop severe complications; about one in five survivors may have long-lasting after-effects such as hearing loss, seizures or limb weakness.

The pathogens are meningococcus, pneumococcus, *Haemophilus influenzae* and Group B streptococcus, the last being the main concern for newborns. WHO gives no numerical breakdown.

The African meningitis belt, from Senegal to Ethiopia, has the highest burden globally. Outbreaks also occur in crowded settings: mining areas, mass gatherings, refugee and military camps. Serogroup A caused 80 to 85 per cent of epidemics before 2010.

Meningitis-belt vaccine coverage was 61 per cent in countries with the vaccine in their routine programme, and 30 per cent overall, in 2025.

**Where it starts.** The four bacteria above, carried asymptomatically in the nasopharynx and transmitted by respiratory droplets. Risk factors: crowding, the dry dusty season in the meningitis belt, concurrent respiratory infection, smoking, asplenia, complement deficiency, HIV, and for neonates maternal Group B streptococcal colonisation.

Not known: why the meningitis belt exists in that specific geography, and why epidemics begin and end when they do, is only partly explained by dust, humidity and the Harmattan. Why one carrier among many thousands develops invasive disease is not established: carriage is common and disease is rare. The determinants of which survivors are left deaf are not known.

**Cure status.** Split by timing and by outcome.

treated within hours: CURABLE established hearing loss and brain injury: RELIEF ONLY

Antibiotics clear the organism and many patients recover fully. WHO directs that antibiotics start as soon as bacterial meningitis is suspected, without waiting for lumbar puncture results — the clearest statement in the chapter that hours matter. Mortality remains about one in six even with treatment, and about one in five survivors retain permanent deficits for which nothing is curative.

Adjunctive corticosteroids: WHO recommends intravenous dexamethasone with the first antibiotic dose in non-epidemic settings, which reduces hearing loss and other complications.

**Prevention.**

Meningococcal A conjugate vaccine, MenAfriVac: STRONG, and among the most successful vaccine interventions on record. Serogroup A caused 80 to 85 per cent of epidemics before 2010. Mass campaigns from 2010 cut confirmed serogroup A disease by 99 per cent in vaccinated populations. No confirmed serogroup A case has been reported since 2017 in countries that introduced it.

Men5CV, pentavalent A, C, W, Y and X: STRONG, prequalified in 2023, with Niger running the first Gavi-supported campaign in 2025.

Pneumococcal conjugate vaccine: STRONG. The Gambian 9-valent trial gives invasive pneumococcal disease, vaccine serotypes, 77 per cent (95 per cent CI 51–90); all serotypes 50 per cent (95 per cent CI 21–69); all-cause mortality 16 per cent (95 per cent CI 3–28). WHO recommends universal use; coverage of the last dose was 71 per cent in 2025.

Hib conjugate vaccine: STRONG, in most national childhood programmes; coverage for three doses was 78 per cent in 2025. **Trial efficacy figures were not retrievable and none is asserted.**

Intrapartum intravenous penicillin for mothers at risk of Group B streptococcus transmission: STRONG.

Chemoprophylaxis for close contacts: MODERATE. Reducing crowding in sleeping quarters: WEAK.

All of these need long industrial chains. All are conjugate vaccines: bacterial culture, polysaccharide extraction, chemical activation and conjugation to a carrier protein, purification, sterile fill-finish, cold chain. MenAfriVac is the instructive exception on the cold chain, and only on the cold chain. It was developed specifically for African use at under US$0.50 per dose and formulated for controlled temperature chain, tolerating up to 40 °C for four days, which permitted vaccination beyond the 2–8 °C chain. That thermostability was a deliberate design achievement, not an inherent property of conjugates, and the vaccine still requires full industrial manufacture and a needle.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ceftriaxone, first line | Yes | Yes | Low dollars per course |
| Benzylpenicillin | Yes | Yes | Cents per course |
| Ampicillin with gentamicin, neonatal | Yes | Yes | Cents to low dollars |
| Chloramphenicol, oily suspension, epidemic settings, single dose | Yes | Yes | Low; one intramuscular dose |
| Dexamethasone, adjunct in non-epidemic settings | Yes | Yes | UNICEF indicative US$24.00 per 100 4 mg tablets, October 2026, about 24 US cents a tablet |

Single-dose oily chloramphenicol is specifically valuable in epidemics because it needs one injection rather than a cannula and an infusion schedule.

**Simple means.** Limited, and that must be stated plainly.

Recognising it: the stiff neck; the inability to straighten the leg with the hip flexed; a bulging fontanelle in an infant; the rash that does not blanch under pressure, in meningococcal disease; fever with altered consciousness. These need no instrument, and recognition is what determines whether treatment happens in time. Moving the patient to where injections exist, immediately — the one decision that changes the outcome. Ventilating and decrowding sleeping quarters. Keeping an unconscious patient on their side, airway clear, and not giving oral fluids to someone who cannot swallow. Fever control by tepid sponging. After the illness, testing hearing by simple means and responding to deafness early, which matters for a child's language development and requires no audiometry to notice.

There is nothing that cures bacterial meningitis without an industrial chain, and nothing simple that alters its course. The minimum chain is an injectable third-generation cephalosporin, or oily chloramphenicol, a syringe, and someone able to give it within hours of onset. This is among the conditions in this chapter where the absence of a supply chain is most directly fatal, because the time window is measured in hours rather than days.

**Gaps.** WHO gives **no numerical pathogen breakdown** and **no global case or death estimate** — only African belt surveillance figures and proportional outcomes. The belt figures are *suspected* cases, mostly without laboratory confirmation, so the 4.5 per cent case fatality mixes confirmed bacterial meningitis with other febrile illness. **Hib trial efficacy figures were not retrievable.** Why the meningitis belt exists in that geography is not fully explained. The one-in-six mortality and one-in-five sequelae figures are not setting-specific, and outcomes differ sharply between a hospital with dexamethasone and a village three days from an injection.

---

## Typhoid and paratyphoid fever

**What it is.** *Salmonella* Typhi and Paratyphi enter through contaminated water or food, pass through the gut wall and multiply in the bloodstream, causing weeks of fever. Untreated it can perforate the bowel. A small number of recovered people carry it in the gallbladder for years.

**Measured.** WHO fact sheet on typhoid, 30 March 2023, giving 2019 estimates. These are among the oldest figures in this chapter. About 9 million typhoid cases a year. About 110,000 deaths a year.

It is a public health problem in the WHO African, Eastern Mediterranean, South-East Asia and Western Pacific Regions. Children are at highest risk, and risk is higher where safe water and adequate sanitation are lacking.

On antibiotic resistance WHO says only “increasing” and “common”, with no figures.

Paratyphoid is included in the same disease framing. WHO gives no separate paratyphoid figures and none is asserted.

**Where it starts.** Ingestion of *S.* Typhi or Paratyphi in water or food contaminated with human faeces or urine. The organisms are human-restricted, so transmission is always ultimately from another person, including from asymptomatic chronic carriers. Risk factors: absence of safe water and sanitation, urban crowding, and food handling by carriers.

Not known: why about 1 to 5 per cent of recovered patients become chronic gallbladder carriers†, and how to identify them without invasive testing, is not settled. Why gallstones predispose to carriage is partly explained by biofilm formation. The relationship between *S.* Typhi carriage and gallbladder cancer is observed but contested. The true burden is poorly measured because blood culture, the only reliable test, is unavailable in most endemic settings.

**Cure status.** Split by strain and state.

acute susceptible infection: CURABLE XDR infection, azithromycin- or carbapenem-susceptible: CURABLE XDR infection, resistant to both: RELIEF ONLY chronic gallbladder carriage: CURABLE

Acute susceptible infection is cured by antibiotics. Extensively drug-resistant typhoid, as circulating in Pakistan since 2016, is resistant to chloramphenicol, ampicillin, co-trimoxazole, fluoroquinolones and third-generation cephalosporins, leaving azithromycin or carbapenems — and azithromycin resistance has now appeared. Where both fail, treatment options approach exhaustion, and the infection is then not curable. This is the clearest example in the chapter of a curable disease being made uncurable by resistance.

Chronic carriage is cured by prolonged antibiotics, sometimes requiring removal of the gallbladder. It is a cure, not a lifelong regimen, which is why the label holds.

**Prevention.**

Safe water and sanitation: STRONG, on settled transmission physiology and on the historical record. Typhoid disappeared from countries that built sewers and treated water, before antibiotics existed.

Typhoid conjugate vaccine: STRONG. WHO states it is a single dose, recommended from six months of age. Two vaccines were WHO-prequalified as of March 2023, the first since December 2017, with Gavi funding from 2019. It is recommended for adults up to 45 or 65 depending on the vaccine. **WHO publishes no efficacy percentage. The randomised trials in Malawi, Nepal and Bangladesh report high efficacy, broadly in the 80 per cent range at one to two years. The primary trial papers could not be retrieved: PMC was blocked by CAPTCHA and the search budget was exhausted. No efficacy figure with a confidence interval is asserted.**

The chain is long: a Vi polysaccharide conjugated to tetanus toxoid, requiring bacterial culture, polysaccharide purification, conjugation chemistry, sterile fill-finish and an unbroken 2–8 °C cold chain, delivered by needle. But it is produced by multiple manufacturers in India at low cost, and a locally manufactured product, Typhocon, has been through non-inferiority trials in Bangladesh under ClinicalTrials.gov NCT05475379. The manufacturing base is broader and cheaper than for most conjugates.

Older vaccines: injectable Vi polysaccharide from age two and oral live attenuated from age six, both less effective and shorter-lasting than the conjugate.

Handwashing with soap: STRONG. Cochrane figures as in the diarrhoeal overview. Food hygiene and excluding carriers from food handling: STRONG. Boiling or treating drinking water: STRONG.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Azithromycin | Yes, 6.2.2 Watch group, first choice for enteric fever | Yes | UNICEF indicative about 9.3 US cents a 250 mg tablet, October 2026 |
| Ceftriaxone | Yes | Yes | Low dollars per course |
| Ciprofloxacin, where susceptible | Yes | Yes | Cents to low dollars |
| Amoxicillin, co-trimoxazole, chloramphenicol — older, widely resisted | Yes | Yes | Amoxicillin about 5.4 US cents a 250 mg dispersible tablet, UNICEF indicative, October 2026 |
| Meropenem, XDR strains | Yes | Yes | Substantially higher; hospital use |
| Oral rehydration salts and fluids, supportive | Yes | Yes | About 4.8 US cents a sachet, UNICEF indicative, October 2026 |

The fact sheet gives no dosing, duration or prices. Which antibiotic works depends entirely on local resistance, and in extensively drug-resistant settings most of the cheap off-patent options above no longer work.

**Simple means.** Boiling drinking water: decisive and sufficient against this organism. Chlorination, filtration, solar disinfection. Separating faeces and urine from water sources, with latrines sited below and away from wells. Handwashing with soap, particularly by anyone preparing food. Not allowing a recently ill person to prepare food for others — the carrier state is the engine of transmission, and this requires only a decision. Oral rehydration and continued feeding during the fever. Watching for sudden severe abdominal pain, which signals perforation and the need for surgery.

Prevention is almost entirely achievable with water, latrines and soap. But nothing simple cures an established bloodstream infection, and bowel perforation requires laparotomy. The minimum chain for cure is an effective antibiotic matched to local resistance, which in extensively drug-resistant settings means an injectable carbapenem and a hospital.

**Gaps. Typhoid conjugate vaccine efficacy with confidence intervals is absent from this entry** and should be filled from the Malawi TyVAC, Nepal and Bangladesh trials. The fact sheet is dated 30 March 2023 and reports 2019 estimates, among the oldest figures here. **WHO gives no numbers at all for antibiotic resistance in typhoid** , describing it only as increasing, while extensively drug-resistant typhoid is the most consequential current development in the condition. **No separate paratyphoid burden figures.** Burden estimates rest on blood culture surveillance at a small number of sites, extrapolated, and the 9 million figure carries wide uncertainty that the fact sheet does not state. Chronic carriage prevalence is not quantified by WHO.

---

## Dengue

**What it is.** A virus carried by *Aedes* mosquitoes that bite in daytime and breed in small containers of clean water around houses. Most infections are mild; a minority develop plasma leakage and shock. A second infection with a different serotype carries higher risk than the first.

**Measured.** WHO fact sheet on dengue, 21 August 2025. Reported cases rose from 505,430 in 2000 to 14.6 million in 2024, a record, with more than 12,000 deaths. The Americas Region reported over 13 million cases in 2024. January to July 2025: over 4 million cases and over 3,000 deaths from 97 countries.

Estimated infections per year: 100 to 400 million. A separate model on the same page gives 390 million infections of which 96 million are clinical, from Bhatt and colleagues, 2013. The page does not link the range to the single estimate.

On population at risk the page gives two figures. Key Facts says about half the world's population, roughly 4 billion. The body says 5.6 billion at risk of dengue and other arboviruses, from Lim and colleagues, 2025. The scopes differ — the body figure covers more than dengue — but the page sets the two against each other without reconciling them. Both stand; the appendix of single-source contradictions carries this as item 5.

Endemic in more than 100 countries. Europe in 2024: 308 cases in France, Italy and Spain; Mayotte and Réunion 1,291 cases and 4 deaths.

WHO states no case fatality rate. Dividing the 2024 reported figures gives about 0.08 per cent; that division is arithmetic performed here, is not a WHO figure, and is biased downward because mild cases dominate reporting in the Americas.

Timing: symptoms 4 to 10 days after infection, lasting 2 to 7 days; most people recover in 1 to 2 weeks; viraemia usually 4 to 5 days and up to 12.

**Where it starts.** Dengue virus serotypes 1 to 4, transmitted by *Aedes aegypti* and *Ae. albopictus*. The vector breeds in small artificial water containers near dwellings — tyres, pots, gutters, drums, plant saucers — and bites in daytime, which is why bed nets do little. The established risk mechanism for severe disease is secondary infection with a different serotype, via antibody-dependent enhancement, in which non-neutralising antibody from the first infection facilitates entry in the second. That is the central established fact of dengue immunology and the reason vaccination is complicated.

Not known: why most secondary infections are nonetheless mild. Which individuals will develop plasma leakage cannot be predicted. The relative contributions of viral factors, antibody-dependent enhancement and T-cell responses to severe dengue are contested. Whether the 2024 record reflects a true transmission increase, climate-driven vector expansion, better surveillance, or all three, is not resolved in the source.

**Cure status.** Split by severity.

most infections: SELF-LIMITING severe dengue: RELIEF ONLY

No antiviral exists. Most infections resolve over one to two weeks. For severe dengue nothing removes the virus, but careful fluid management is the difference between roughly 20 per cent mortality and under 1 per cent — supportive care that is not a cure and yet determines survival. WHO directs that pain be managed with paracetamol and that NSAIDs such as ibuprofen, and aspirin, be avoided because of bleeding risk; severe dengue often requires hospitalisation.

**Prevention.**

Source reduction — emptying and covering water containers: STRONG on settled vector ecology, though community-level trial evidence of sustained effect is MODERATE, because programmes decay without maintenance.

*Wolbachia*-infected mosquito release: STRONG. The AWED cluster-randomised trial in Yogyakarta, Indonesia, reported a large protective effect against virologically confirmed dengue, widely cited as about 77 per cent efficacy†. **The primary paper was not retrievable, so the figure with its confidence interval is not asserted, and the widely cited figure carries a dagger.** This is the most promising dengue intervention and its effect size should be sourced.

QDenga, TAK-003: MODERATE, with important restrictions. WHO states it is available and licensed in some countries and recommended only for ages 6 to 16 in high-transmission settings. **WHO gives no efficacy figure and none is asserted.** The age and setting restriction exists because of the serostatus problem below.

Dengvaxia, CYD-TDV: CONTESTED, and now largely withdrawn. It increased severe dengue risk in seronegative recipients, confirmed after deployment in the Philippines — a vaccine that harmed those it was meant to protect. Both the protective effect in seropositive recipients and the harm in seronegative recipients are established, and both belong in any account of it. **Neither magnitude is asserted here, because neither could be confirmed to its source.** This is the reason subsequent dengue vaccines carry serostatus-dependent recommendations.

Both dengue vaccines need long chains. They are live attenuated chimeric viruses requiring cell culture, sterile fill-finish, needles and an unbroken 2–8 °C cold chain.

Personal protection — repellent, long sleeves, daytime avoidance: MODERATE. Bed nets are of limited value against a daytime biter, in contrast to malaria. Window screens: MODERATE.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Oral fluids | n/a | n/a | Minimal |
| Paracetamol, the only recommended analgesic | Yes | Yes | Cents per course |
| Intravenous crystalloid, carefully titrated, for severe dengue | Yes | Yes | Low dollars |
| NSAIDs, aspirin | — | — | Contraindicated |

There is no antiviral and no specific treatment. Platelet transfusion is not routinely indicated despite low platelet counts, and is frequently given without benefit.

**Simple means.** Substantial, and concentrated on the container.

Emptying, scrubbing and covering every water container around the dwelling, weekly. The vector breeds nowhere else in any quantity, so this is the single most effective measure, and it needs nothing but labour. Removing tyres, tins, bottles, blocked gutters and plant saucers; putting sand in plant trays. Covering stored water with tight lids, or adding a mesh. Keeping fish in ornamental ponds and water tanks, which eat larvae. Oral fluids, in quantity, for the ill person — the core of treatment. Paracetamol only, and specifically not aspirin or ibuprofen. Watching for the warning signs as fever falls, which is when deterioration occurs: severe abdominal pain, persistent vomiting, bleeding gums or nose, lethargy, cold clammy skin. Recognising these needs no instrument and is what prompts transfer in time.

What requires a chain: intravenous fluids for shocked patients, and vaccination. Severe dengue needs careful intravenous fluid titration — too little causes shock, too much causes fluid overload — and that requires sterile fluids, a cannula and repeated clinical assessment.

**Gaps. The *Wolbachia* effect size with its confidence interval is missing** and is the most important gap for dengue prevention. **No vaccine efficacy figures are published on the WHO fact sheet for QDenga and none were sourced.** Reported cases, 14.6 million, and estimated infections, 100 to 400 million, differ by a factor of about 7 to 27, so case fatality derived from reported figures is not interpretable. The two model-based estimates WHO cites are not reconciled on the page. The population-at-risk figures, about 4 billion and 5.6 billion, sit unreconciled on the same page; see the appendix, item 5. The page also prints 21 August 2025 while carrying a 2026 copyright and a June 2026 news item; see the appendix, item 6. Whether the 2024 record reflects transmission or surveillance is unresolved. Dengvaxia's serostatus-dependent harm is established but its magnitude differs between analyses, and good sources disagree on whether pre-vaccination screening makes the product usable.

---

## COVID-19

**What it is.** A coronavirus, SARS-CoV-2, that entered the human population in late 2019 and spread worldwide. It causes respiratory illness ranging from nothing to fatal pneumonia, with risk rising steeply with age. It is now a recurring seasonal infection rather than a novel one.

**Measured.** WHO fact sheet, 27 November 2025. Nearly 780 million reported cases worldwide since December 2019. More than 7.1 million reported deaths, with WHO noting that actual numbers are thought to be higher. Over 13.64 billion vaccine doses administered by the end of 2024. About 6 per cent of people develop post-COVID-19 condition, long COVID.

Symptoms usually begin 3 to 6 days after exposure and last up to 10 days. Revaccination may be needed 6 to 12 months after the most recent dose for high-risk groups.

The central measurement fact of this condition is the gap between counted and estimated deaths. WHO's excess mortality analysis of 5 May 2022 gives 14.9 million excess deaths associated with the pandemic in 2020 and 2021, with a range of 13.3 to 16.6 million, against about 5.4 million reported COVID deaths for those two years. The excess figure is roughly three times the reported count for that period.

By 2023 the disease had receded in the rankings. WHO's Global Health Estimates place COVID-19 fourteenth among causes of death in 2023, at about 0.9 million. GBD 2023 places it twentieth, having been the leading age-standardised cause of death in 2021, and gives 797,600 deaths (95 per cent UI 722,900–857,000) and 12.5 million YLDs (95 per cent UI

5.33–25.7), ranking it twenty-first among YLD causes. The two agencies disagree on rank — fourteenth against twentieth — from different cause hierarchies.

**Where it starts.** SARS-CoV-2, transmitted by respiratory aerosols and droplets, with airborne transmission in indoor spaces established after initial dispute. Risk factors for severe disease: older age, being unvaccinated, and underlying conditions — diabetes, heart, lung, liver and kidney disease, obesity, cancer, dementia, immunosuppression including HIV. Pregnancy and health-care work are also listed. The age gradient in mortality is steep and is the dominant risk factor.

Not known: the origin of SARS-CoV-2 is genuinely unresolved. Zoonotic spillover and a laboratory-associated origin are both held by serious scientists, intelligence assessments differ, and no consensus exists. The mechanism of long COVID is not established, and candidate explanations — viral persistence, autoimmunity, microclotting, reactivated herpesviruses, dysautonomia — are all under investigation without resolution; the 6 per cent figure rests on varying case definitions. Why children were largely spared severe acute disease is not fully explained.

**Cure status.** Split.

most infections: SELF-LIMITING severe disease: RELIEF ONLY long COVID: RELIEF ONLY

Most infections resolve over about ten days. In severe disease antivirals given early reduce progression, and dexamethasone and oxygen reduce death in the hypoxic, but nothing removes the established lung injury. The RECOVERY trial established that dexamethasone reduces mortality in patients requiring oxygen or ventilation, while showing no benefit and possible harm in those not requiring oxygen. For long COVID no treatment removes it and no agent has established efficacy; management is symptomatic and rehabilitative.

**Prevention.**

Vaccination: STRONG against severe disease and death; weaker and waning against infection. The original mRNA trials reported about 95 per cent efficacy against symptomatic disease, but that figure applies to the ancestral strain in 2020 and does not describe current protection against current variants. Protection against severe disease has proved durable; protection against infection wanes within months. WHO gives no efficacy figure and recommends revaccination every 6 to 12 months for high-risk groups. **No single efficacy number is quotable for this condition now** , and presenting the 2020 trial figure as current protection would be wrong.

The chains are long and differ by platform, and this chapter's coldest requirement sits here. mRNA vaccines require nucleotide synthesis, enzymatic transcription, lipid nanoparticle formulation by controlled mixing, sterile fill-finish and, for some, an ultra-cold chain at −70 °C — the most demanding cold chain of any product in this chapter except Ervebo. Viral vector vaccines require mammalian cell culture. Inactivated vaccines require large-scale virus culture under high containment. Protein subunit vaccines have the lowest chain burden of the group. None is producible by simple means, and the mRNA cold chain was a decisive constraint on equitable distribution.

Ventilation of indoor spaces: STRONG, on aerosol physics.

Masks, meaning respirators: CONTESTED. Good sources disagree, and the disagreement is not resolvable by picking one. Mechanistic and observational evidence supports filtration efficacy for well-fitted respirators. The Cochrane review of randomised trials of mask *mandates and promotion* in community settings found no clear effect on respiratory illness. Both findings are real and they answer different questions: the filtration capacity of a device, against the population effect of asking people to wear one. **No single effect size is asserted for either.**

Isolation of cases: MODERATE, limited by presymptomatic transmission. Distancing and crowd avoidance: MODERATE.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Dexamethasone, hypoxic patients only | Yes | Yes | UNICEF indicative about 24 US cents per 4 mg tablet, October 2026 — the most cost-effective treatment established in the pandemic |
| Oxygen | Yes | n/a | Variable; the principal requirement |
| Nirmatrelvir/ritonavir, early and high-risk | Yes | Ritonavir yes; nirmatrelvir no | High-income price around US$500–1,400 per course; generic licences exist for low-income countries; no verified price |
| Remdesivir | Yes | No | Several hundred US dollars per course |
| Tocilizumab, severe disease, with steroids | Yes | Biosimilars available | Hundreds of US dollars |
| Anticoagulation, selected inpatients | Yes | Yes | Low |

Dexamethasone and oxygen are the two interventions that reduced mortality at scale, and both are cheap and off-patent. Nirmatrelvir/ritonavir must be started early to work, which in practice limits its use.

**Simple means.** Opening windows. Ventilation is the principal non-pharmaceutical measure and requires nothing. Moving gatherings outdoors. Rest, fluids and paracetamol, which is the actual management of most cases. Isolating the ill person from the elderly and the chronically ill in the household. Prone positioning of the breathless patient — awake proning — which improves oxygenation and requires only turning the person, and is one of the few genuinely supply-chain-free interventions discovered during the pandemic. Counting breaths and watching lips and nails for colour change, to recognise deterioration.

What requires a chain: oxygen, dexamethasone, antivirals and vaccines. Oxygen was the binding constraint on survival in most of the world, and it cannot be improvised. The oxygen shortages of 2021 killed people for whom no simple substitute existed. The minimum chain is a pressure-swing-adsorption plant or concentrators plus uninterrupted electricity, or cylinder logistics.

**Gaps.** Reported deaths of 7.1 million against 14.9 million excess deaths for 2020 and 2021 alone differ by a factor WHO acknowledges but does not resolve; the true toll is not known. **No current vaccine efficacy figure is quotable** ; the widely remembered 95 per cent describes a strain and a population that no longer exist. **Masks are genuinely contested** between mechanistic and observational evidence on one side and randomised-trial evidence on the other; both positions are printed above and neither effect size is asserted. **The origin of the virus is unresolved** and good sources disagree. On long COVID, the 6 per cent prevalence figure depends on case definition, which varies widely between studies, and no mechanism and no treatment are established. WHO and GBD place COVID-19 at different ranks for 2023, fourteenth against twentieth, from different cause hierarchies. The fact sheet is dated 27 November 2025 and reports doses to end-2024; case and death reporting has largely ceased in most countries, so the figures are no longer updated meaningfully.

---

## Pertussis (whooping cough)

**What it is.** A bacterial infection of the airway lining, *Bordetella pertussis*, causing weeks of violent coughing fits. In infants it causes apnoea rather than the classic whoop, and that is how it kills. Immunity from vaccination and from infection both wane.

**Measured.** The WHO pertussis fact sheet could not be retrieved. The URL returned only navigation, the corrected URL returned a client error, and the web search budget was exhausted before an alternative primary source could be reached. The 19 October 2026 retrieval pass did not close it.

**Global cases. Global deaths. Case fatality.** No pertussis-specific burden figure is asserted.

What exists, from retrieved sources. DTP3 coverage was 85 per cent of infants globally in 2025, about 110 million infants. About 15 per cent, nearly 20 million, had no or incomplete coverage. Of that nearly 20 million, about 6 million were partially vaccinated and 13.5 million

were zero-dose children who received no vaccination at all; about 53 per cent of the un- and under-vaccinated live in ten countries. Pertussis vaccination is listed by WHO as pneumonia prevention.

Age pattern, established clinically rather than from a retrieved figure: deaths concentrate overwhelmingly in infants under six months, particularly under three months, who are too young to have completed the primary series.

**Where it starts.** *B. pertussis*, transmitted by respiratory droplets, highly infectious. The risk structure is infancy before completion of the primary series; waning immunity in older children and adults, who then transmit to infants; and absence of maternal immunisation. The established transmission pattern is that adults and adolescents with mild or unrecognised disease infect newborns.

Not known: why acellular vaccines protect against disease but less well against infection and transmission than whole-cell vaccines. The finding is genuine and consequential — baboon studies show vaccinated animals can carry and transmit — and its implications for herd immunity are not fully resolved. The resurgence of pertussis in countries using acellular vaccines is attributed variously to faster waning, reduced transmission-blocking, pathogen adaptation through pertactin-deficient strains, and better diagnosis; good sources weight these differently. The duration of protection is not precisely established for either vaccine type.

**Cure status.** SELF-LIMITING, over weeks.

Macrolides eradicate *B. pertussis* from the nasopharynx and end infectiousness, which is their main value. They do not shorten the cough unless given in the first week or two, before the paroxysmal stage, and most patients present after that. So the organism is removable while the illness, once established, runs its course over weeks regardless, with the cough persisting up to three months. For infants, management is supportive: oxygen, feeding support, and monitoring for apnoea.

**Prevention.**

Primary infant immunisation, DTP or DTaP: STRONG. WHO recommends three primary doses from six weeks of age, and coverage was 85 per cent in 2025. **Precise efficacy figures with confidence intervals are not asserted** , because the WHO pertussis fact sheet could not be retrieved; acellular and whole-cell vaccines differ and should be reported separately when the source is consulted.

Maternal immunisation in pregnancy: STRONG. This is the single most effective measure for preventing infant deaths, because it protects the infant in the first months before their own doses take effect, via transplacental antibody. Observational studies report high effectiveness against infant hospitalisation and death. **No figure with a confidence interval is asserted.**

Booster doses in childhood and adolescence: STRONG, given waning immunity. Cocooning, meaning vaccinating household contacts of newborns: MODERATE. Post-exposure macrolide prophylaxis for close contacts of infants: MODERATE.

Whole-cell against acellular vaccine: CONTESTED. Whole-cell vaccines give longer-lasting protection and better transmission-blocking. Acellular vaccines have markedly fewer adverse effects, which is why high-income countries switched. Both positions are evidence-based and the trade-off is real: the switch reduced reactogenicity and is implicated in resurgence. Most low- and middle-income countries continue to use whole-cell vaccine, and WHO does not recommend switching. **Neither the protection differential nor the reactogenicity differential is asserted as a figure here.**

The chain is long for both, and markedly shorter for whole-cell. Whole-cell vaccine requires bacterial fermentation, inactivation and adjuvanting — a comparatively low technological threshold, achievable in many middle-income countries. Acellular vaccine requires purification of individual antigens — pertussis toxin, filamentous haemagglutinin, pertactin — chemical detoxification and precise formulation, which is substantially more complex and expensive. Both need sterile fill-finish, a needle and an unbroken 2–8 °C cold chain, and both are normally delivered combined with diphtheria and tetanus toxoids.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Azithromycin, first line | Yes, 6.2.2 Watch group | Yes | UNICEF indicative about 9.3 US cents a 250 mg tablet, October 2026 |
| Erythromycin | Yes | Yes | Cents to low dollars |
| Co-trimoxazole, alternative | Yes | Yes | Cents per course |
| Oxygen and feeding support, infants | Yes, oxygen | n/a | Variable |
| DTP-containing vaccine | Yes | Yes | Low; no verified unit price |

Cough medicines, bronchodilators and corticosteroids do not help pertussis — a well-established negative.

**Simple means.** Keeping newborns away from anyone with a persistent cough, including adults who think they merely have a cold. Since adults are the usual source of infant infection, this single decision prevents infant deaths. Recognising the pattern: coughing fits ending in vomiting; a cough lasting more than two weeks; and in infants, pauses in breathing and going blue rather than whooping — apnoea is the lethal sign and it is observable without instruments. Small frequent feeds between coughing fits, and holding the infant upright. Keeping the air free of smoke and irritants. Isolating the case for the first days of antibiotic treatment, or for about three weeks without treatment. Patience: the cough lasts weeks to months and nothing shortens it.

Prevention of infant death ultimately requires vaccination, of the mother in pregnancy and of the infant from six weeks, and that requires an industrial chain — bacterial fermentation at minimum for whole-cell vaccine, plus sterile fill-finish and cold chain. Simple means can reduce an infant's exposure but cannot substitute for maternal immunisation. The severely affected infant needs oxygen and sometimes ventilation, which cannot be improvised.

**Gaps. This entry lacks burden figures entirely** : the WHO pertussis fact sheet was not retrievable and the search budget was exhausted. Global case and death estimates, and vaccine efficacy with confidence intervals for both acellular and whole-cell products, are the additions this entry needs. The acellular-against-whole-cell question is genuinely contested and has direct policy consequences. Pertussis surveillance is poor: the disease is under-diagnosed in adults, and case counts largely reflect testing intensity. Whether resurgence reflects vaccine properties, pathogen adaptation or better detection is unresolved. Maternal immunisation effectiveness figures are observational, not trial-based.

---

## Tetanus (including neonatal tetanus)

**What it is.** *Clostridium tetani* spores live in soil and dust and enter through wounds. The bacterium does not spread through the body; its toxin does, locking muscles into spasm so the jaw clamps and the back arches. In newborns it follows infection of the cut umbilical stump.

**Measured.** WHO fact sheet on tetanus, 15 July 2026. Neonatal tetanus deaths: just over 7,700 newborns in 2021, down from an estimated 46,898 in 2000, an 84 per cent reduction. 85 per cent of infants worldwide received three doses of DTP-containing vaccine in 2025. Eight countries had yet to achieve maternal and neonatal tetanus elimination as of July 2026; the source does not name them.

The elimination threshold is fewer than one neonatal tetanus case per 1,000 live births in every district.

Timing: incubation 3 to 21 days, with most cases within 14 days. Neonatal tetanus occurs within the first 28 days of life, and the confirmed case definition is normal suckling and crying for the first two days, then loss of that ability between days 3 and 28. Maternal tetanus occurs during pregnancy or within six weeks of its end.

**All-age cases. All-age deaths. Case fatality.** WHO gives none of these on the fact sheet. This entry therefore has neonatal figures only.

**Where it starts.** *C. tetani* spores entering a wound, germinating in low-oxygen tissue, and releasing tetanospasmin. Risk factors: deep or dirty wounds, puncture wounds, burns, un-

clean delivery and unclean cord care, unsafe injection, and absence of maternal or individual immunisation.

Tetanus is not transmissible between people. It is an environmental infection, which is why it cannot be eliminated by herd immunity and why every individual must be vaccinated.

Not known: very little about causation is unresolved; this is among the best-understood conditions in the chapter. The open questions are therapeutic. The optimal dose and route of antitoxin, and the management of autonomic instability in severe tetanus, are not settled. Why some patients develop catastrophic autonomic dysfunction is not well explained.

**Cure status.** SELF-LIMITING in those who survive the spasm phase. Survival of the spasm phase depends on airway control and ventilation. The label does not mean that the patient needs no treatment. Once toxin is bound to nerve endings nothing removes it. Antitoxin neutralises only circulating, unbound toxin, so it prevents worsening but cannot reverse what has bound. Recovery occurs as nerve terminals regenerate over weeks. Treatment is therefore to neutralise free toxin, remove the source, control spasms, and support breathing until the toxin's effect wears off.

The label rests on the course of the illness. The body completes it, and survivors recover completely without sequelae. What treatment changes is whether the patient survives the spasm phase. Case fatality without intensive care is very high, particularly in neonates, and falls substantially where ventilation is available. **WHO publishes no case fatality figure.**

**Prevention.**

Tetanus toxoid vaccination: STRONG — one of the most reliable vaccines in existence. WHO specifies six doses for lifelong protection, three primary and three boosters. The primary series can start at six weeks with at least four weeks between doses. Boosters fall at 12–23 months, 4–7 years and 9–15 years, with a recommended minimum four-year gap between them. **WHO publishes no efficacy percentage with a confidence interval on the fact sheet, and none is asserted.** The historical trial evidence is unusually strong and tetanus toxoid is generally regarded as near-fully protective when the series is complete.

Maternal immunisation: STRONG. Vaccinating the mother protects the newborn through transplacental antibody and is the basis of the 84 per cent reduction in neonatal deaths since 2000.

Clean delivery and clean cord care: STRONG. Together with maternal immunisation this is the whole of neonatal tetanus prevention.

Wound cleaning and debridement: STRONG on settled physiology. Removing devitalised, low-oxygen tissue removes the conditions the organism requires.

Post-exposure prophylaxis, toxoid with or without immunoglobulin according to wound type and vaccination history: STRONG.

The chain is long, and it is the lowest of any vaccine in this chapter. Tetanus toxoid is made by culturing *C. tetani*, harvesting the toxin, inactivating it with formaldehyde, and adsorbing it onto aluminium salt. That is bacterial fermentation plus chemical inactivation — a nineteenth-century-adjacent technology, produced cheaply in many low- and middle-income countries. It is heat-stable enough to tolerate brief cold-chain breaks better than measles or mRNA vaccines, so it sits on the forgiving side of the cold-chain dividing line. It still requires sterile fill-finish and a needle, and it cannot be made outside a pharmaceutical facility.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Tetanus toxoid vaccine | Yes | Yes | Cents per dose; among the cheapest vaccines; no verified price |
| Tetanus immunoglobulin (human) or antitoxin | Yes | Yes | Higher; requires plasma fractionation |
| Metronidazole, to eradicate the organism | Yes | Yes | Cents per course |
| Diazepam or midazolam, spasm control | Yes | Yes | Cents to low dollars |

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Magnesium sulfate, spasm and autonomic control | Yes, 5.1.1 Antiseizure medicines, core — but listed for severe pre-eclampsia and eclampsia, with the restrictive note “not for other convulsant disorders” | Yes | UNICEF indicative US$33.11 per 100 ampoules of 5 g in 10 mL, October 2026, about 33 US cents an ampoule |
| Mechanical ventilation with neuromuscular blockade, severe disease | n/a | n/a | High; intensive care required |
| Wound debridement | n/a | n/a | Surgical, but basic |

Note the EML qualification on magnesium sulfate: it is a listed medicine, but its listed indication is eclampsia and severe pre-eclampsia, and the 24th List carries an explicit note excluding other convulsant disorders. Its use in tetanus is outside that listing.

Ventilation is what determines survival in severe tetanus. No drug substitutes for it.

**Simple means.** Prevention is largely achievable. Treatment is not.

Clean cord cutting: a new or boiled blade, a clean tie, and the stump left dry, clean and uncovered. Applying nothing to the umbilical stump — no cow dung, ash, oil, mud or herbal paste. These practices are a direct and established cause of neonatal tetanus, and stopping them requires no resource at all. That is the highest-value simple intervention in this entry. Washing hands before delivery and before handling the newborn. A clean delivery surface. Wound care: washing wounds with clean water and soap, removing dirt and dead tissue, and leaving them open to the air rather than sealing deep puncture wounds. Not using contaminated instruments for piercing, circumcision or injection; boiling or flaming what must be reused. Keeping the patient in a dark, quiet room and minimising touch, since light, noise and handling trigger spasms — genuine symptomatic care requiring nothing.

Once tetanus is established, simple means cannot save a patient with respiratory spasm. The minimum chain is antitoxin, which means plasma fractionation; benzodiazepines or magnesium; and above all mechanical ventilation with reliable power and trained staff. A neonate with tetanus in a setting without a ventilator will usually die, and nothing available locally changes that. That is why the entire effort sits in maternal immunisation and the clean cord.

**Gaps. WHO publishes no all-age case or death count, no case fatality rate, and no vaccine efficacy figure on the tetanus fact sheet.** The eight countries yet to achieve elimination are not named in the source. Neonatal tetanus deaths are reported for 2021 while vaccine coverage is reported for 2025, so the figures are not contemporaneous. Neonatal tetanus is substantially under-reported, because deaths occur at home in exactly the settings without surveillance, so the 7,700 figure is a floor. Optimal antitoxin dose and route, and the management of autonomic instability, are not settled.

---

## Diphtheria

**What it is.** *Corynebacterium diphtheriae* grows in the throat and produces a toxin that forms a grey membrane which can obstruct breathing. The toxin also damages heart muscle and nerves. It returns wherever immunisation programmes break down.

**Measured.** WHO fact sheet on diphtheria, 15 July 2026. Without proper treatment, diphtheria is fatal in around 30 per cent of unvaccinated cases, and children under five are at greater risk of dying.

**Global cases. Global deaths.** WHO gives neither on the fact sheet — a notable absence for a vaccine-preventable disease with 30 per cent untreated fatality.

Coverage in 2025: about 85 per cent of infants, 110 million, received the recommended three doses; about 15 per cent, nearly 20 million, had no or incomplete coverage. 83 countries have all three WHO-recommended booster doses in their national programmes, and 42 countries have no boosters.

No WHO region is completely free of diphtheria. Outbreaks were noted in Guinea and Nigeria in 2023, and prevention work in Rohingya refugee camps in Bangladesh in 2017.

Symptoms usually begin 2 to 5 days after exposure, and a grey coating may form in the respiratory tract within 2 to 3 days.

**Where it starts.** Toxigenic *C. diphtheriae*, and occasionally *C. ulcerans*, transmitted by respiratory droplets and by contact with skin lesions. The risk structure is absence or lapse of immunisation, crowding, displacement and camp settings, and waning adult immunity where boosters are absent — which is why 42 countries without booster programmes are a structural vulnerability. The toxin, not the organism's spread, causes the damage.

Not known: that toxin production requires a bacteriophage carrying the *tox* gene is understood mechanistically, but what governs the circulation of toxigenic against non-toxigenic strains in a population is not epidemiologically predictive. The duration of vaccine-induced protection in adults, and therefore the necessity and timing of boosters, is not precisely established — which is reflected in the fact that 42 countries use none. Antitoxin dosing rests on century-old empirical practice rather than on modern trials.

**Cure status.** Split by timing, on the same mechanism as tetanus.

treated early with antitoxin plus antibiotics: CURABLE toxin already bound: RELIEF ONLY

Antitoxin neutralises only unbound toxin. Once the toxin has entered heart and nerve cells nothing removes it, and myocarditis and neuropathy run their course. Treated early, full recovery is usual. Treated late, case fatality rises sharply with delay.

Antibiotics — penicillin or erythromycin — eradicate the organism, stop toxin production and end infectiousness, but do not neutralise toxin already released. Timing is the determinant, and the 30 per cent untreated fatality reflects what happens without antitoxin.

**Prevention.**

Diphtheria toxoid vaccination: STRONG. WHO states that combination diphtheria vaccines prevented more than 90 per cent of cases between 1980 and 2000. That is a programme-level effectiveness estimate, not a trial efficacy, and WHO states no confidence interval. The schedule is three primary doses in infancy plus three boosters in childhood and adolescence.

Booster doses: STRONG, and their absence in 42 countries is the identified weak point.

Maintaining coverage during conflict and displacement: STRONG, given that outbreaks follow programme collapse. Antibiotic prophylaxis and vaccination of close contacts: STRONG. Case isolation until no longer infectious: STRONG.

The chain is long but among the lowest in this chapter, comparable to tetanus. Diphtheria toxoid is made by culturing *C. diphtheriae*, harvesting toxin, inactivating it with formaldehyde and adsorbing it onto aluminium salt — bacterial fermentation plus chemical inactivation, normally formulated with tetanus toxoid and pertussis as DTP. It is cheap, widely manufactured and relatively heat-tolerant, so like tetanus toxoid it sits on the forgiving side of the cold-chain line. It requires sterile fill-finish, a needle and a cold chain, and it is not producible by simple means.

Antitoxin supply is a separate and serious problem, and it is a different kind of problem from the vaccine. Diphtheria antitoxin is equine serum, produced by immunising horses and fractionating their plasma. Global supply is small, few manufacturers remain, and shortages are recurrent. The specific treatment for the disease is the least secure item in this chapter's supply picture.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Diphtheria antitoxin (equine) | Yes | Yes | Scarce; global supply constrained, few manufacturers; no reliable market price |
| Benzylpenicillin or procaine penicillin | Yes | Yes | Cents per course |
| Erythromycin | Yes | Yes | Cents to low dollars per course |
| DTP-containing vaccine | Yes | Yes | Low; no verified unit price |
| Airway management, intubation or tracheostomy | n/a | n/a | Requires surgical capability |

WHO gives no antitoxin dosage figures on the fact sheet. Antitoxin scarcity, not cost, is the binding constraint.

**Simple means.** Recognising it: a sore throat with a grey-white membrane that bleeds when scraped, a swollen neck — "bull neck" — hoarseness and stridor in a child. Recognition needs only a light and a look, and it is what triggers the search for antitoxin. Isolating the case and keeping them from other children. Keeping the airway clear; sitting the child upright; not attempting to scrape the membrane, which causes bleeding. Watching for stridor and breathing difficulty, which signal imminent obstruction. Moving the patient toward antitoxin immediately — the decision that determines survival. Handwashing and covering coughs.

Nothing simple treats diphtheria. The minimum chain is equine antitoxin — horses, immunisation, plasma collection, fractionation and an existing manufacturer — plus antibiotics, plus the surgical ability to secure an obstructed airway. Antitoxin cannot be improvised, and unlike many items in this chapter it cannot readily be substituted or scaled up quickly, because the manufacturing base has contracted. A child with obstructive diphtheria and no antitoxin and no airway capability will often die.

**Gaps. WHO publishes no global case or death count.** The "more than 90 per cent of cases prevented, 1980–2000" figure is a programme-level estimate without a confidence interval, and it is now a quarter-century old. The duration of adult immunity is not established, which is why 42 countries omit boosters and 83 include them — a genuine policy divergence from the same evidence base. **Antitoxin supply is fragile and unquantified in the source** ; no figures on global production or stockpiles are published. Antitoxin dosing practice predates modern trial methods.

---

## Rabies

**What it is.** A virus transmitted in the saliva of infected mammals, almost always dogs. It travels up nerves to the brain over weeks to months. Once symptoms appear it is essentially always fatal and there is no treatment. It is also entirely preventable after exposure.

**Measured.** WHO fact sheet on rabies, 17 September 2026. The page gives the death figure two ways. Key Facts says only "tens of thousands" annually. The body gives 44,203, from the 2021 Global Health Estimates model. WHO notes that the true number is likely substantially underreported. The appendix of single-source contradictions carries this page as item 7, because the same hedging pattern runs through three of its headline figures.

Fatality once clinical symptoms appear: 100 per cent in Key Facts, "virtually 100 per cent" in the body.

Dogs cause 99 per cent of human cases in Key Facts, "up to 99 per cent" in the body.

40 per cent of deaths are in children under 15, a figure in Key Facts that the body nowhere supports; the body says only that children aged 5 to 14 are frequent victims.

Geography: mainly Asia and Africa, and present on all continents except Antarctica. Dog-mediated rabies is largely controlled in the Americas, where haematophagous bats are now the primary source of human rabies. Dog-mediated human rabies elimination is validated in three countries — Bhutan, Chile and Mexico — and 17 countries have self-declared freedom from rabies virus infection to WOAH.

Over 29 million people receive human rabies vaccine annually, and three WHO-prequalified human rabies vaccines existed as of 2024.

Costs: about US$8.6 billion a year globally; average post-exposure prophylaxis cost US$108, as of 2018, excluding travel and lost income, while affected people often earn US$1–2 a day. Intradermal administration reduces costs by 60 to 80 per cent.

Incubation is typically 2 to 3 months, with a range of one week to one year. Paralytic rabies accounts for about 20 per cent of human cases.

**Where it starts.** Lyssavirus in saliva, entering through a bite, scratch or mucous-membrane contact, then travelling along peripheral nerves to the central nervous system. The long and variable incubation is established, and it is precisely what makes post-exposure prophylaxis possible: there is a window between exposure and the virus reaching the brain. The risk structure is dog bites, up to 99 per cent; children, who are shorter, take more bites to head and hands, and are less likely to report; and absence of dog vaccination.

Not known: what determines the incubation period, which ranges from a week to a year, is not explained. Why a few people have survived symptomatic rabies — a handful of documented cases — is unexplained, and the Milwaukee protocol derived from one such case has not been reproducible. It is not an established treatment. Whether abortive, subclinical rabies infection occurs in humans is suggested by serosurveys and contested.

**Cure status.** The starkest split in this chapter.

after exposure, before symptoms: CURABLE once symptomatic: RELIEF ONLY — death near-certain

Prompt wound washing, vaccine and, for severe exposures, rabies immunoglobulin prevent the disease reliably. WHO states that post-exposure prophylaxis prevents the virus reaching the central nervous system, and gives no failure-rate figure; failures are almost always attributable to delayed or incorrect administration. Once clinical symptoms appear, care is palliative — sedation and analgesia — no treatment exists, and the Milwaukee protocol is not established therapy.

**Prevention.**

Mass dog vaccination: STRONG — the only measure that eliminates human rabies at source. **WHO does not state the coverage threshold on the fact sheet. The widely used figure of 70 per cent† of the dog population could not be confirmed from the retrieved page, and carries a dagger.** The evidence that it works is the elimination record: three countries validated, and the near-disappearance of dog-mediated rabies from the Americas.

Post-exposure prophylaxis: STRONG. Over 29 million people receive it annually.

Immediate wound washing: STRONG, on settled physiology. WHO recommends washing with water and soap for at least 15 minutes. **WHO gives no numerical effect estimate** ; the mechanism — mechanical and detergent removal of virus from the inoculation site — is physiologically settled, and historical animal data show substantial risk reduction from washing alone.

Pre-exposure prophylaxis: STRONG for those at occupational or travel risk.

Keeping children away from unknown dogs, and teaching them to report every bite and scratch: MODERATE, given that 40 per cent of deaths are in children and that under-reporting by children is a known failure.

Both products need long chains. Human rabies vaccine is grown in cell culture — Vero cells or chick embryo fibroblasts — inactivated, purified, sterile-filled and cold-chained at 2–8 °C. Rabies immunoglobulin is either human plasma-derived, requiring plasma collection and fractionation, or equine. Monoclonal antibody replacements are now available and reduce dependence on plasma supply. Neither vaccine nor immunoglobulin can be produced by simple means.

One access measure is worth isolating. Intradermal administration — giving a fraction of the intramuscular dose into the skin — stretches the same vial across several patients and cuts cost by 60 to 80 per cent. That is a delivery innovation rather than a manufacturing one, and it is the single most important access measure in this entry.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Rabies vaccine, post-exposure prophylaxis | Yes | Yes | Part of an average PEP cost of US$108, 2018; the intradermal route cuts cost by 60–80 per cent |
| Rabies immunoglobulin, severe exposures | Yes | Yes, plasma-derived | The expensive component of PEP; frequently unavailable |
| Monoclonal antibody, immunoglobulin substitute | Recently included | No | Variable; intended to be cheaper than the plasma product |
| Wound washing with soap and water | n/a | n/a | Essentially free |
| Palliative sedation, symptomatic rabies | Yes | Yes | Cents |

For symptomatic rabies there is no treatment. The entire therapeutic effort is prophylactic.

**Simple means.** This condition has one outstanding simple intervention and one hard limit.

Washing the wound with soap and water for at least 15 minutes, immediately. This is free, requires nothing but water and soap, is explicitly WHO-recommended, and substantially reduces the risk of infection taking hold. It is the most important thing any person can do after a bite, anywhere, and it must happen within minutes to hours — not after travelling to a clinic. Flushing the wound under running water, and not suturing it closed. Reporting and seeking vaccine regardless, because washing reduces but does not eliminate risk. Teaching children to report every dog bite and scratch, which costs nothing and addresses the 40 per cent of deaths in under-fifteens. Confining and observing the biting animal for ten days where possible, which can spare unnecessary prophylaxis. Community dog population management: confining and caring for owned dogs, reducing free-roaming dog numbers, removing the food waste that sustains them.

The hard limit is absolute. No simple means prevents rabies once the virus has established, and nothing treats symptomatic disease. The minimum chain is cell-culture vaccine plus cold chain plus a clinician able to administer it, ideally intradermally, and for severe exposures immunoglobulin or a monoclonal antibody. A child bitten on the face in a village a week from a vaccine supply will probably die, and washing the wound — while genuinely worth doing — is not reliably sufficient for severe head and neck exposures.

**Gaps. WHO does not state the dog vaccination coverage threshold** ; the commonly used 70 per cent figure is not asserted here. **WHO gives no numerical post-exposure prophylaxis effectiveness figure and no numerical effect estimate for wound washing** , despite both being central recommendations. Deaths are substantially under-reported, as WHO itself states; 44,203 is a modelled floor and the Key Facts section retreats to “tens of thousands”. The cost figure is from 2018. The handful of survival reports and the Milwaukee protocol are not reproducible and should not be presented as treatment. Whether human abortive infection occurs is contested. Three of the page’s headline figures are stated flatly in Key Facts and hedged in the body; see the appendix, item 7.

---

## Schistosomiasis

**What it is.** Blood flukes whose larvae emerge from freshwater snails and penetrate skin during contact with infested water. Adult worms live in blood vessels around the bladder or bowel for years, and their eggs cause chronic inflammation, scarring, bleeding and bladder cancer.

**Measured.** WHO fact sheet on schistosomiasis, 23 February 2026. At least 253.7 million people required preventive treatment in 2024, and more than 100.5 million were reported treated — a global coverage of 39.6 per cent. Among school-aged children requiring preventive chemotherapy, 61.7 per cent were treated.

39.6 per cent of 253.7 million is about 100.47 million, so the “more than 100.5 million” headline is a derived and rounded value that the body does not independently confirm. The figures are consistent.

At least 93.9 per cent of those requiring treatment live in Africa. Estimated deaths: 14,353 a year, which WHO itself says is likely an underestimate.

**WHO gives no figure for the number currently infected** — only the number requiring treatment, which is a programmatic denominator.

Transmission is reported from 79 countries, and preventive chemotherapy is needed in 50 endemic countries with moderate-to-high transmission. Sub-Saharan campaigns over the past ten years reduced school-aged prevalence by almost 60 per cent.

Species and geography: *S. mansoni* in Africa, the Middle East, the Caribbean, Brazil, Venezuela and Suriname; *S. haematobium* in Africa, the Middle East and Corsica; *S. japonicum* in China, Indonesia and the Philippines; *S. mekongi* in Cambodia and Lao PDR; *S. guineensis* and *S. intercalatum* in the central African rainforest. Human–animal hybrids are reported in many sub-Saharan countries, and the 2013 Corsica outbreak was linked to them.

**Where it starts.** Cercariae released by freshwater snails penetrating intact skin during contact with infested water — wading, washing, fishing, swimming, irrigation work. The risk structure is occupational and domestic water contact; children playing in water carry the

highest intensity; and absence of safe water supply and sanitation, since human urine and faeces complete the cycle.

Dams and irrigation schemes reliably increase transmission by creating snail habitat. This is an established and repeatedly documented effect of water development projects.

Not known: the contribution of animal reservoirs and hybrid schistosomes to human transmission is an active and unresolved question, with implications for whether elimination is achievable by treating people alone. Whether *S. haematobium*'s association with bladder cancer is causal in the strict sense is well supported, but the mechanism is not fully established. The determinants of individual morbidity at a given worm burden are not known. Praziquantel's mechanism of action is still not fully elucidated, and it does not kill immature worms — which is why single-dose treatment fails in some people and why re-treatment is needed.

**Cure status.** Split.

the infection: CURABLE established bladder, liver and portal fibrosis: RELIEF ONLY

A single oral dose of praziquantel kills adult worms and clears infection in the large majority. The cure is cheap, single-dose and off-patent. Two qualifications: praziquantel does not kill immature schistosomes, so people in active transmission need re-treatment; and established organ damage — bladder fibrosis, liver fibrosis, portal hypertension — is not reversed by killing the worms.

**Prevention.**

Mass preventive chemotherapy with praziquantel: STRONG. Sub-Saharan campaigns reduced school-aged prevalence by almost 60 per cent over ten years. This is the principal intervention, and coverage is 39.6 per cent overall and 61.7 per cent in school-aged children.

Safe water supply: STRONG, on settled transmission physiology. The parasite requires skin contact with infested freshwater, so an alternative water source removes exposure.

Sanitation: STRONG, as human excreta complete the life cycle.

Snail control, by molluscicides or habitat modification: MODERATE, but logistically demanding and now less emphasised than chemotherapy.

Health education to reduce water contact: WEAK where no alternative water source exists. People cannot avoid water they depend on.

Avoiding new transmission from dam and irrigation projects: STRONG in principle, by design and by accompanying control measures; routinely neglected in practice.

No vaccine is licensed. Candidates are in trials.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Praziquantel, single oral dose | Yes, 6.1.1 Intestinal anthelminthics core, 6.1.3 Antischistosomals core, 6.1.4 Cysticidal complementary; tablets 150 and 500 mg, scored 600 mg | Yes | WHO describes it only as "effective, safe and low-cost" and gives no numerical price. Merck KGaA has pledged supply sufficient to treat more than 100 million school-aged children a year through donation. **No per-tablet price was retrievable** |
| Paediatric formulation, arpraziquantel | Recently developed for under-sixes | No | Developed by the Pediatric Praziquantel Consortium; price not confirmed |
| Surgery for advanced complications | n/a | n/a | Variable |

Praziquantel is one of the clearest cases in this chapter of a cheap, single-dose, off-patent cure that is nonetheless reaching under 40 per cent of those who need it. That is a distribution failure, not a pharmaceutical one.

**Simple means.** Substantial for prevention, nothing for cure.

Not entering infested freshwater, where any alternative exists, which is the whole of exposure avoidance. Drawing water and using it on land rather than washing and bathing in the water body. Boiling or storing water for 48 hours before use: cercariae survive only around 48 hours after leaving the snail and die in stored or heated water, which makes this a genuinely effective zero-chain measure. Towel-drying vigorously and immediately after unavoidable water contact, which removes cercariae still penetrating the skin — partial, but free. Using latrines, keeping urine and faeces out of water bodies, which breaks the cycle at the human end. Clearing vegetation at water-contact points, reducing snail habitat at the places people actually use. Siting water-collection points and washing slabs away from snail habitat.

Prevention is largely achievable without any industrial chain. Cure is not: praziquantel requires pharmaceutical synthesis, and there is no plant preparation or simple remedy that kills schistosomes. But the chain is among the shortest in this book: praziquantel manufacture plus periodic mass distribution, with no cold chain, no needles and no clinician. That is precisely why 39.6 per cent coverage is a logistical and funding failure rather than a technical limit.

**Gaps. WHO publishes no figure for the number of people currently infected** — only the number requiring treatment. **WHO publishes no numerical price for praziquantel, and none was confirmed primarily** , despite cost being central to mass treatment. The retrieval pass reached the UNICEF catalogue, but praziquantel was not on the pages read. The drug is largely donated rather than purchased, so a tender price may not be the right figure for it in any case. The death estimate, 14,353, is stated by WHO itself to be likely an underestimate; schistosomiasis deaths occur through bladder cancer, renal failure and liver disease and are rarely attributed to the parasite. The role of animal reservoirs and hybrid schistosomes in sustaining human transmission is unresolved and bears directly on whether elimination is feasible. Praziquantel's failure to kill immature worms means single-round coverage figures overstate effect. Emerging praziquantel resistance is a theoretical concern with limited current evidence, and sources differ on how seriously to weight it.

---

## Soil-transmitted helminths

**What it is.** Intestinal worms — roundworm, whipworm and hookworm — whose eggs or larvae are in soil contaminated by human faeces. They are swallowed or they penetrate the feet. They rarely kill, but they consume nutrients and blood, stunting growth and causing anaemia.

**Measured.** WHO fact sheet on soil-transmitted helminth infections, 18 January 2023. The Key Facts section of this page carries no numeric figures at all.

About 1.5 billion people infected, or 24 per cent of the world's population, with no year stated anywhere on the page. *Strongyloides stercoralis* separately: over 600 million people.

Populations requiring preventive treatment: preschool-age children over 260 million; school-age children 654 million; adolescent girls 108 million; pregnant and lactating women 138.8 million. The page's own metadata gives an estimated 836 million children in need. Adding the page's two child categories gives about 914 million. The metadata figure is about 78 million below the page's own body figures and appears nowhere in Key Facts or body. Both stand; the appendix of single-source contradictions carries this as item 9.

Coverage in 2021: over 500 million children treated, 62 per cent of all at-risk children; over 99 million women of reproductive age treated with albendazole through lymphatic filariasis programmes.

DALYs lost to soil-transmitted helminths fell by more than 50 per cent between 2010 and 2019.

**WHO publishes no death figure.** Mortality is low and the burden is morbidity.

Species: *Ascaris lumbricoides* (roundworm), *Trichuris trichiura* (whipworm), *Necator americanus* and *Ancylostoma duodenale* (hookworms), plus *S. stercoralis*. Geography: tropical and subtropical areas with poor sanitation, with highest prevalence in sub-Saharan Africa, China, South America and Asia.

Recommended effective treatment coverage is 75 per cent or higher, with epidemiological assessment after five to six years of preventive chemotherapy. Eggs mature in soil in about three weeks.

**Where it starts.** The routes differ by species. *Ascaris* and *Trichuris* eggs are ingested from contaminated soil, food or hands. Hookworm larvae penetrate the skin of bare feet. *Strongyloides* likewise penetrates skin and can autoinfect, persisting for decades. The risk structure is open defecation and absence of latrines, absence of footwear, absence of handwashing, and soil contact. The transmission cycle requires human faeces to reach soil, which is the single point at which it is broken.

Not known: the morbidity attributable to light-intensity infections is genuinely contested. Whether mass deworming of lightly infected populations improves growth, haemoglobin, school attendance and later earnings is one of the sharpest active disputes in global health; see PREVENTION. The determinants of heavy worm burden in particular children, beyond exposure, are not established. The immunological consequences of chronic helminth infection, including possible effects on vaccine responses and allergic disease, are suggested and unresolved.

**Cure status.** CURABLE. A single oral dose of albendazole or mebendazole clears most infections, and the drugs are among the safest in medicine. Two qualifications: reinfection is rapid where sanitation is unchanged, so cure at the individual level is temporary without environmental change; and *Trichuris* responds poorly to single-dose therapy compared with *Ascaris* and hookworm, so the cure rate varies substantially by species. *Strongyloides* requires ivermectin rather than a benzimidazole.

**Prevention.**

Sanitation — latrines and safe faeces disposal: STRONG on settled transmission physiology, and the only measure that is permanent. The cycle cannot continue if human faeces do not reach soil.

Footwear: STRONG for hookworm and *Strongyloides* specifically, since the larvae penetrate skin. Shoes are not an industrial chain in any meaningful sense.

Handwashing with soap, and washing food: STRONG for the orally transmitted species. Cochrane handwashing figures as in the diarrhoeal overview.

Preventive chemotherapy, mass deworming: CONTESTED on broader outcomes, STRONG on worm burden. This requires both numbers.

On parasitological outcomes: STRONG. The drugs reliably reduce worm burden and intensity; WHO reports DALYs fell more than 50 per cent from 2010 to 2019, and that 62 per cent of at-risk children were treated in 2021.

On growth, haemoglobin, cognition, school attendance and later economic outcomes: CONTESTED. The Cochrane review of community deworming concluded that there is substantial evidence that mass deworming of children in endemic areas does *not* improve average weight, haemoglobin, cognition, school performance or survival. Against this, long-term follow-up of the Kenyan “Worms at Work” trial reports significant gains in school participation and adult earnings, and WHO maintains its recommendation. Good sources genuinely disagree, the dispute has run for over a decade, and both positions stand. Part of the disagreement is about which populations and intensities are studied: benefit is more plausible in heavily infected children than in lightly infected ones, and trials have mixed the two. **No single effect size is asserted for either position.**

Deworming in pregnancy: MODERATE, for maternal anaemia; 99 million women of reproductive age were treated via lymphatic filariasis programmes.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Albendazole 400 mg, single dose | Yes, 6.1.1 Intestinal anthelminthics core, 6.1.2 Antifilarials core, 6.1.4 Cysticidal complementary; chewable scored 400 mg core, chewable 200 mg complementary | Yes | WHO describes the drugs as "effective, inexpensive and easy to administer by non-medical personnel" and gives no numerical price. Both are donated in large volumes for mass campaigns. **No per-tablet price was retrievable** |
| Mebendazole 500 mg, single dose | Yes | Yes | As above |
| Ivermectin, for *S. stercoralis* | Yes, 6.1.1 core, 6.1.2 core, 6.6 Medicines for ectoparasitic infections core; tablet 3 mg | Yes | WHO states generic ivermectin has been available at an affordable price since 2021, and gives no figure |
| Iron supplementation, hookworm anaemia | Yes | Yes | UNICEF indicative US$1.43 on one catalogue page and US$1.60 on another per bottle of 100 iron 60 mg tablets, October 2026, about 1.4 to 1.6 US cents a tablet |

These are among the cheapest and safest medicines in existence, administrable by non-medical personnel without diagnosis, which is the basis of school-based mass treatment.

**Simple means.** This is the condition in the chapter where simple means come closest to being a complete answer for prevention.

Latrines, and using them. Keeping human faeces out of soil and water breaks every one of these life cycles permanently, and needs no technology beyond a pit and a slab. Wearing shoes: hookworm and *Strongyloides* enter through the soles of bare feet, and footwear is close to a complete barrier for those species. Handwashing with soap before eating and food preparation. Washing and peeling vegetables, and avoiding raw produce fertilised with untreated human waste. Not using untreated human faeces as fertiliser, or composting it long enough to kill eggs — *Ascaris* eggs are exceptionally durable, so composting must be prolonged. Keeping children's play areas away from defecation sites, and covering sandy soil near dwellings. Cutting and cleaning fingernails, which is trivial but relevant to egg transmission. Iron-rich food for hookworm anaemia: green leaves, legumes, offal.

Cure requires a chain, but a very short one: benzimidazole synthesis and tablet distribution, with no cold chain, no needle, no diagnosis and no clinician. The permanent solution, however, is sanitation, and that requires no industrial chain at all — which is why these infections disappeared from high-income countries before deworming drugs existed.

**Gaps. WHO publishes no prices for albendazole or mebendazole, and none was confirmed primarily** , despite cost being central. **The deworming benefit dispute is genuinely unresolved** and is the most significant evidentiary conflict in this entry; the Cochrane conclusion and the WHO recommendation point in different directions, and both are printed above. The fact sheet is dated 18 January 2023 with coverage data from 2021, among the older sources in this chapter, and it gives no data year at all for the 1.5 billion prevalence figure. **No mortality figure** , so the burden is expressed only as prevalence and DALYs. The 1.5 billion figure derives from prevalence mapping and modelling, not from individual diagnosis; intensity of infection, which determines morbidity, is not captured by prevalence at all. *Trichuris* responds poorly to single-dose benzimidazoles, so uniform coverage figures conceal differential cure. The page's metadata figure for children needing treatment, 836 million, does not match its own body figures, which sum to about 914 million; see the appendix, item 9. The long-term immunological consequences of chronic helminth infection are unresolved.

---

## Lymphatic filariasis

**What it is.** Thread-like worms transmitted by mosquitoes that live in the lymphatic vessels for years. Most infected people have no symptoms, but damage to lymph drainage causes

grossly swollen limbs — lymphoedema, elephantiasis — and scrotal swelling, hydrocele. The disfigurement is permanent.

**Measured.** WHO fact sheet on lymphatic filariasis, 21 November 2024. 51 million people infected as of 2018, a 74 per cent decline since 2000. The infection figure is from 2018 while the programme figures around it are from 2023, so the burden estimate is stale relative to its own page.

Baseline chronic disease estimates, with no year stated: 25 million men with hydrocele and over 15 million people with lymphoedema. At least 36 million people remain with chronic manifestations, not broken down.

Over 657 million people in 39 countries live in areas requiring preventive chemotherapy, dated 2023 in the body and undated in Key Facts. 871 million people no longer require it, a 58.6 per cent reduction in the population needing mass drug administration, and ten countries were found not to require it.

Cumulative treatments: 9.7 billion delivered between 2000 and 2023, to more than 943 million people in 71 countries.

81 countries were endemic at programme start in 2000. 21 countries and territories have been acknowledged as having eliminated lymphatic filariasis as a public health problem. 14 have stopped large-scale treatment and are under surveillance. 39 still require preventive chemotherapy, six of which had not reached all endemic areas by end-2023.

Those country counts do not reconcile on the page. 81 endemic at start minus ten not requiring chemotherapy gives 71 treated countries, which matches the cumulative-treatment figure. But 39 still requiring, plus 14 stopped, plus 21 eliminated, gives 74. The page does not explain the overlap between the stopped and eliminated groups, and 74 is not 71. The appendix of single-source contradictions carries this as item 10. The same page's metadata mentions six countries certified clear in 2016, a claim appearing nowhere in Key Facts or body.

Economic: about US$24 billion in benefit for 2000–2007, described as conservative, and at least US$100.5 billion in economic loss averted by treatments up to 2015.

*W. bancrofti* causes 90 per cent of cases, and adult worms live six to eight years.

**WHO publishes no death figure.** This is a morbidity and disability condition, not a fatal one.

**Where it starts.** *Wuchereria bancrofti* in the large majority, with *Brugia malayi* and *B. timori* elsewhere, transmitted by *Culex*, *Anopheles*, *Aedes* and *Mansonia* mosquitoes. The risk structure is repeated infective bites over years: single exposure rarely causes disease, so transmission is sustained in endemic communities with high vector density and poor housing.

The morbidity mechanism is lymphatic damage by adult worms, compounded by recurrent bacterial superinfection of the compromised limb, which is what drives progression to elephantiasis. That point is the basis of the entire morbidity-management approach, and it is the reason simple means matter so much here.

Not known: why most infected people never develop lymphoedema while a minority progress severely is not established. The role of the *Wolbachia* endosymbiont in worm viability is established enough to make doxycycline effective, but why its elimination sterilises and kills adult worms is incompletely understood. The relative contribution of adult-worm damage against bacterial superinfection to final disability is contested. There is no reliable test to confirm that adult worms have died.

**Cure status.** Split, and the split is the central fact of the condition.

infection, with doxycycline: CURABLE infection, with standard MDA regimens: CONTROLLABLE established lymphoedema: RELIEF ONLY hydrocele, corrected by surgery: CURABLE

Standard mass-treatment regimens — albendazole with ivermectin or diethylcarbamazine — kill microfilariae reliably and reduce transmission, but have limited action on adult worms, which live years. The person remains infected, which is control rather than cure. Doxycycline for four to six weeks, by killing the *Wolbachia* endosymbiont, does kill adult worms. Killing

the *Wolbachia* bacteria kills the adult worm, and that cures the infection. The long course makes it unsuitable for mass campaigns.

Killing the worms does not reverse lymphatic damage. Lymphoedema is managed, not cured, for life. Hydrocele can be corrected by surgery.

**Prevention.**

Mass drug administration: STRONG, and among the most successful programmes in this chapter. The evidence is the outcome: infection down 74 per cent since 2000, 871 million people no longer requiring treatment, 21 countries having eliminated it as a public health problem, and 9.7 billion treatments delivered.

Triple-drug therapy — ivermectin plus diethylcarbamazine plus albendazole, "IDA": STRONG where conditions permit. WHO lists the regimen for countries without onchocerciasis where programmatic conditions are met, and gives no numerical figures. It clears microfilariae far more completely and durably than two-drug therapy, shortening the number of annual rounds needed. It cannot be used where onchocerciasis or loiasis is co-endemic, because of severe reactions, which is why two-drug regimens persist in much of Africa.

Vector control, bed nets and indoor spraying: MODERATE, and notably synergistic. Malaria bed-net programmes have reduced lymphatic filariasis transmission as a side effect where *Anopheles* is the vector.

Limb hygiene to prevent progression: STRONG. See SIMPLE MEANS. This prevents disability rather than infection.

No vaccine exists and none is in prospect.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Albendazole, 400 mg | Yes, 6.1.2 Antifilarials, core | Yes | Donated for mass drug administration; no price published by WHO and none confirmed |
| Ivermectin, 200 µg/kg | Yes, 6.1.2 Antifilarials, core | Yes | Donated through the Mectizan Donation Program; no price confirmed |
| Diethylcarbamazine, 6 mg/kg | Yes | Yes | Very low; no price confirmed |
| Doxycycline, 4–6 weeks, kills adult worms via *Wolbachia* | Yes | Yes | Cents to low dollars for a 4–6 week course† — the cheapest true cure in this entry |
| Hydrocele surgery | n/a | n/a | Low-cost surgical procedure; curative |
| Limb hygiene and skin care, for lymphoedema | n/a | n/a | Essentially free |

The three mass-administration drugs are donated by their manufacturers, which is why 9.7 billion treatments were deliverable.

**Simple means.** Unusually large, and decisive for disability.

Washing the affected limb daily with soap and clean water, drying carefully between toes and skin folds. This is the core of lymphoedema management and it demonstrably reduces the acute bacterial attacks that drive progression to elephantiasis. It requires soap, water and a cloth, nothing else, and it is the single highest-value simple intervention in this entry. Treating small wounds, cracks and fungal infections between the toes promptly, because these are the entry points for the bacterial attacks. Elevating the limb when resting, and moving and exercising it to assist lymph drainage. Wearing footwear to prevent the cuts and abrasions that start infections. Keeping nails trimmed and feet clean. Sleeping under a net, which reduces both lymphatic filariasis and malaria transmission. Draining standing water and covering latrines, since *Culex* breeds in polluted water and in pit latrines.

Prevention of infection requires the drug chain — a short one: oral tablets, no cold chain, no needles, administered by non-medical personnel once a year. But prevention of disability is almost entirely achievable by simple means. This is a condition where soap and water applied daily genuinely alter the outcome for the 36 million people already affected, for whom no drug will reverse the damage.

**Gaps.** The infection figure, 51 million, is from 2018 on a page dated 21 November 2024. The hydrocele and lymphoedema figures are described as baseline estimates, so they do not reflect current prevalence, and the current "at least 36 million with chronic manifestations" is not broken down. **WHO publishes no prices for any of the mass-administration drugs.** The page's country counts do not reconcile with each other, and its metadata contradicts its body on countries certified clear; see the appendix, item 10. **WHO gives no numerical figures for triple-drug therapy performance** despite recommending it. No reliable test exists to confirm adult worm death, so cure at the individual level cannot be verified. Why only a minority progress to elephantiasis is unknown.

---

## Onchocerciasis (river blindness)

**What it is.** A worm transmitted by blackflies that breed in fast-flowing rivers. Adult worms live in nodules under the skin and release larvae that cause intense itching, skin damage and, over years, blindness. It depopulated fertile river valleys in West Africa.

**Measured.** WHO fact sheet on onchocerciasis, 4 December 2025. At least 252.3 million people required preventive treatment in 2024. More than 99 per cent of infected people live in Africa and Yemen; the remaining 1 per cent are on the Brazil–Venezuela border.

Burden estimates, from GBD 2017 — the oldest burden data cited in this chapter: 14.6 million infected people had skin disease and 1.15 million had vision loss. **WHO gives no separate figure for permanent blindness** , only vision loss.

Treatment in 2024: 26 countries treated, reaching 171.6 million people, against a minimum therapeutic coverage requirement of 80 per cent. By end-2024, 25.5 million people lived in areas no longer needing ivermectin, with Nigeria accounting for more than 16.6 million.

Treatment must continue 10 to 15 years, which is the lifespan of the adult worm.

Five countries are verified free: Colombia in 2013, Ecuador in 2014, Mexico in 2015, Guatemala in 2016, and Niger in 2025, the first African country. Senegal stopped treatment in 2022 and is under surveillance, and nine further countries have stopped mass administration in at least one focus. 25 African countries have National Onchocerciasis Elimination Committees, and ten countries are endemic for *Loa loa*.

**WHO publishes no death figure.**

**Where it starts.** *Onchocerca volvulus*, transmitted by *Simulium* blackflies that breed in rapidly flowing, well-oxygenated rivers and streams. The risk structure is living and working near such rivers — which is why the disease concentrates on the most agriculturally valuable land, and why it drove people away from it. Repeated bites over years are required; the disease is one of cumulative exposure. The morbidity mechanism is the inflammatory response to dying microfilariae in skin and eye, mediated substantially by the *Wolbachia* endosymbiont.

Not known: the relationship between onchocerciasis and epilepsy, including "river epilepsy" and nodding syndrome, is genuinely unresolved. A consistent epidemiological association exists, with a plausible but unproven causal link, and good sources differ on whether it is causal. Why ivermectin does not kill adult worms is understood — it is microfilaricidal — but it means no individual cure exists within mass programmes. Reports of sub-optimal ivermectin response in some Ghanaian and Cameroonian foci are contested as evidence of emerging resistance.

**Cure status.** Split, and the split has to be made explicitly because the standard of care is not a cure.

with ivermectin, the standard of care: CONTROLLABLE with doxycycline, 4–6 weeks: CURABLE established blindness and skin scarring: RELIEF ONLY

Ivermectin kills microfilariae, stopping transmission and preventing progression, but does not kill adult worms, which live 10 to 15 years. That is why WHO states treatment must continue for that period, and the person remains infected throughout. Doxycycline for four to six weeks kills *Wolbachia* and thereby sterilises and kills adult worms, which is a cure, but the course length and the contraindications in pregnancy and childhood make it unsuitable for

mass administration. Moxidectin, approved in 2018, gives longer microfilarial suppression but also does not reliably kill adults. Nothing reverses established blindness or skin scarring.

**Prevention.**

Community-directed mass treatment with ivermectin: STRONG — one of the clearest successes in this chapter. The evidence is the outcome: five countries verified free, 25.5 million people in areas no longer needing treatment, and transmission interrupted in nine further foci. Required coverage is 80 per cent.

Vector control, larviciding of blackfly breeding sites: STRONG. The Onchocerciasis Control Programme in West Africa, 1974 to 2002, relied substantially on aerial larviciding and interrupted transmission across large areas before ivermectin was available. That is historical proof that the vector route works, independent of drugs.

Doxycycline for individuals: MODERATE, as a curative option outside mass campaigns.

Protective clothing and avoiding blackfly biting sites during peak hours: WEAK. Blackflies bite outdoors in daytime near rivers, so avoidance conflicts with farming and water collection.

Bed nets: NOT EFFECTIVE against this vector, which bites outdoors in daylight. That is a clear contrast with malaria and lymphatic filariasis and it should not be glossed.

No vaccine exists.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ivermectin, annual or biannual single dose | Yes, 6.1.2 Antifilarials, core; tablet 3 mg | Yes | Donated free by Merck through the Mectizan Donation Program since 1987, without time limit — the reason 171.6 million people were treated in 2024. No market price applies in endemic programmes |
| Doxycycline, 4–6 weeks, kills adult worms | Yes | Yes | Cents to low dollars per course |
| Moxidectin | Not confirmed on the 24th List | No; approved 2018 | Not established for endemic programmes |
| Nodulectomy | n/a | n/a | Minor surgery |
| Cataract and eye surgery for established damage | n/a | n/a | Variable |

Ivermectin's donation is the single most important economic fact in this entry, and it is the reason a 10- to 15-year treatment requirement is affordable at all.

**Simple means.** Limited for prevention, real for comfort.

Settling and farming away from fast-flowing river stretches where blackflies breed — the historical adaptation, at the cost of abandoning the best land. Covering arms and legs during peak biting hours near rivers. Avoiding riverside work at dawn and dusk where possible. Clearing vegetation at river crossings and water-collection points used daily. Skin care: washing, keeping skin moisturised with available oils, treating scratch wounds, which reduces the secondary infection and the misery of onchocercal dermatitis, the most common manifestation. Not scratching open, and keeping nails short, to limit secondary bacterial infection. Guiding and supporting the blind within the household and community, with orientation and mobility practices that need no equipment.

Bed nets do not work here. There is no simple means of preventing or treating the infection itself. The minimum chain is ivermectin manufacture and annual community distribution — a short chain, with no cold chain, no needles and non-medical administrators — but it must run for 10 to 15 years without interruption to clear a community. Larviciding requires an organised programme. Blindness, once established, has no remedy simple or otherwise.

**Gaps.** The infection and disability figures are from GBD 2017, the oldest burden data in this chapter, while treatment figures are from 2024. **WHO gives no figure for permanent blindness** , only vision loss. **The onchocerciasis-epilepsy and nodding syndrome link is genuinely contested** and unresolved. Reports of sub-optimal ivermectin response are contested as resistance. **No death figure is published** , so the condition's mortality contribution is unstated. Whether the 2030 road-map targets are achievable depends on 10-

to 15-year treatment continuity through conflict and funding interruption, which the source does not assess.

---

## Leishmaniasis

**What it is.** A protozoan parasite transmitted by sandflies. The visceral form attacks spleen, liver and bone marrow and kills almost everyone untreated. The cutaneous form causes disfiguring skin ulcers that heal slowly and scar.

**Measured.** WHO fact sheet on leishmaniasis, 12 January 2023. Overall, an estimated 700,000 to 1 million new cases annually.

Visceral leishmaniasis, kala-azar: an estimated 50,000 to 90,000 new cases annually, with only 25 to 45 per cent reported to WHO. Cutaneous leishmaniasis: an estimated 600,000 to 1 million new cases annually, with about 200,000 reported.

Visceral leishmaniasis is fatal if untreated in over 95 per cent of cases. **WHO gives no annual death count** — the most striking data gap in this entry, for a disease that is over 95 per cent fatal untreated.

Post-kala-azar dermal leishmaniasis develops in 5 to 10 per cent of kala-azar patients on the Indian subcontinent.

Geography, by form. Cutaneous: about 95 per cent of cases in the Americas, the Mediterranean basin, the Middle East and central Asia, with the Eastern Mediterranean Region accounting for 80 per cent of reported cases worldwide. Mucocutaneous: over 90 per cent in Bolivia, Brazil, Ethiopia and Peru. Visceral: mostly Brazil, east Africa and India, and highly endemic in Iraq, Somalia, Sudan and Yemen.

HIV co-infection was reported from 45 countries in 2021, with high rates in Brazil, Ethiopia and Bihar, India.

Diversity: over 20 *Leishmania* species, over 90 sandfly species, and about 70 animal species that can be a source.

**Where it starts.** *Leishmania* species inoculated by female phlebotomine sandflies. The risk structure is poverty, and poor housing, since cracked mud walls and organic debris are sandfly habitat. Malnutrition is an established risk factor for progression to visceral disease. So are population displacement, deforestation and urban encroachment. HIV co-infection markedly increases visceral risk and treatment failure. Reservoirs differ by species: human-to-human via sandfly on the Indian subcontinent, which is anthroponotic; dogs and rodents elsewhere, which is zoonotic. That difference determines whether control can target humans alone.

Not known: why most infections remain asymptomatic while a minority progress to visceral disease is not established beyond nutrition and immune status. The mechanism of post-kala-azar dermal leishmaniasis, and its role as a transmission reservoir between epidemics, is incompletely understood but programmatically important. Why cutaneous lesions self-heal over months in some species and not others is not fully explained. No human vaccine exists despite the fact that recovery confers immunity, which suggests one should be possible; its absence is unexplained by immunology alone.

**Cure status.** Split by form.

visceral leishmaniasis: CURABLE cutaneous, small single lesions: SELF-LIMITING cutaneous, large, multiple or facial: CURABLE mucocutaneous leishmaniasis: CURABLE visceral with HIV co-infection: CONTROLLABLE established scars and tissue loss: RELIEF ONLY

Visceral leishmaniasis is cured in the great majority by liposomal amphotericin B, miltefosine, paromomycin or antimonials, where these are accessible. Untreated, over 95 per cent die, so the gap between treated and untreated outcome is as wide as anything in this chapter.

Cutaneous disease largely heals over months to a year, leaving scars; treatment accelerates healing and limits scarring and is indicated for large, multiple, facial or mucosal lesions. Mucocutaneous disease is curable but destructive, requiring systemic treatment, and established tissue destruction of nose and palate is not reversed. With HIV co-infection, relapse

is frequent and secondary prophylaxis is often needed, which is control rather than reliable cure.

**Prevention.**

Early diagnosis and treatment of cases: STRONG. In anthroponotic settings, on the Indian subcontinent, it is also transmission control, because humans are the reservoir.

Insecticide-treated nets and indoor residual spraying: MODERATE. Sandflies are small enough to pass through ordinary netting, so fine-mesh or insecticide-treated nets are required. A standard net is not sufficient, unlike for malaria.

House improvement — plastering cracked walls, removing organic debris and rubble: MODERATE on settled vector ecology. Sandflies breed and rest in exactly these micro-habitats.

Reservoir control: culling or treating infected dogs in zoonotic settings is CONTESTED on both effectiveness and ethics, and good sources disagree on whether dog culling achieves anything. Rodent control: MODERATE.

Vector control around dwellings, and avoiding sleeping outdoors at ground level: MODERATE. Nutrition: MODERATE, as malnutrition is an established progression risk.

No human vaccine exists. Canine vaccines exist in some countries.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Liposomal amphotericin B, visceral first line in south Asia; single-dose regimens used | Yes | Yes for the originator formulation; generics exist | Preferential pricing for endemic public programmes has been reported at US$16–18 per vial historically†; cost per course depends on weight-based dosing |
| Miltefosine, oral, visceral and cutaneous | Yes | Yes | Low hundreds of US dollars per course historically |
| Paromomycin, injectable, visceral | Yes | Yes | Low |
| Pentavalent antimonials: sodium stibogluconate, meglumine antimoniate | Yes | Yes | Low, but toxic — cardiotoxicity, pancreatitis; resistance is high in Bihar, India |
| Combination therapies, e.g. liposomal amphotericin B with miltefosine | — | — | Used to shorten courses and limit resistance |
| Thermotherapy, cryotherapy, intralesional antimony, for cutaneous disease | n/a | Partly | Low-cost local treatment |

WHO states that anti-leishmanial medicines are effective and safe, particularly for visceral disease, but can be difficult to use. **It does not name liposomal amphotericin B or miltefosine and gives no treatment costs.** The drug names and roles above are standard practice, and the absence of WHO-published prices is a gap.

**Simple means.** Meaningful for prevention and for cutaneous care.

Plastering and repairing cracked walls, and removing rubble, rubbish and organic debris from around the house. This removes the sandfly's breeding and resting habitat and requires only mud, lime and labour. Fine-mesh netting over sleeping places, since ordinary netting is too coarse — a material choice rather than an industrial product. Sleeping on raised beds rather than on the floor, since sandflies fly low. Keeping animal pens away from and downwind of sleeping quarters. Covering skin at dusk and at night, when sandflies bite. Wound care for cutaneous lesions: cleaning with clean water, keeping lesions covered and dry, preventing secondary bacterial infection — which is the main avoidable harm in a lesion that will largely heal on its own. Thermotherapy: localised heat applied to cutaneous lesions is an established treatment and can be delivered with simple heat sources, though controlled devices are better. Feeding the malnourished child, since malnutrition drives progression to visceral disease.

Nothing simple treats visceral leishmaniasis, and untreated it kills over 95 per cent. The minimum chain is substantial: liposomal amphotericin B requires lipid formulation manufacture and a cold chain, miltefosine requires synthesis and a 28-day supervised course, and the injectables require sterile delivery. This is one of the clearest cases in the chapter where a person beyond the reach of a supply chain dies of a curable disease.

**Gaps.** The fact sheet is dated 12 January 2023 and **gives no annual death count** for a disease that is over 95 per cent fatal untreated. **Only 25 to 45 per cent of visceral cases are reported to WHO**, so incidence is substantially unmeasured. **WHO names no first-line drugs and publishes no prices** ; the drug names and prices here are from standard practice and are marked as not primary-sourced. **Dog culling is genuinely contested** on both effectiveness and ethics. Antimonial resistance in Bihar is established but not quantified in the source. No human vaccine exists despite recovery conferring immunity — an unexplained gap. Outcomes in HIV co-infected visceral disease are poor and the optimal regimen is not settled.

---

## Chagas disease (American trypanosomiasis)

**What it is.** A parasite transmitted by blood-sucking triatomine bugs that live in the walls and roofs of poor housing and defecate on the skin while feeding. After a mild acute phase it hides for decades, then damages the heart or gut in about a third of those infected.

**Measured.** WHO fact sheet on Chagas disease, 8 April 2026. About 8 million people infected worldwide, mostly in Latin America. More than 10,000 deaths each year. More than 100 million people at risk. Congenital transmission produces over 10,000 new cases annually.

In the chronic phase, one to three decades after infection, up to a third develop cardiac disorders and up to one in ten develop digestive, neurological or mixed alterations. The acute phase lasts about two months.

Geography: endemic in 21 continental Latin American countries, with infection detected in 44 countries, but national information systems existing in only six of those 44. Vector-transmission interruption is verified in eight countries: entirely in Chile, Paraguay and Uruguay, and partially in Argentina, Brazil, Colombia, Peru and Bolivia.

Economics: medical care costs for chronic cases are more than 80 per cent higher than the cost of residual insecticide spraying.

Treatment: courses last up to two months, with adverse reactions in up to 40 per cent of adults. WHO has donated nifurtimox for all ages since 2011 and benznidazole for children under 19 since 2020. The neglected tropical disease road map targets 75 per cent coverage of antiparasitic treatment among the eligible population.

**Where it starts.** *Trypanosoma cruzi*, by four established routes. Triatomine bug faeces entering through the bite site, mucous membranes or conjunctiva. Congenital transmission from mother to child. Blood transfusion and organ transplantation. And oral transmission through food or drink contaminated with bug faeces or infected bug material, which causes discrete outbreaks with higher acute mortality. The risk structure is housing with cracked walls, thatch and mud brick in which the bugs live; rural poverty; and, in non-endemic countries, migration from endemic areas plus unscreened blood.

Not known: why only about a third of infected people develop organ damage, and why some develop cardiac and others digestive disease, is genuinely unexplained. Parasite strain, host genetics, immune response and parasite persistence in tissue all have support without resolution. Whether antiparasitic treatment in the established chronic phase prevents progression of cardiomyopathy is contested. The BENEFIT trial found that benznidazole reduced parasite detection but did not reduce cardiac clinical deterioration in patients with established cardiomyopathy. Treatment remains recommended earlier in the chronic phase. There is no reliable test of cure.

**Cure status.** Split by stage, and the split is unusually consequential.

acute phase, congenital infection: CURABLE early chronic phase: CURABLE, parasitological cure established cardiomyopathy or megacolon: RELIEF ONLY

The cure in the early chronic phase is parasitological. The parasite is cleared. Established heart muscle damage is not reversed.

WHO states that benznidazole and nifurtimox are “fully effective in curing the disease when given early in the acute phase, including congenital cases”. Congenitally infected infants treated early are cured at high rates. In the early chronic phase — children and younger

adults without organ damage — a substantial proportion are cured, and the figure could not be reached, with efficacy declining the longer the person has been infected.

For established cardiomyopathy or megacolon, antiparasitic treatment does not reverse the damage, and the BENEFIT trial found no reduction in cardiac deterioration. Management is then heart failure treatment, pacemakers, antiarrhythmics and surgery. **WHO gives no numerical cure rates by stage** , despite stage being the determinant of curability. The proportion cured in the early chronic phase is therefore not known, and falls with the years of infection.

**Prevention.**

Indoor residual insecticide spraying and house improvement: STRONG — the measure that achieved actual interruption of transmission. The evidence is the outcome: vector transmission interrupted entirely in three countries and partially in five more. WHO gives no numerical effectiveness data for vector control, but notes that chronic care costs exceed spraying costs by more than 80 per cent.

Housing improvement — plastering walls, replacing thatch roofs, laying cement floors: STRONG on settled vector ecology. The bug cannot colonise a house without crevices.

Blood and organ donor screening: STRONG. It effectively eliminates transfusion transmission where implemented, and it is the principal measure in the 44 non-endemic countries where infection is detected.

Antenatal screening and treating infected newborns: STRONG, given that early congenital infection is curable and that over 10,000 congenital cases occur annually.

Bed nets: MODERATE, where the vector is present and bites at night indoors. Food hygiene against oral transmission: MODERATE, for açaí, sugarcane juice and similar products.

No vaccine exists.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Benznidazole, up to two months | Yes | Yes | Donated by WHO for children under 19 since 2020. No price published by WHO and none confirmed |
| Nifurtimox, up to two months | Yes | Yes | Donated by WHO for all ages since 2011. No price published |
| Heart failure therapy, antiarrhythmics, pacemakers, for chronic cardiac disease | Partly | Partly | Variable; cardiology infrastructure |
| Surgery for megacolon or megaoesophagus | n/a | n/a | Variable |

Adverse reactions occur in up to 40 per cent of adults on a course lasting up to two months — a major reason treatment uptake is low even where the drugs are free.

**Simple means.** Substantial for prevention, concentrated on the house.

Plastering and sealing cracked walls, and replacing thatch roofs. The triatomine bug lives in crevices, and a smooth-walled, well-sealed house cannot sustain a colony. Mud plaster, lime wash and labour are sufficient, and this is the single most effective simple intervention here. Cement or smoothed floors, removing crevices. Keeping animals — chickens, dogs, guinea pigs — out of and away from sleeping quarters, since they sustain bug populations. Clearing woodpiles, rubble and debris from against house walls. Inspecting walls and beds for bugs and their droppings at night with a light, which is how infestation is detected without any equipment. Sleeping under a net where bugs are present. Not consuming unpasteurised sugarcane or açaí juice of uncertain preparation, which prevents oral transmission. Treating the newborn of an infected mother early, which requires the drug but is the point at which cure is most achievable.

Nothing simple cures the infection. The minimum chain is benznidazole or nifurtimox synthesis plus a supervised two-month course with monitoring for adverse effects in up to 40 per cent of adults. For established cardiomyopathy the chain extends to cardiology: pacemakers, antiarrhythmics and sometimes transplantation, none of which is improvisable. But

house improvement genuinely prevents the disease, and three countries have interrupted transmission largely by that route plus spraying.

**Gaps. WHO publishes no numerical cure rates by stage** , despite stage being the determinant of curability — the central gap in this entry. **WHO publishes no prices for either drug. Whether treating established chronic infection prevents cardiac progression is genuinely contested**; the BENEFIT trial result and the continued treatment recommendations point in different directions, and both are stated above. **There is no reliable test of cure**, so individual treatment success cannot be confirmed. National information systems exist in only six of 44 countries where infection is detected, so burden outside endemic Latin America is essentially unmeasured. Why only a third progress to organ damage is unknown. The 8 million infected figure predates most current surveillance and is widely regarded as uncertain.

---

## Human African trypanosomiasis (sleeping sickness)

**What it is.** A parasite transmitted by tsetse flies that eventually crosses into the brain, destroying the sleep-wake cycle before causing coma and death. Untreated it is almost always fatal. Reported cases have fallen from tens of thousands to under a thousand a year.

**Measured.** WHO fact sheet on human African trypanosomiasis, 2 May 2023. Gambiense disease accounts for 92 per cent of reported cases and rhodesiense for 8 per cent.

On the decline the page contradicts itself. The body text gives a 97 per cent fall in new cases over the last 20 years; the page's metadata cites an 85 per cent reduction since 2000, using a different baseline. Both stand; the appendix of single-source contradictions carries this as item 8.

Counts: in 1998, almost 40,000 cases reported against an estimated 300,000 undetected and untreated; in 2017, under 2,000 cases; in 2018, under 1,000, and below that threshold as of 2022. In the mid-1960s the figure was below 5,000 annual cases continent-wide. Prevalence reached 50 per cent in several villages in Angola, the DRC and South Sudan at the peak.

Over the last five years the DRC reported 61 per cent of cases, a mean of 522 a year. Angola, Central African Republic, Chad, Congo, Gabon, Guinea, Malawi and South Sudan each declared 10 to 100 cases; Cameroon, Côte d'Ivoire, Equatorial Guinea, Uganda, Tanzania, Ethiopia and Zambia each declared 1 to 10.

**WHO gives no annual death count.** The page's metadata describes near-100 per cent fatality without prompt diagnosis and treatment.

Geography: *T. b. gambiense* in 24 countries of west and central Africa; *T. b. rhodesiense* in 13 countries of eastern and southern Africa. 55 million people were at risk for 2016–2020, with 3 million at moderate-to-high risk.

Melarsoprol's reactive encephalopathy is 3 to 10 per cent fatal — a treatment that itself killed a substantial fraction of those receiving it. Outcome assessment requires follow-up for up to 24 months.

**Where it starts.** *Trypanosoma brucei gambiense* or *T. b. rhodesiense*, transmitted by *Glossina*, the tsetse fly. The risk structure is rural occupational exposure — farming, fishing, hunting, animal husbandry — in tsetse habitat.

The two forms differ fundamentally, and the difference determines what control can achieve. Gambiense is chronic and anthroponotic: humans are the main reservoir, so treating people can interrupt transmission. Rhodesiense is acute and zoonotic: cattle and wild animals are the reservoir, so elimination in humans alone is not achievable.

Not known: the size and significance of the asymptomatic human carrier reservoir in gambiense disease is unresolved and bears directly on whether elimination of transmission by 2030 is achievable. Whether skin-dwelling trypanosomes constitute a hidden reservoir is an active question. Why the disease remained at very low levels in the 1960s and then produced massive epidemics from the 1970s to the late 1990s is attributed to the collapse of surveillance and control, but the dynamics are not fully modelled. The determinants of progression speed from first to second stage vary widely and are not established.

**Cure status.** CURABLE, both stages. The change over the last decade has been substantial. Untreated, the disease is near-uniformly fatal.

Fexinidazole, an oral treatment effective for both first- and second-stage gambiense disease, removed the need in most cases for the lumbar puncture that previously determined staging, and for the arsenical melarsoprol, whose reactive encephalopathy was 3 to 10 per cent fatal. NECT, nifurtimox-eflornithine combination therapy, remains for severe second-stage cases and requires four times fewer eflornithine infusions than eflornithine alone. Acoziborole, a single-dose oral treatment, has completed trials and represents the near-term prospect of single-dose cure.

**WHO gives no efficacy percentage for fexinidazole and none for NECT** , beyond describing NECT as safer and more effective. Cure must be confirmed by follow-up for up to 24 months, which is the practical limit on declaring individual cure.

**Prevention.**

Active case-finding and treatment: STRONG, and for gambiense disease it is also transmission control, since humans are the reservoir. This is what produced the 97 per cent decline.

Tsetse vector control — insecticide-impregnated targets and traps, insecticide-treated cattle, sterile insect technique: MODERATE. Tiny insecticide-impregnated targets deployed along waterways have proved cheap and effective in gambiense foci.

Avoiding tsetse habitat during peak biting, and wearing neutral-coloured clothing: WEAK but genuinely free. Tsetse are attracted to dark blue and black and to movement.

Screening of at-risk populations with rapid diagnostic tests: STRONG, for finding the cases that sustain transmission.

Veterinary treatment of cattle: MODERATE for rhodesiense disease specifically, since cattle are the reservoir.

No vaccine exists, and the parasite’s antigenic variation — continuous switching of its surface glycoprotein coat — makes one a remote prospect. That is the established immunological reason, not a funding gap.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Fexinidazole, oral, both stages, gambiense | Yes | No; developed by DNDi with Sanofi | Donated by Sanofi to WHO for endemic countries; no market price applies |
| NECT: nifurtimox with eflornithine, severe second stage | Yes | Yes | Donated to WHO by Sanofi and Bayer; no market price applies |
| Pentamidine, first-stage gambiense | Yes | Yes | Donated; low |
| Suramin, first-stage rhodesiense | Yes | Yes | Donated; low |
| Melarsoprol, second-stage rhodesiense, now limited | Yes | Yes | Donated; 3–10 per cent fatal reactive encephalopathy |
| Acoziborole, single-dose oral, in development | Not yet | No | Not yet deployed |

All drugs for this disease are donated to WHO by their manufacturers, which is the only reason treatment exists for a condition with a few hundred annual cases and no market. This is the clearest example in the chapter of a disease whose treatment is entirely outside market economics.

**Simple means.** Limited, and this must be stated plainly.

Wearing long sleeves and trousers in medium-weight, neutral-coloured fabric: tsetse bite through thin cloth and are attracted to dark blue and black. Avoiding known tsetse habitat — riverine thickets and dense vegetation near water — particularly during the day, since tsetse are day-biters. Avoiding bushes during the hottest part of the day, where tsetse rest. Clearing vegetation around dwellings, water points and paths used daily, which removes tsetse resting habitat. Not travelling through tsetse areas in open vehicles, as tsetse are attracted to moving vehicles and dust. Reporting prolonged fever, swollen neck glands and sleep disturbance to whoever can test — recognition is what gets a person treated.

Bed nets are of little value against a daytime biter, as with onchocerciasis and dengue.

There is nothing simple that treats sleeping sickness, and untreated it is almost always fatal. The minimum chain is the most restrictive in this chapter: these drugs are made by a handful of manufacturers for a few hundred patients a year, donated rather than sold, and distributed through WHO. There is no generic market, no local production and no alternative. A person with second-stage disease and no access to the WHO supply chain will die, and no simple means alters that.

**Gaps. WHO gives no annual death count** and **no efficacy figures for fexinidazole or NECT.** The source contradicts itself on the decline: 97 per cent over 20 years in the body text, 85 per cent since 2000 in the metadata; see the appendix, item 8. The fact sheet is dated 2 May 2023 with "last five years" case figures. **The asymptomatic carrier reservoir is unquantified** and determines whether the 2030 transmission-interruption target is achievable. Cure requires 24-month follow-up, which is rarely completed, so cure rates in practice are not well measured. Case numbers are now so low that surveillance sensitivity, rather than true incidence, dominates the reported figures — and the 1998 comparison, 40,000 reported against 300,000 estimated, shows how far reporting can diverge from reality for this disease.

---

## Leprosy (Hansen disease)

**What it is.** A slow-growing bacterium, *Mycobacterium leprae*, that damages skin and peripheral nerves. Loss of sensation means injuries go unnoticed, and the deformity that follows comes from unfelt wounds rather than from the organism. It has been curable since the early 1980s.

**Measured.** WHO fact sheet on leprosy, 23 January 2026. The Key Facts section carries no case counts at all; its only number is the six WHO regions.

Around 200,000 new cases are reported every year. The disease occurs in more than 120 countries.

Elimination as a public health problem means prevalence below one per 10,000 population, a threshold achieved globally in 2000 and in most countries by 2010.

2024 country data: Brazil, India and Indonesia each reported more than 10,000 new cases; 12 countries each reported 1,000 to 10,000; 117 countries reported fewer than 1,000; and 55 countries reported zero. Countries with 1,000 or more new cases in 2024 beyond the top three were Bangladesh, DR Congo, Ethiopia, Madagascar, Mozambique, Myanmar, Nepal, Nigeria, the Philippines, Somalia, Sri Lanka and Tanzania.

Most new case detection is in the South-East Asia Region, and cases are reported from all six WHO regions.

**WHO gives no death figure**, leprosy not being primarily fatal, and **no numerical disability figures** ; the 2021–2030 strategy targets "zero disability". The share of children among new cases and the grade-2 disability count are not stated on the page.

Multidrug therapy is three drugs — dapsone, rifampicin and clofazimine — for six months in paucibacillary disease, defined as one to five skin lesions, or twelve months in multibacillary disease, more than five lesions. **WHO gives no cure rate percentage.**

**Where it starts.** *M. leprae*, and *M. lepromatosis*, transmitted probably by respiratory droplets during prolonged close contact, typically within households. The risk structure is prolonged household contact with an untreated case — and, notably, most exposed people never become infected; susceptibility appears largely host-determined. Incubation averages about five years and can exceed twenty. Armadillos are an established zoonotic reservoir in the southern United States, and red squirrels in Britain.

Not known: the transmission route is not definitively established. Respiratory transmission is most likely, but soil, armadillos and amoebae have all been proposed as reservoirs, and this is one of the oldest unresolved questions about any human pathogen. Why the overwhelming majority of exposed people never develop disease, and why some develop paucibacillary and others multibacillary forms, reflects host immune variation that is characterised genetically but not predictively. *M. leprae* cannot be cultured in vitro, which is the fundamental reason so much remains unknown. Why nerve damage continues or begins after bacteriological cure, through immune reactions, is incompletely understood.

**Cure status.** Split, and the split is essential and frequently misunderstood.

the infection: CURABLE established nerve damage, sensory loss and deformity: RELIEF ONLY

Multidrug therapy reliably cures leprosy — six months for paucibacillary disease, twelve for multibacillary. WHO states no cure-rate percentage, but relapse rates after completed therapy are low, and the drugs have been free since 1995.

Established nerve damage, sensory loss, paralysis and deformity are not reversed by curing the infection. WHO states that untreated disease may cause progressive, permanent disability, and that early treatment can prevent it — so the whole of disability prevention lies in early detection.

Immune reactions, type 1 and type 2, can occur during or after treatment and cause further nerve damage. These require corticosteroids and are the main cause of disability in people already cured of the infection.

**Prevention.**

Early detection and treatment of cases: STRONG, both to prevent that person's disability and to remove the source of transmission.

Single-dose rifampicin post-exposure prophylaxis for contacts: MODERATE. WHO recommends contact screening plus a single dose of rifampicin and **gives no effectiveness figure** . The underlying COLEP trial reported roughly a 50 to 60 per cent reduction in incidence among contacts over two years, with the effect concentrated in the first two years and in more distant contacts. **That figure could not be confirmed to a primary source, and carries a dagger.**

BCG vaccination: MODERATE. It affords partial protection against leprosy as well as tuberculosis, an incidental and well-replicated cross-protection.

Contact tracing and screening of household members: STRONG, for early detection. Treating reactions early with corticosteroids: STRONG, for preventing disability.

No leprosy-specific vaccine is in routine use; candidates have been trialled.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Multidrug therapy: dapsone with rifampicin and clofazimine | Yes | Yes | Free to all patients worldwide since 1995, donated through WHO — originally by the Nippon Foundation and since 2000 by Novartis. No market price applies |
| Single-dose rifampicin, prophylaxis for contacts | Yes | Yes | Cents per dose |
| Prednisolone, nerve reactions | Yes | Yes | Cents per course |
| Clofazimine or thalidomide, type 2 reactions | Yes; thalidomide partly | Partly | Low; thalidomide is restricted |
| Protective footwear, self-care materials | n/a | n/a | Low to free |
| Reconstructive surgery, tendon transfers | n/a | n/a | Variable |

Multidrug therapy has been free worldwide for thirty years. The barrier to leprosy control is not drug cost but detection, stigma, and the five-year incubation that hides new cases.

**Simple means.** Unusually large, because the disability — not the infection — is what disables, and the disability is prevented by daily self-care.

Daily self-examination of hands and feet for cuts, blisters, burns and pressure areas that were not felt. This is the single most important practice, and it requires only eyes and a few minutes. Soaking, filing and oiling dry, insensitive skin to prevent cracking, and moisturising with any available oil. Protective footwear — even simple sandals with a soft insole — to prevent plantar ulcers in feet that cannot feel pressure. That prevents more deformity than any drug. Checking the temperature of water and objects with a part of the body that still has sensation, before using insensitive hands. Wound care: cleaning, dressing, and above all resting an ulcerated foot until it heals. Rest is free and is the treatment. Protecting an

eye that cannot close or blink: a cloth cover, keeping it moist, conscious blinking. Exercising weak hands and feet to prevent contractures. Recognising early signs: pale or reddish patches with loss of sensation, numbness, weakness — detectable by touching skin with a wisp of cotton, which costs nothing and is the standard field test.

Cure requires the drug chain — three-drug synthesis and a six- to twelve-month supply — but that chain is short, needs no cold chain and no needles, and the drugs are free. Prevention of disability, which is the actual harm of leprosy, is overwhelmingly achievable by simple means, and self-care training is the core of modern leprosy work.

**Gaps. WHO publishes no cure rate, no disability figures and no post-exposure prophylaxis effectiveness figure** , despite all three being central; the COLEP effect estimate, given above, carries a dagger. **The transmission route is still not definitively established** — remarkable for a disease known since antiquity. *M. leprae* cannot be cultured, which limits drug-susceptibility testing and resistance surveillance; emerging rifampicin resistance is detected by molecular methods and is not well quantified. New case detection fell during COVID-19 disruption, so the reported figures for 2020 to 2022 reflect detection rather than incidence, and the 2024 figures may include a backlog. The 55 countries reporting zero cases may reflect absence of disease or absence of detection; the source does not distinguish. Why most exposed people never develop disease is unknown.

---

## Trachoma

**What it is.** Repeated chlamydial infection of the inner eyelid in early childhood, spread by flies, fingers and shared cloths. Decades of scarring turn the eyelid inward so the lashes scrape the cornea, which eventually blinds. It is the world's leading infectious cause of blindness. That blindness is preventable at every stage before it.

**Measured.** WHO fact sheet on trachoma, 7 September 2026, with country elimination data as of 4 September 2026 and at-risk population from March 2026.

About 1.9 million people are blind or visually impaired from trachoma. Trachoma causes about 1.4 per cent of all blindness worldwide. 92 million people live in trachoma-endemic areas and are at risk of trachoma blindness, and require interventions.

Up to 90 per cent of preschool-aged children in endemic areas can have active, inflammatory trachoma. Visual impairment typically begins between the ages of 30 and 40. Blinding trichiasis appears in adults.

Women are blinded up to four times as often as men — the largest sex disparity of any condition in this chapter, attributed to close contact with infected children.

Economic: lost productivity is estimated at US$2.9–5.3 billion a year, rising to US$8 billion when trichiasis is included.

2025 activity: 47.4 million people treated with antibiotics, a global antibiotic coverage of 47 per cent, and 98,829 people receiving corrective surgery for trichiasis.

33 countries have been validated by WHO as having eliminated trachoma as a public health problem: Algeria, Australia, Benin, Burundi, Cambodia, China, Egypt, El Salvador, Fiji, Gambia, Ghana, India, Iran, Iraq, Lao PDR, Libya, Malawi, Mali, Mauritania, Mexico, Morocco, Myanmar, Nepal, Oman, Pakistan, Papua New Guinea, Saudi Arabia, Senegal, Timor-Leste, Togo, Tunisia, Vanuatu and Viet Nam.

It remains a public health problem in at least part of 29 countries according to Key Facts, while the page's own metadata says 32. The body gives no endemic count, so the conflict sits squarely between Key Facts and page metadata. Both stand; the appendix of single-source contradictions carries this as item 11.

The trend is falling sharply. The elimination target was 2020 under World Health Assembly resolution 51.11 and is now 2030.

Elimination thresholds: trichiasis unknown to the health system under 0.2 per cent in adults aged 15 and over, and trachomatous inflammation-follicular under 5 per cent in children aged 1 to 9, sustained at least two years without ongoing antibiotic mass administration.

**Where it starts.** Repeated conjunctival infection with *Chlamydia trachomatis* serovars A, B, Ba and C, transmitted by eye-seeking flies — *Musca sorbens*, which breeds in exposed human faeces — by fingers, and by shared face cloths and bedding. The risk structure is water scarcity, absence of latrines, crowded sleeping conditions, and proximity to livestock and flies.

Close contact with infected young children is the main route of transmission, and children are the reservoir. Lack of facial cleanliness matters, because ocular and nasal discharge on the face attracts the fly and carries the organism. Water scarcity limits face washing. Latrines interrupt transmission, because *M. sorbens* breeds in exposed human faeces. Female sex carries a higher risk of trichiasis.

Blindness is the cumulative result of *repeated* infection over years, not of a single episode. That is why it affects adults who were infected as children, and why interrupting childhood reinfection prevents adult blindness.

Not known: why some individuals progress to scarring and trichiasis while others with similar infection history do not is not established, though host immune and genetic factors are implicated. Whether mass azithromycin's observed reduction in all-cause child mortality, reported in the MORDOR trial, is a real and generalisable effect, and whether it justifies broader distribution given antimicrobial resistance concerns, is genuinely contested. The relative contribution of fly control, facial cleanliness and latrines to the F and E components of the SAFE strategy has never been cleanly separated. Why trichiasis sometimes recurs after apparently good surgery is not fully explained. The immunological determinants of progressive scarring are not settled. The part played by antibiotic coverage in the observed declines, beside fly control and face washing, has not been separated in practice.

**Cure status.** Split into three distinct states.

active chlamydial infection: CURABLE trichiasis, corrected by surgery: CURABLE established corneal opacity and blindness: RELIEF ONLY

A single oral dose of azithromycin clears active infection. Reinfection is the problem, not treatment failure, which is why treatment is given to whole communities repeatedly rather than to individuals. Trichiasis is corrected by a simple lid-rotation operation, performable by trained non-physician surgeons, which stops the lashes abrading the cornea and prevents blindness; 98,829 such operations were done in 2025. Established corneal opacity is not reversible, and corneal transplantation has poor outcomes in this setting.

Trichiasis surgery stops further scraping and prevents future loss. It does not clear an opaque cornea, which requires transplantation. The infection is curable. The blindness it has already caused is not.

Eliminating transmission in a district is achievable and has been achieved. 33 countries have been validated by WHO as having eliminated trachoma as a public health problem. That is cure at population scale, verified by an external body. It can be said of few diseases in this book.

**Prevention.** The WHO-adopted SAFE strategy, adopted in 1993: Surgery, Antibiotics, Facial cleanliness, Environmental improvement. **WHO gives no numerical targets or effect sizes for the individual components.**

Antibiotics, mass azithromycin: STRONG for clearing infection at community level. 47.4 million people treated in 2025, at 47 per cent coverage. **WHO gives no figure for azithromycin's clinical effect.**

Surgery for trichiasis: STRONG, for preventing blindness in those already scarred. It prevents the corneal damage that causes the blindness.

Facial cleanliness: MODERATE. Washing children's faces removes the ocular and nasal discharge that attracts flies and carries the organism. Trial evidence is consistent in direction but modest in size, and the mechanism is settled. Face washing reduces active trachoma. Whether the effect is modest is not settled: trial effect sizes could not be retrieved. Effect sizes vary between trials, and adherence is the limiting factor.

Environmental improvement — latrines and water access: MODERATE. *M. sorbens* breeds in exposed human faeces, so latrines remove the fly's breeding medium. This is the most

durable component, and it is the reason trachoma vanished from Europe without any antibiotic.

The whole package, delivered together, has taken 33 countries to validated elimination. That is the strongest available evidence that the strategy works.

Mass azithromycin for child survival: CONTESTED. The MORDOR trial reported a reduction in all-cause under-five mortality with biannual mass azithromycin in high-mortality settings, while concerns about driving macrolide resistance are substantial and well founded. Good sources genuinely disagree on whether this justifies distribution beyond trachoma indications. Both the mortality benefit and the resistance concern are real and belong together. **The magnitude of the MORDOR mortality reduction is not asserted here.**

No vaccine exists.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Azithromycin, single oral dose, by body weight with a maximum | Yes, 6.2.2 Watch group, first choice for trachoma | Yes | Donated through the International Trachoma Initiative by Pfizer, which is why 47.4 million treatments were delivered in 2025. No market price applies in endemic programmes. For comparison, UNICEF indicative price, October 2026: US$0.56 for a pack of six 250 mg tablets, about 9.3 US cents per tablet; an indicative tender price, not a market price. Generic cost otherwise well under a dollar per dose. |
| Tetracycline eye ointment, alternative where azithromycin is unavailable; usable in pregnancy and infancy | Yes | Yes | Cents per course, or cents per tube; requires twice-daily application for weeks, hence poorer adherence. |
| Trichiasis surgery, bilamellar tarsal rotation, the standard operation | n/a | n/a | Low-cost; performable by trained non-physician surgeons in field conditions, under local anaesthesia in a health post. Reported in the low tens of US dollars per eyelid in programme settings. |
| Corneal transplantation, for established opacity | n/a | n/a | Rarely available where trachoma is endemic; outcomes in trachomatous eyes are poor. |
| Epilation, plucking lashes | n/a | n/a | Free — a temporary measure where surgery is unavailable |

Azithromycin cures the infection. It is used both for individual treatment and for mass administration. The dose is set by body weight, with a maximum. Tetracycline ointment is the alternative where azithromycin is unavailable, and it can be used in pregnancy and infancy.

**Simple means.** This is among the conditions in this chapter most amenable to simple means. Two of the four SAFE components require no supply chain at all. Trachoma is the clearest case in the book of a blinding disease held off by water, soap and latrines.

Washing children’s faces, daily and whenever discharge appears. Water and a clean cloth. This is the F of SAFE and it requires nothing industrial. One cloth or towel per child, not shared, since shared cloths transfer the organism directly between eyes. Latrines, and using them, which removes the breeding medium of the eye-seeking fly: this is the E of SAFE and it is the measure that permanently ended trachoma in Europe and North America before antibiotics existed. Covering or burying faeces, especially children’s, which are the preferred breeding substrate. Keeping livestock and their dung away from dwellings and from where children play. Reducing fly contact with children’s faces: brushing flies away, screening, keeping food covered. Not sharing bedding and eye cosmetics. Epilation: plucking in-turned lashes with simple forceps gives temporary relief and protects the cornea where surgery is not available — imperfect, since lashes regrow, but free and genuinely sight-preserving in the interim. Recognising in-turned lashes by looking, and referring that person for surgery, which is the step that prevents blindness.

Face washing targets the transmission route directly, by removing the discharge that attracts the fly and carries the organism. Trials show an effect on active trachoma; the effect sizes were not retrievable. A pit latrine is a hole, a slab and a superstructure. That is environmental engineering at village cost. Donated azithromycin is free to programmes through the

International Trachoma Initiative. It is one oral dose, with no cold chain and no needle, and a community health worker can deliver it to a whole village. Trichiasis surgery is done by trained non-physician surgeons, under local anaesthesia, in a health post, with a reusable instrument set.

Antibiotics and surgery require chains, but short ones: a donated single-dose oral tablet with no cold chain, and an operation performable by a trained non-physician with basic instruments. The durable solution — water, face-washing and latrines — needs no chain whatsoever, which is the central fact about trachoma.

The measured effect of the package is 33 countries validated as having eliminated trachoma as a public health problem. The remaining burden costs US$2.9 to 5.3 billion a year, rising to US$8 billion when trichiasis is included, and the drug component of the intervention is donated.

**Gaps.** The source contradicts itself on the number of countries where trachoma remains a public health problem: 29 in Key Facts, 32 in the metadata; see the appendix, item 11. **WHO gives no effect size for azithromycin or for any individual SAFE component** , despite SAFE being the entire strategy. The 1.9 million blind-or-visually-impaired figure is not dated on the page, while the at-risk population is dated March 2026. **The mass azithromycin child-mortality question is genuinely contested** and has major implications for antimicrobial resistance. Antibiotic coverage is 47 per cent, and the source does not state what coverage is required for interruption. The relative contributions of F and E have never been experimentally separated, so programme design rests on plausibility rather than on comparative trial evidence. Some analyses find that antibiotic mass administration does most of the work. Others find that durable decline requires the other two components. Trial effect sizes for the facial cleanliness and environmental components could not be retrieved. The number of people who currently need trichiasis surgery is not stated, only the number who received it. Recurrence rates after trichiasis surgery vary widely between programmes.

---

## Scabies

**What it is.** A mite that burrows in the outer skin, provoking intense itching, especially at night. Scratching breaks the skin and lets bacteria in, which is how it causes serious disease. It spreads by prolonged skin-to-skin contact, so it runs through households. The mite lays eggs in the skin it burrows into. The rash appears in the finger webs, wrists, waist and genitals.

**Measured.** WHO fact sheet on scabies, 31 May 2023. At least 200 million people have scabies at any one time, in Key Facts, and more than 200 million in the body — a difference of qualifier, not of value. More than 400 million people are affected cumulatively each year. The fact sheet does not attribute either figure to a specific year.

An estimated 5 to 50 per cent of children in resource-poor areas are affected. That range is extremely wide and reflects heterogeneity rather than measurement.

Children and older people in resource-poor areas are affected. Infants and small children get a more widespread rash, including the palms, soles, ankles and scalp. Scabies is found in every country.

National survey prevalences: Fiji 23 per cent of all ages and 45 per cent of children aged 5 to 9, on a 2007 national survey. Solomon Islands 19 per cent of the total population and 34 to 45 per cent of children aged 5 to 9, on research surveys over the past decade.

Acute renal damage is found in up to 10 per cent of children with scabies in resource-poor settings, via secondary streptococcal infection, which is the principal serious consequence.

Impetigo can progress to abscess and invasive disease, including septicaemia. The renal damage is acute post-streptococcal glomerulonephritis, which can persist for years. There is growing evidence that *S. pyogenes* impetigo contributes to rheumatic fever and rheumatic heart disease. Crusted (Norwegian) scabies affects immunocompromised people, including those with HIV. It is life-threatening and highly infectious.

Most individuals are infested with only 10 to 15 mites. Mass drug administration is recommended where prevalence is 10 per cent or greater.

Geography: worldwide, most common in hot, tropical, low-income, densely populated areas. Large-scale mass administrations are ongoing in Papua New Guinea, Vanuatu, Fiji and the Solomon Islands. In high-income countries it is sporadic, with outbreaks in institutions.

**WHO gives no death figure.** DALYs are not reported on the page; the only burden source cited in its references is GBD 2015. Scabies was added to the neglected tropical disease list in 2017.

Timing: symptoms usually begin four to six weeks after infestation, earlier on reinfestation; eggs hatch in three to four days; mites mature in one to two weeks; mites usually die after two to three days away from human skin.

**Where it starts.** *Sarcoptes scabiei* var. *hominis*, transmitted by prolonged direct skin-to-skin contact and, less efficiently, via bedding and clothing. The risk structure is crowding, shared beds, institutional living and poverty.

The mite is the necessary cause. Crowding and high population density are named by the World Health Organization. Shared bedding and clothing are a secondary route, because mites survive off the host for two to three days. Poverty, limited water and inability to launder bedding add to the risk. Institutional settings, such as care homes, prisons and hospitals, carry outbreaks, and the World Health Organization notes outbreaks in health institutions and vulnerable communities in high-income countries. Immunosuppression and HIV matter for crusted scabies, where mite numbers reach thousands and transmissibility is extreme. Children and older people are the age groups affected.

The consequence chain, not the mite, is why scabies matters as a disease of populations: scabies, then scratching, then bacterial superinfection with *Streptococcus pyogenes* and *Staphylococcus aureus*, then impetigo and cellulitis, and then acute post-streptococcal glomerulonephritis and acute rheumatic fever.

Not known: the quantitative contribution of scabies to the global burden of rheumatic heart disease and chronic kidney disease is suspected to be substantial but is not established. Whether a single ivermectin dose is sufficient for mass administration is explicitly still under research in WHO's own words. WHO states that the evidence for mass administration is convincing where prevalence is 10 per cent or greater and less clear at lower prevalence, so the threshold is a judgement rather than a measured inflection. Emerging ivermectin and permethrin resistance is reported in some settings and is not well quantified. Why some people develop crusted scabies, and others with similar immunosuppression do not, is not known. Why the itch persists for weeks after successful treatment is not known. It is a hypersensitivity response and not ongoing infestation, and it is the commonest reason for unnecessary re-treatment.

**Cure status.** CURABLE. Topical or oral scabicides kill the mites and the infestation ends. The condition is straightforwardly curable and cheaply so. Three qualifications matter in practice.

The itch persists for weeks after successful cure. WHO notes that itchiness often worsens for one to two weeks after treatment starts. A second account gives the itch as persisting for two to four weeks after cure. Treatment failure must not be assumed from continued itching. Different numbers, both loosely attributed. Both stand. Either way the cause is the same: an immune reaction to dead mites and their products, not evidence of live infestation. That distinction is what prevents endless unnecessary re-treatment.

Reinfestation from untreated household members is the usual cause of apparent failure, which is why treating the whole household simultaneously is required whether or not others have symptoms. Treating the index case alone reliably fails.

Crusted, or Norwegian, scabies in immunosuppressed or neurologically impaired people involves thousands to millions of mites and requires repeated combined oral and topical treatment. It is curable but much harder.

Measured at population scale, in studies reported in PLOS Neglected Tropical Diseases, 2026:

- Fiji, ivermectin-based mass administration arm: prevalence fell from 32 per cent to under 2 per cent one year after mass administration, a 94 per cent relative reduction.

- Fiji, standard-care control arm: prevalence fell from 36.6 to 18.8 per cent, a 49 per cent reduction.
- Solomon Islands, single-arm mass administration integrated with trachoma control, about 26,000 people: prevalence fell from 18.7 to 2.3 per cent, an 88 per cent reduction.
- Impetigo fell by 60 to 88 per cent across all three studies.
- Fiji, mass administration integrated with lymphatic filariasis control, about 135,000 people: hospitalisations for skin and soft tissue infection fell 17 per cent in the following year.

The source read reports no confidence intervals for any of these figures.

The comparison that matters: individual standard care achieved a 49 per cent reduction, while community-wide mass administration achieved 88 to 94 per cent. Treating the individuals who present does not clear a community. Treating everyone at once does, because the reservoir is removed.

**Prevention.**

Treating the whole household simultaneously: STRONG, on established transmission dynamics. It is the single most important individual-level measure, because untreated asymptomatic contacts reinfest, and it costs only more of a cheap drug.

Mass drug administration in endemic communities: STRONG above 10 per cent prevalence, and lower below it, below. WHO states that mass administration can substantially reduce prevalence and impetigo, and that the evidence is convincing at prevalence of 10 per cent or more and less clear below. **WHO gives no quantified reduction.** The ivermectin mass-administration dose is two doses of 200 µg/kg. Where ivermectin is contraindicated or unavailable, a topical agent such as 5 per cent permethrin is used. Below 10 per cent prevalence the grade is CONTESTED: one research line graded the evidence weaker there and another graded it contested, and WHO states no threshold of its own The large island programmes in Fiji, the Solomon Islands, Vanuatu and Papua New Guinea are the evidence base, and reported reductions in both scabies and impetigo have been large.

Published studies give 88 to 94 per cent reductions in scabies prevalence from mass drug administration, citing PLOS Neglected Tropical Diseases 2026. That is not a contradiction of fact. The WHO fact sheet records the absence of a quantified figure, and the published studies supply one.

Washing clothing and bedding in hot water, or sealing it for a week: CONTESTED on settled mite biology. Mites die after two to three days off the skin, so WHO advises sealing unwashable items in a plastic bag for a week. A second account grades the washing of bedding and clothing MODERATE, because the main route is skin contact and bedding is secondary.

Avoiding crowded sleeping arrangements and shared beds, and improving access to washing water: MODERATE, structural. Treating secondary bacterial infection: STRONG, for preventing kidney and heart sequelae.

Treating institutional outbreaks by treating the whole institution at once: STRONG. Prompt treatment of crusted scabies cases: STRONG, because they are the source of institutional outbreaks, on account of their extreme mite burden.

Treating scabies to prevent impetigo, glomerulonephritis and possibly rheumatic heart disease: the measured impetigo reduction is 60 to 88 per cent, against renal damage in up to 10 per cent of affected children. STRONG for impetigo. MODERATE for the renal and rheumatic sequelae, which follow logically and are not directly measured as mass-administration endpoints.

No vaccine exists and none is in prospect.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ivermectin, oral, two doses of 200 µg/kg | Yes, 6.6 Medicines for ectoparasitic infections, core; tablet 3 mg | Yes | Low; donated for some mass programmes. Not for pregnant women or children under 15 kg. No price confirmed; a second account gives a few US cents per dose in generic and donation-supported programmes, among the cheapest drugs in this book. |
| Permethrin 5 per cent cream | **Yes.** Section 13.5, Scabicides and pediculicides, core list, cream 5 per cent and lotion 1 per cent, with scabies among three listed indications | Yes | Low dollars per tube; no price confirmed. A band a second account puts a tube at under a dollar to a few US dollars, naming no market; prices in high-income markets are far higher. |
| Benzyl benzoate 10–25 per cent | Yes. Section 13.5, listed first in that section, lotion 25 per cent, footnoted for over-twos | Yes | UNICEF indicative US$3.38 per 1,000 mL bottle of 25 per cent lotion, October 2026 — among the cheapest effective treatments in this chapter. Cents per application. It is irritant and it stings, especially in children. |
| Sulphur 5–10 per cent ointment, safe in pregnancy and infancy | Yes; precipitated sulfur topical ointment is listed as the therapeutic alternative to benzyl benzoate in section 13.5 | Yes | Very low; compoundable locally. Malodorous and messy. |
| Malathion 0.5 per cent aqueous | Not established | Yes | Low. |
| Antibiotics for secondary infection | Yes | Yes | Cents to low dollars |
| Antihistamines, topical steroid and emollients for post-treatment itch | Yes | Yes | Low. Chlorphenamine and hydrocortisone are listed and off-patent, at cents. |

On the EML question: section 13.5 of the 24th List carries both benzyl benzoate and permethrin, with benzyl benzoate listed first, and permethrin is a listed medicine in its own right, for scabies, pediculosis capitis and pediculosis corporis. A doubt recorded elsewhere in the book, to the effect that only benzyl benzoate appears in that section, was checked against both the list PDF and the electronic EML and is withdrawn: both are listed.

**WHO gives no efficacy percentages for permethrin or ivermectin.**

Permethrin cream is the topical standard. It is applied to the whole body and left on for hours, and it is safe in young children and pregnancy. Retreatment after 7 days is needed, because treatment does not kill eggs†. Oral ivermectin is given as two doses of 200 µg/kg, 7 to 14 days apart†. It is highly effective.

The WHO scabies fact sheet lists benzyl benzoate 10 to 25 per cent, sulphur 5 to 10 per cent and malathion 0.5 per cent aqueous as treatment options. Crusted scabies is treated with repeated ivermectin doses combined with topical treatment and a keratolytic, over weeks. Antibiotics treat secondary impetigo; see the entry on bacterial skin infections in the skin chapter. Mass-administration programmes co-administer azithromycin, and the World Health Organization notes the co-administration.

Sulphur ointment is notable and deserves its own sentence. It is effective, extremely cheap, safe in pregnancy and in infants under two months, and it can be compounded locally from elemental sulphur and any available ointment base — petrolatum, or fat. It is the nearest thing in this chapter to a scabicide producible without a pharmaceutical industry, and it has been used for over a century. It is the option where permethrin and ivermectin may be avoided.

**Simple means.** Substantial, and nearly sufficient. It is among the best cases in the book of a cheap intervention against a large burden.

Treating everyone in the household at the same time, which is a decision rather than a resource. Washing all clothing and bedding in hot water and drying in full sun; ironing seams. Sealing unwashable items in a bag for a week, since mites die in two to three days off skin. Sulphur ointment is a locally makeable treatment where no manufactured scabicide is avail-

able. Its preparation and strength are a pharmacy task and are not given here. Keeping fingernails short and clean, which limits skin-breaking and bacterial entry. Washing the skin and keeping it clean, and treating sores promptly with clean water and whatever antiseptic is available: this interrupts the chain to kidney and heart disease, which is where the real harm lies. Not sharing beds, towels and clothing during an outbreak. Understanding that itch persists for weeks after cure, so that families do not re-treat endlessly or conclude that treatment failed. Recognising it: itch that is worse at night, affecting several household members, with burrows in finger webs, wrists, waist and genitals, and in infants on palms, soles and scalp.

Ivermectin by mass administration is two oral doses at a few cents each. It reduced community scabies prevalence by 88 to 94 per cent and community impetigo by 60 to 88 per cent. It needs no cold chain, no needle and no clinician. The tablet is dosed by weight or by height stick, and community health workers can deliver it to a whole village.

Programme coverage achieved: register-based first-dose coverage was 49 per cent in the Solomon Islands (350,217 people) and 26 per cent in Fiji (231,351 people). Coverage-survey estimates were 78 and 45 per cent respectively. Of survey respondents, 86 to 87 per cent received ivermectin and 11 to 13 per cent received permethrin for a contraindication. Mild side effects occurred in 2 to 5 per cent.

Treating the whole household at once costs only more cheap drug, and it is the difference between cure and endless reinfestation. The 49 per cent reduction with individual standard care, against 88 to 94 per cent with community mass administration, is the measured demonstration.

Washing and sun-drying bedding and clothing costs nothing. Explaining that the itch continues for weeks after cure costs nothing, and it prevents repeated unnecessary re-treatment and the conclusion that the drug failed.

Integration with existing mass drug administration programmes shares the delivery cost with programmes already running. The Solomon Islands campaign was integrated with trachoma control and the Fijian one with lymphatic filariasis control. Compounded locally, sulphur ointment costs near nothing, and where nothing else is available it still works.

The minimum chain for ivermectin or permethrin is pharmaceutical synthesis and distribution — short, with no cold chain and no needles. But sulphur ointment means that even without any pharmaceutical supply an effective treatment exists, and the preventive measures are entirely free. Of all conditions in this chapter, scabies is among the least dependent on industrial medicine.

What the chain minimally requires: a tablet, or a tube, or sulphur and an ointment base. There is essentially no supply chain requirement beyond the drug itself.

**Gaps. WHO publishes no efficacy figures for any scabicide, and no quantified mass-administration effect** ; published studies give a figure for the latter, set out under Cure status and Prevention. **Whether one ivermectin dose suffices is explicitly unresolved** by WHO's own statement. The prevalence range in children, 5 to 50 per cent, is extremely wide. The fact sheet is dated 31 May 2023, and DALYs are not reported on it. **The contribution of scabies to rheumatic heart disease and chronic kidney disease is unquantified** — the most important gap, because it is where scabies actually kills. Emerging ivermectin and permethrin resistance is reported but not quantified. Mass-administration evidence below 10 per cent prevalence is acknowledged by WHO to be unclear, so programme thresholds rest on limited data. The post-treatment itch duration is given as one to two weeks by WHO and as two to four weeks by a second account; both stand. The 200 million and 400 million figures are not attributed to a year on the fact sheet. Its cited sources span a 2015 Global Burden of Disease estimate, a 2019 consultation and a 2015 study, so the vintage of the global estimate is unspecified. The mass-administration source reports no confidence intervals for any prevalence or reduction figure, including the headline 94, 88 and 60 to 88 per cent values. Ivermectin cannot be given to pregnant women or children under 15 kg, and the optimal regimen for those groups in mass administration is not settled. Whether treating scabies reduces the incidence of rheumatic heart disease has not been measured, though the pathway is documented.

## Syphilis (including congenital syphilis)

**What it is.** A bacterial infection, *Treponema pallidum*, acquired sexually or passed from mother to fetus. It progresses in stages over years and can eventually damage brain, nerves and heart. In pregnancy it causes stillbirth and infant death. It has been curable with penicillin since the 1940s.

**Measured.** Two WHO fact sheets, and they do not agree. The syphilis-specific sheet of 29 May 2025 and the sexually transmitted infections sheet of 10 September 2025 both carry syphilis figures.

8 million adults aged 15 to 49 acquired syphilis in 2022, in the Key Facts of the STI sheet. 7.1 million new infections in 2020 among the same age group, in the body of the same sheet. Two different magnitudes and two different years on one page, nowhere reconciled. Both stand; the appendix of single-source contradictions carries this as item 12.

About 1.1 million pregnant women were infected in 2022, resulting in over 390,000 adverse birth outcomes. Among pregnancies that are untreated, treated late, or treated with the wrong antibiotic, 50 to 80 per cent result in adverse birth outcomes.

Syphilis roughly doubles the risk of acquiring HIV.

Related, from WHO's stillbirth health-topic page: syphilis treatment could prevent an estimated 200,000 stillbirths.

Timing: the primary chancre usually lasts about 21 days and heals in 3 to 10 days; transmission typically occurs up to two years after infection.

**No geography is published**: no regional or country figures appear on either sheet, despite marked regional variation. Gay men and other men who have sex with men are described as disproportionately affected, without figures. Denmark was reported as the first EU country to eliminate mother-to-child transmission of HIV and syphilis, WHO news item, 27 February 2026.

**WHO gives no death figures for syphilis or congenital syphilis on these pages** , and no congenital syphilis case count — only "adverse birth outcomes".

**Where it starts.** Sexual contact with a person who has primary or secondary lesions, and transplacental transmission in pregnancy. The risk structure is unprotected sex with multiple or untreated partners, absence of antenatal screening, HIV co-infection, and — for congenital syphilis — failure of antenatal testing and treatment, which is a health-system failure rather than a biological one.

The established biological fact underlying prevention is that a single intramuscular injection of benzathine penicillin G before the third trimester prevents almost all congenital syphilis.

Not known: *T. pallidum* cannot be cultured in vitro by routine means, which limits resistance surveillance and has held back vaccine development. Why latent syphilis progresses to tertiary disease in only a minority is not established. The reasons for the global resurgence of syphilis since 2000, in high-income countries with good access to testing and penicillin, are debated — behavioural change, HIV treatment optimism, network effects and testing patterns are all proposed. Optimal treatment of neurosyphilis and of syphilis in HIV co-infection is not fully settled.

**Cure status.** Split.

the infection: CURABLE established tertiary organ and nerve damage: RELIEF ONLY

A single intramuscular dose of benzathine penicillin G cures early syphilis; later stages require weekly doses for three weeks. **WHO gives no cure-rate percentage.** There is no established penicillin resistance in *T. pallidum* after eighty years of use — a notable fact in a chapter dominated by resistance. Established tertiary organ and neurological damage is not reversed by cure, and cure confers no immunity, so reinfection is common.

**Prevention.**

Antenatal screening and treatment: STRONG — the highest-value intervention in this entry. Treating an infected pregnant woman with benzathine penicillin before the third trimester prevents the great majority of the 390,000-plus annual adverse birth outcomes. The arithmetic is stark: 1.1 million infected pregnancies, a single injection costing cents, and over 390,000 bad outcomes that largely need not occur.

Condoms: STRONG for sexual transmission, though lesions outside the covered area reduce protection relative to HIV.

Partner notification and treatment: STRONG. Screening and treating key populations: STRONG. Treating syphilis to reduce HIV acquisition: STRONG, given that syphilis roughly doubles HIV risk.

Dual HIV and syphilis rapid testing in antenatal care: STRONG — a single point-of-care test, requiring no laboratory, that enables same-visit treatment.

No vaccine exists, and the inability to culture the organism is part of the reason.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Benzathine penicillin G, single intramuscular dose for early syphilis, weekly for three weeks for late | Yes, 6.2.1 Access group antibiotics, core, first choice for syphilis with no second-choice indication; injectable powder 1.2 and 2.4 million IU | Yes | UNICEF indicative US$29.49 per box of 50 2.4 MIU vials, October 2026, about 59 US cents a vial; the single-vial-with-solvent pack is US$3.01, five times as much per dose |
| Doxycycline, penicillin allergy, non-pregnant | Yes | Yes | Cents per course |
| Ceftriaxone, alternative | Yes | Yes | Low dollars |
| Aqueous crystalline penicillin G, neurosyphilis | Yes | Yes | Low; requires intravenous administration |
| Rapid point-of-care syphilis test | Yes, diagnostics list | Yes | A few US dollars or less per test |

The UNICEF indicative price is dated and indicative, not a price: the same material number returned US$29.49 on one catalogue page and US$29.12 on another when read on 19 October 2026. Both values are recorded. What the figures establish is the order of magnitude: the curative dose costs well under a dollar, and the packaging choice changes the per-dose cost fivefold.

**WHO publishes no cure rate and no prices on these fact sheets.** Penicillin desensitisation is preferred for pregnant women with penicillin allergy, since no alternative reliably protects the fetus.

**Simple means.** Limited for treatment, real for prevention.

Condoms, which are manufactured but need no prescription, cold chain or clinician. Fewer concurrent partners, and partner notification — behavioural measures requiring nothing. Recognising the primary sore: a painless ulcer on the genitals, anus or mouth, which heals by itself and is therefore frequently ignored — and recognising that its healing does *not* mean the infection has gone. Knowing that single fact changes whether a person seeks treatment. Recognising secondary syphilis: a rash including palms and soles, often with mouth lesions, weeks to months later. Attending antenatal care at all, and asking for a syphilis test, which is the step that prevents congenital syphilis. Abstaining from sex while a lesion is present and during treatment.

Nothing simple cures syphilis. The minimum chain is modest but irreducible: benzathine penicillin G requires penicillin fermentation and sterile injectable manufacture, plus a syringe and someone able to give an intramuscular injection. There is no oral single-dose equivalent for pregnancy, and no plant or household preparation works.

Given that the cure costs cents and has existed since the 1940s, congenital syphilis is almost entirely a failure of delivery. The recurrent global shortages of this cheap off-patent injectable are a manufacturing-economics failure, not a scientific one.

**Gaps. WHO's two fact sheets give different figures for different years** — 8 million in 2022 and 7.1 million in 2020 — without reconciliation; see the appendix, item 12. **WHO publishes no congenital syphilis case or death count on the syphilis fact sheet, and no death figures at all** — only adverse birth outcomes. **No geography is published** : no regional or country figures, despite marked regional variation. **No cure-rate figure and no prices. Recurrent benzathine penicillin shortages are documented in the wider literature but are not mentioned on the WHO fact sheets.** The reasons for the global

resurgence since 2000 are genuinely debated. Optimal management of neurosyphilis and of syphilis with HIV co-infection is unsettled.

---

## Gonorrhoea

**What it is.** A bacterial infection of the genital tract, throat, rectum or eyes, *Neisseria gonorrhoeae*. It often causes discharge and pain, but frequently nothing at all, especially in women. Untreated it damages fallopian tubes and causes infertility. It is becoming resistant to every antibiotic used against it.

**Measured.** WHO fact sheet on sexually transmitted infections, 10 September 2025, and the fact sheet on antimicrobial resistance, 16 July 2026.

82 million new infections in 2020 among people aged 15 to 49. That figure sits within a total of 374 million new infections of one of four curable sexually transmitted infections in 2020, and more than 1 million curable infections acquired per day.

Gonorrhoea resistance to ciprofloxacin: 75 per cent.

WHO's Gonococcal Antimicrobial Surveillance Programme shows high rates of resistance to quinolones, azithromycin and extended-spectrum cephalosporins; the STI fact sheet gives no percentages for these.

**WHO reports no deaths from gonorrhoea.** The burden is morbidity, infertility and neonatal eye infection. No geography or age breakdown is published on these pages. The STI sheet gives no treatment figures, stating only that gonorrhoea is generally curable with single-dose antibiotics.

**Where it starts.** *N. gonorrhoeae*, transmitted by unprotected vaginal, anal and oral sex, and from mother to baby during delivery, causing ophthalmia neonatorum — a cause of neonatal blindness. The risk structure is unprotected sex, multiple or concurrent partners, and asymptomatic infection, which in women especially sustains transmission and leads to untreated tubal damage.

The resistance mechanism is established: *N. gonorrhoeae* readily acquires and recombines resistance determinants, including from commensal *Neisseria* species in the pharynx. Pharyngeal infection, often asymptomatic, is the recognised crucible in which cephalosporin resistance develops, because antibiotic concentrations there are marginal.

Not known: whether a durable vaccine is achievable is unresolved. Natural infection confers no protective immunity and repeated reinfection is common, so the immunological basis for a vaccine is unclear. The observation that the meningococcal B vaccine, 4CMenB, affords partial cross-protection against gonorrhoea is established enough to have prompted programme recommendations in some countries, and it is the most promising current lead; its durability and magnitude are not settled. How quickly resistance to ceftriaxone will become widespread is not predictable, and extensively resistant strains have already been reported.

**Cure status.** CURABLE. This is the condition in the chapter with the clearest trajectory *away* from curability.

Ceftriaxone, given as a single injection, currently cures it. Ciprofloxacin is at 75 per cent resistance and effectively lost. Penicillins, tetracyclines, sulphonamides and macrolides are substantially lost, with azithromycin resistance rising. Ceftriaxone is the last reliable single-agent option, and extensively drug-resistant strains resistant to it have been reported in several countries.

WHO classifies drug-resistant *N. gonorrhoeae* as a high-priority pathogen. The honest classification is CURABLE today, with a credible prospect of becoming untreatable with existing agents. New agents, zoliflodacin and gepotidacin, have completed trials and represent the near-term alternative.

**Prevention.**

Condoms: STRONG. The barrier blocks the transmission route.

Screening of asymptomatic high-risk and pregnant people: STRONG, because asymptomatic infection drives both transmission and sequelae.

Partner notification and treatment: STRONG.

Neonatal eye prophylaxis at birth: STRONG on settled physiology. A topical antimicrobial applied to the newborn's eyes prevents gonococcal ophthalmia and consequent blindness. Cheap, topical, long-established.

Treating promptly to limit transmission and resistance: STRONG.

4CMenB meningococcal vaccine cross-protection: MODERATE. Observational and some trial evidence supports partial protection; magnitude and duration are unsettled, and **no effect size is asserted here** . It is the only vaccine-based option currently available, and it is recommended for specific populations in some countries. The chain is long: a recombinant protein meningococcal vaccine requiring fermentation, protein purification, adjuvanting, sterile fill-finish, a needle and an unbroken 2–8 °C cold chain.

No gonorrhoea-specific vaccine exists.

Avoiding antibiotic use that selects for resistance, including azithromycin mass distribution: CONTESTED in its weighting against the benefits of such programmes; see the trachoma entry.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ceftriaxone, single intramuscular dose, current first line | Yes | Yes | Low dollars per dose |
| Azithromycin, formerly dual therapy; resistance rising | Yes, 6.2.2 Watch group, first and second choice for gonorrhoea | Yes | UNICEF indicative about 9.3 US cents a 250 mg tablet, October 2026 |
| Cefixime, oral alternative, declining reliability | Yes | Yes | Low |
| Ciprofloxacin | Yes | Yes | Cents — but at 75 per cent resistance, largely useless |
| Spectinomycin, gentamicin, alternatives | Yes | Yes | Low |
| Topical neonatal eye prophylaxis: tetracycline or erythromycin ointment, povidone-iodine | Yes | Yes | Cents per newborn |
| Zoliflodacin, gepotidacin, new agents | Not yet | No | Not yet widely deployed; zoliflodacin developed partly through a non-profit partnership, GARDP |

**Simple means.** Condoms, which prevent transmission entirely when used. Fewer concurrent partners; partner notification. Recognising symptoms — discharge, pain on urinating, testicular or pelvic pain — and recognising that absence of symptoms does not mean absence of infection, particularly in women and in pharyngeal and rectal infection. Abstaining from sex during treatment and until partners are treated, which prevents the reinfection that sustains transmission in couples. Cleaning the newborn's eyes at birth and applying whatever topical antimicrobial is available — and recognising purulent conjunctivitis in the first days of life as an emergency, because untreated gonococcal ophthalmia blinds within days. Noticing it requires only looking.

Nothing simple cures gonorrhoea. The minimum chain is injectable ceftriaxone — cephalosporin synthesis, sterile injectable manufacture, a syringe and an injector. There is no oral household remedy, and self-treatment with partial or inappropriate antibiotics is a direct contributor to the resistance that threatens the last working drug. For the newborn, topical ointment is a very short chain and prevents blindness for cents.

**Gaps. WHO publishes resistance only as "high rates" for azithromycin and cephalosporins, with a figure for ciprofloxacin alone** , so the state of resistance to the actual first-line drug is not quantified in the sources used. **No geography, no age pattern, no infertility burden figures.** The infection figure is for 2020. **Whether a vaccine is achievable is genuinely unresolved**, given that natural infection confers no immunity. 4CMenB cross-protection magnitude and durability are unsettled, and policy differs between countries from the same evidence. The timeline to untreatable gonorrhoea is unpredictable, and sources differ on urgency. **Neonatal ophthalmia burden is not quantified by WHO.**

## Chlamydia

**What it is.** The most common bacterial sexually transmitted infection, *Chlamydia trachomatis*. In most people it causes no symptoms at all, which is why it spreads widely. Untreated, it scars fallopian tubes and causes infertility and ectopic pregnancy.

**Measured.** WHO fact sheet on sexually transmitted infections, 10 September 2025. 129 million new infections in 2020 among people aged 15 to 49 — the largest number of any bacterial sexually transmitted infection in this chapter, and the second largest of the four curable infections after trichomoniasis at 156 million.

**WHO reports no deaths and no drug resistance for chlamydia.** No geography, age breakdown or infertility burden figures are published on the page. WHO gives no treatment figures, stating only that it is generally curable with single-dose antibiotics.

The same organism, in different serovars and transmitted non-sexually, causes trachoma, the leading infectious cause of blindness. The two conditions share a pathogen and nothing else epidemiologically.

**Where it starts.** *C. trachomatis* serovars D to K, transmitted by unprotected vaginal, anal and oral sex, and from mother to baby at delivery, causing neonatal conjunctivitis and pneumonia. The risk structure is unprotected sex, young age — incidence is highest in adolescents and young adults — multiple or new partners, and above all asymptomatic carriage. The majority of infections in both sexes produce no symptoms, so infection persists unrecognised for months and is transmitted onward and causes tubal damage silently. Serovars L1 to L3 cause lymphogranuloma venereum.

Not known: whether population screening programmes actually reduce pelvic inflammatory disease and infertility at population level is genuinely contested. Screening is recommended in several high-income countries on the logic that treating asymptomatic infection prevents sequelae. But trial and programme evidence of population-level impact has been weaker than expected, and some analyses suggest screening may interfere with the development of partial protective immunity. Good sources disagree, and some countries have scaled screening back while others maintain it. Why only a minority of untreated infections progress to tubal damage is not established. No vaccine exists, although trachoma and genital chlamydia vaccine research is converging and early-phase candidates have shown immunogenicity.

**Cure status.** Split.

the infection: CURABLE established tubal scarring and infertility risk: RELIEF ONLY

Chlamydia is cured reliably by a short course of doxycycline or a single dose of azithromycin. There is no established clinically significant antimicrobial resistance in *C. trachomatis*, which WHO's own fact sheet reflects by reporting none — a genuine exception in this chapter.

Established tubal scarring, infertility and ectopic pregnancy risk are not reversed by curing the infection, and infertility treatment is a separate and expensive matter. Cure confers no durable immunity, so reinfection is common, particularly from untreated partners. Doxycycline has been shown superior to azithromycin for rectal infection.

**Prevention.**

Condoms: STRONG.

Partner notification and treatment: STRONG, and the principal determinant of whether cure holds.

Screening of asymptomatic young and pregnant people: CONTESTED at population level, STRONG at individual level. Both must be stated. Treating a detected infection in an individual prevents that person's sequelae. Whether organised screening programmes measurably reduce population rates of pelvic inflammatory disease and infertility is disputed, programme evaluations have given mixed results, and countries differ in policy from the same evidence base. **No single effect size is asserted for the population-level question.**

Retesting after treatment: MODERATE, given high reinfection rates.

Neonatal eye prophylaxis: MODERATE — topical prophylaxis is less effective against chlamydial than gonococcal ophthalmia.

No vaccine exists.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Doxycycline, 7 days, first line | Yes | Yes | Cents per course — among the cheapest curative treatments in medicine |
| Azithromycin, single dose, alternative and preferred in pregnancy | Yes, 6.2.2 Watch group, first choice for chlamydial STI | Yes | UNICEF indicative about 9.3 US cents a 250 mg tablet, October 2026 |
| Amoxicillin, pregnancy alternative | Yes | Yes | About 5.4 US cents a 250 mg dispersible tablet, UNICEF indicative, October 2026 |
| Erythromycin, neonatal | Yes | Yes | Cents per course |
| Nucleic acid amplification test, for diagnosis | Yes, diagnostics | Partly | The expensive component; several US dollars per test, requiring laboratory capacity |

The diagnostic, not the drug, is the costly part. Doxycycline costs cents, while confirming the infection requires molecular testing. In low-resource settings that inverts the usual economics, and it is why syndromic management — treating on symptoms — persists, despite most infections being asymptomatic and therefore invisible to it.

**Simple means.** Condoms. Partner notification and simultaneous treatment — a conversation, not a resource. Fewer concurrent partners. Abstaining from sex during treatment and until partners complete treatment. Recognising that most infection is silent, so that symptoms are not used as the criterion for seeking testing: this single piece of knowledge is the main non-material intervention available. Recognising neonatal conjunctivitis and infant pneumonia in the weeks after birth as possible chlamydial infection requiring treatment.

Nothing simple cures chlamydia, and nothing simple detects it. The second half of that sentence is the key limitation. Unlike syphilis, which produces a visible sore, and gonorrhoea, which often produces discharge, chlamydia is usually invisible without a molecular test. The minimum chain therefore has two parts: doxycycline manufacture, which is short, cheap, oral and needs no cold chain; and nucleic acid amplification testing capability, which needs a laboratory, reagents, a cold chain and trained staff. Without the second, most infections are never found. Syndromic management catches only the symptomatic minority.

**Gaps. WHO publishes no deaths, no geography, no age pattern and no infertility burden** for the most common bacterial sexually transmitted infection — the thinnest WHO data in this chapter relative to case numbers. The infection figure is for 2020. **Whether screening programmes reduce population-level sequelae is genuinely contested**, with countries diverging in policy. The proportion of untreated infections progressing to tubal damage is not well established. Whether screening interferes with partial natural immunity is an open and contested hypothesis. No vaccine, and no licensed candidate. The diagnostic cost barrier is not addressed in WHO's framing of the condition as curable with single-dose antibiotics.

---

## Varicella (chickenpox) and herpes zoster (shingles)

**What it is.** One virus causing two diseases. Varicella-zoster virus causes chickenpox on first infection, then stays dormant in nerve roots for life. Decades later it can reactivate along a single nerve as shingles, which is painful and can leave lasting nerve pain.

**Measured.** No WHO fact sheet for varicella or herpes zoster was retrieved. The web search budget was exhausted before alternative primary sources could be reached, and the 19 October 2026 retrieval pass did not close it.

**Varicella cases. Varicella deaths. Zoster incidence. Zoster lifetime risk. Post-herpetic neuralgia frequency.** No case or death figures are asserted for either condition.

What can be stated without a numerical claim. Varicella is near-universal in unvaccinated populations, with infection typically in childhood in temperate climates and somewhat later in some tropical settings. It is substantially more severe in adults, in pregnancy and in the immunocompromised. Herpes zoster incidence rises steeply with age, and post-herpetic neuralgia risk rises with age as well. The commonly repeated figure, that roughly a third

of people in unvaccinated populations experience zoster in a lifetime, was not sourced here and is **not asserted.**

**Where it starts.** Varicella-zoster virus, transmitted by respiratory aerosols and by contact with vesicle fluid. It is highly contagious.

Shingles is not caught from another person. It is reactivation of virus already latent in the person's own dorsal root or cranial nerve ganglia since their childhood chickenpox. A person with shingles can, however, transmit varicella to a susceptible person through vesicle contact. Risk factors for reactivation: increasing age, immunosuppression from HIV, chemotherapy, transplantation or corticosteroids, and physical and psychological stress.

Not known: what triggers reactivation in a given individual at a given time is not established. Declining cell-mediated immunity with age is the general explanation but not a predictive one. The mechanism of post-herpetic neuralgia, and why some patients develop persistent pain and others do not, is not established, and treatment is poor.

Whether childhood varicella vaccination increases zoster incidence in older adults — by removing the natural immune boosting that comes from exposure to infected children — is a genuinely contested hypothesis, with substantial modelling literature on both sides and no resolution. It has influenced some countries' decisions not to introduce universal varicella vaccination.

**Cure status.** Split three ways, and all three statements are needed.

varicella in a healthy child: SELF-LIMITING varicella in adults, pregnancy, immunosuppression: RELIEF ONLY latency: CONTROLLABLE herpes zoster and post-herpetic neuralgia: RELIEF ONLY

Varicella in a healthy child resolves unaided in about a week, and antivirals are not routinely indicated. In adults, pregnancy and immunosuppression antivirals materially reduce severity and are indicated, but nothing removes the virus; severe varicella pneumonia and disseminated infection can be fatal.

Nothing removes latent virus from nerve ganglia, so no one who has had chickenpox can be freed of the risk of shingles. That state is held at best, by vaccination to boost immunity.

For herpes zoster, antivirals started within about 72 hours reduce duration and severity and may reduce post-herpetic neuralgia, but nothing removes the virus. Post-herpetic neuralgia is often poorly relieved, managed with amitriptyline, gabapentin or pregabalin, topical lidocaine or capsaicin — all partial.

**Prevention.**

Varicella vaccination: STRONG, with a one-dose against two-dose distinction. This is a live attenuated vaccine. **Precise efficacy figures with confidence intervals are not asserted** , because no primary source was retrievable. The established pattern from the meta-analytic literature is that one dose gives good protection against severe varicella but incomplete protection against any varicella, with breakthrough cases, while two doses give substantially higher protection against any disease. The figures belong in the WHO position paper on varicella vaccines and in the one- against two-dose meta-analyses.

Varicella vaccine needs an unbroken cold chain and is among the more fragile vaccines in distribution terms. It requires human diploid cell culture, it is notably heat- and light-labile, and some formulations require frozen storage rather than 2–8 °C.

Herpes zoster vaccination: STRONG for the recombinant adjuvanted vaccine. The recombinant adjuvanted product, containing glycoprotein E with AS01B adjuvant, has substantially higher and more durable efficacy than the older live attenuated zoster vaccine, including in older age groups where the live vaccine performed poorly. **Figures with confidence intervals are not asserted** for want of a retrievable primary source; the ZOE-50 and ZOE-70 trials are the sources.

The recombinant zoster vaccine's chain is long. It needs recombinant protein expression plus AS01B adjuvant, which requires QS-21 saponin from *Quillaja saponaria* and MPL. Then sterile fill-finish, an unbroken 2–8 °C cold chain, a needle, and reconstitution of two components at the point of use.

Varicella-zoster immunoglobulin for susceptible high-risk contacts — pregnant women, neonates, the immunocompromised: STRONG. It requires plasma fractionation.

Post-exposure varicella vaccination within three to five days: MODERATE for susceptible healthy contacts.

Isolation of cases: MODERATE, limited by infectiousness beginning before the rash.

Universal childhood varicella vaccination: CONTESTED as policy — not on its direct efficacy but on the zoster-boosting question above. Some countries vaccinate universally and others deliberately do not, from the same evidence. **Neither side's modelled magnitude is asserted here.**

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Aciclovir, oral or intravenous; varicella in at-risk groups, and zoster | Yes | Yes | Cents to low dollars per course generically |
| Valaciclovir, famciclovir, better oral bioavailability | Partly | Yes | Low dollars per course |
| Paracetamol, symptom relief; **avoid aspirin in children** | Yes | Yes | Cents |
| Calamine, cool compresses, antihistamines, for itch | Partly | Yes | Cents |
| Amitriptyline, gabapentin, pregabalin, for post-herpetic neuralgia | Yes for amitriptyline and gabapentin | Yes | Cents to low dollars per month |
| Topical lidocaine, capsaicin | Partly | Yes | Low to moderate |
| Varicella-zoster immunoglobulin | Yes | Yes | High; plasma-derived |
| Varicella vaccine; recombinant zoster vaccine | Varicella yes; zoster status not confirmed on the 24th List | Varicella yes; recombinant zoster no | Varicella low; the recombinant zoster vaccine is expensive — roughly US$150–200 per dose in high-income markets, two doses required† — and is largely unavailable in low-income settings |

Aspirin must not be given to children with varicella, because of Reye syndrome. This is a well-established and important contraindication.

**Simple means.** Considerable for varicella, modest for zoster.

Rest, fluids and time — the whole treatment for a healthy child with chickenpox. Keeping nails short and hands clean, and preventing scratching, which prevents the bacterial superinfection and scarring that are the main avoidable harms. Cool baths, oatmeal or baking-soda soaks, calamine, cool wet compresses for itch. Paracetamol, never aspirin in children. Keeping the case away from pregnant women, newborns and anyone immunosuppressed, for whom varicella is dangerous — a decision, not a resource, and the highest-value simple measure here. Keeping zoster lesions covered, which prevents transmitting varicella to susceptible people. For zoster pain: cool compresses, loose clothing avoiding pressure on the area, and keeping the rash clean and dry. Recognising zoster affecting the eye or the tip of the nose, the ophthalmic distribution, as needing urgent care, since it threatens sight — recognisable by looking. Watching for the danger signs in varicella: breathlessness, confusion, extensive or bleeding rash, high persistent fever, or any varicella in an adult or immunosuppressed person.

Nothing simple prevents shingles, and nothing simple relieves post-herpetic neuralgia well. Prevention of both diseases requires vaccines with long and fragile chains, and the recombinant zoster vaccine is additionally expensive and patent-protected — which makes it one of the least accessible interventions in this chapter, despite addressing a condition of universal old age. Aciclovir, by contrast, is cheap, off-patent and oral.

**Gaps. This entry lacks burden figures entirely.** No WHO fact sheet was retrieved and the search budget was exhausted. Varicella and zoster incidence, mortality and post-herpetic neuralgia frequency are all missing and belong in the WHO position papers and in GBD. **Vaccine efficacy figures with confidence intervals are absent** for varicella, one and two dose, and for both zoster vaccines; these are the most important additions needed, and ZOE-

50, ZOE-70 and the varicella dose meta-analyses are the sources. **The zoster-boosting hypothesis is genuinely contested** and has driven divergent national policy. The mechanism and treatment of post-herpetic neuralgia are poorly established, and treatment is frequently inadequate. The recombinant zoster vaccine's price places it outside most of the world, and no low-income pricing arrangement is documented. Zoster burden in HIV-endemic settings, where reactivation occurs in younger adults, is poorly quantified.

---

## Ebola virus disease and other viral haemorrhagic fevers

**What it is.** A group of severe viral illnesses causing fever, organ failure and, in some, bleeding. Ebola spreads through direct contact with the body fluids of the sick and the dead, so it concentrates in families and in those who care for them. Case fatality has ranged from a quarter to nine-tenths.

**Measured.** WHO fact sheet on Ebola virus disease, 24 April 2025. Case fatality averages around 50 per cent, and past outbreaks have ranged from 25 to 90 per cent. Six *Orthoebolavirus* species have been identified, of which three cause large outbreaks.

Incubation is 2 to 21 days, and contacts are monitored for 21 days. Ebola virus has been found in semen up to fifteen months after recovery, and male survivors without access to a semen testing programme are advised to practise safer sex for 12 months.

The 1976 index outbreaks were Sudan virus disease in Nzara, now South Sudan, and Ebola virus disease in Yambuku, now DR Congo; the virus is named after the Ebola River near Yambuku.

**WHO gives no case or death counts on this fact sheet** — not for any outbreak, including the 2014–2016 West African epidemic, the largest on record. WHO's navigation listed a May 2026 public health emergency declaration for a Bundibugyo virus outbreak, but the fact sheet body carries no figures for it.

Other haemorrhagic fevers within this chapter's scope, for which no fact sheets were retrieved and **no figures are asserted** : Marburg virus disease, Lassa fever, Crimean-Congo haemorrhagic fever, Rift Valley fever, yellow fever and hantavirus infections. Lassa fever is endemic in West Africa with a large annual burden and a much lower case fatality than Ebola. Yellow fever is vaccine-preventable with a highly effective single-dose vaccine; WHO's immunization coverage sheet of 15 July 2026 gives yellow fever vaccine coverage at 53 per cent in the 40 at-risk countries and territories, against a recommended 80 per cent. Lassa fever and yellow fever carry substantial burden and warrant their own entries.

**Where it starts.** Ebolaviruses, with fruit bats the probable reservoir, introduced to humans through contact with infected wildlife — bats, non-human primates, forest antelope. From there it passes human to human by direct contact with blood, secretions, organs or other body fluids of infected people, with contaminated surfaces and materials, and with the bodies of the dead.

Two amplifying factors are established, and they are what the response addresses: funeral practices involving washing and touching the body, and care of the sick at home and in facilities without protective equipment. That is why health workers and family carers are disproportionately infected. Viral persistence in semen, eye and central nervous system is established, with documented transmission from survivors months after recovery.

Not known: the reservoir has not been definitively confirmed. Bats are strongly implicated but the complete ecology of spillover is not established, and it is not known why outbreaks begin where and when they do. Why case fatality varies from 25 to 90 per cent across outbreaks is not explained: virus species, availability of supportive care, host factors and reporting completeness all contribute in unquantified proportions. The determinants and duration of viral persistence in survivors, and the frequency of survivor-derived transmission, are not well quantified. The mechanisms of post-Ebola syndrome — joint pain, eye disease, neurological symptoms — are unestablished.

**Cure status.** Split by species. The split is recent and it matters.

Zaire ebolavirus: CURABLE Sudan, Bundibugyo and other species: RELIEF ONLY

WHO names mAb114, ansuvimab, and REGN-EB3, Inmazeb, as WHO-recommended for Zaire ebolavirus, and **gives no efficacy figures** . These were established in the PALM randomised trial during the 2018–2020 DRC outbreak, which showed markedly lower mortality with these two agents than with the comparators; **the trial figures could not be retrieved**, so none is asserted. With early presentation and these agents plus intensive supportive care, survival is now the expected outcome rather than the exception. The label rests on a trial whose figures are not printed here.

The licensed monoclonals are specific to Zaire ebolavirus and do not work against Sudan ebolavirus, and neither does the licensed vaccine. The 2022 Uganda Sudan virus outbreak and the 2026 Bundibugyo outbreak had no licensed specific treatment or vaccine.

Supportive care alone substantially reduces mortality — aggressive fluid and electrolyte replacement, treatment of co-infections, and organ support. That is not a cure, but it is the difference between the high and low ends of the 25 to 90 per cent range.

**Prevention.**

Infection prevention and control in care settings: STRONG. Barrier precautions, isolation, safe injection and safe waste handling. This is what ends outbreaks.

Safe and dignified burial: STRONG. Funeral practices involving contact with the body are a major amplifier, and modifying them while respecting mourning is established outbreak practice.

Contact tracing and 21-day monitoring: STRONG.

Ervebo, rVSV-ZEBOV-GP vaccine: STRONG for Zaire ebolavirus. WHO notes that SAGE recommended it for outbreak response in July 2024, and **gives no efficacy percentage** . The Guinea “Ça Suffit” ring vaccination trial reported 100 per cent efficacy in the immediate-vaccination arm in its interim analysis, with no cases occurring ten or more days after randomisation. **The exact confidence interval could not be retrieved from a primary source and is not given.** It protects only against Zaire ebolavirus. A second vaccine regimen, Zabdeno with Mvabea — Ad26.ZEBOV and MVA-BN-Filo — is also available for preventive use.

Ervebo has the longest and most demanding chain of any product in this chapter. It is a live recombinant vesicular stomatitis virus requiring mammalian cell culture under containment, sterile fill-finish, and storage at −60 °C to −80 °C. That is an ultra-cold chain comparable to the mRNA COVID vaccines, deployed in some of the least electrified regions in the world. Ring vaccination in such settings required purpose-built passive cold boxes.

Ring vaccination strategy: STRONG, vaccinating contacts and contacts of contacts rather than whole populations.

Avoiding contact with bats, bushmeat and sick wildlife, and cooking meat thoroughly: MODERATE, for preventing spillover.

Survivor semen testing and safer sex for 12 months: STRONG, on the established persistence data.

**Treatment.**

| Treatment | EML | Off-patent | Price |
|---|---|---|---|
| Ansuvimab (mAb114), Zaire ebolavirus only | Status on the 24th List not confirmed | No, patented | No published price for outbreak use; supplied through stockpiles |
| REGN-EB3 (Inmazeb), Zaire ebolavirus only | Status not confirmed | No, patented | No published price; US list prices for monoclonals of this class are in the tens of thousands of US dollars per course; outbreak supply is through donation and stockpile |
| Aggressive supportive care: oral and intravenous fluids, electrolyte correction, antimalarials and antibiotics for co-infection, oxygen | Yes, for fluids and oxygen | Yes | Low per patient, but requires staffed treatment units |
| Ervebo vaccine, prevention, Zaire only | Status not confirmed | No | Supplied via the ICG global stockpile; no market price applies |
| Nothing species-specific for Sudan or Bundibugyo | — | — | — |

The monoclonals exist only for Zaire ebolavirus. That is the single most important qualification in this entry.

**Simple means.** Substantial for stopping transmission, almost nothing for curing.

Not touching the sick or the dead without protection. This is the central measure, and it is a matter of knowledge and practice rather than of supply. Safe and dignified burial: burial without washing and touching the body, conducted by trained teams or by families instructed in it, with mourning practices adapted rather than forbidden. Isolating the sick person in a separate space, with one designated carer rather than many. Improvised barrier protection: gloves, plastic sheeting, impermeable aprons, boots, eye covering — imperfect, far better than bare hands, and historically what available staff used. Handwashing with soap, and chlorine solution for surfaces and hands, which can be made from locally available bleach powder — a genuinely low-chain, highly effective measure. The dilutions are set by the outbreak response team and are not given here. Oral rehydration, given early and in volume: Ebola kills substantially through fluid and electrolyte loss, and oral rehydration alone measurably improves survival before any intravenous access exists, which makes it the single most valuable simple treatment here. Separating the carer's clothing and bedding; burning or chlorinating contaminated material. Contact tracing by local knowledge — listing who visited and who touched, which requires only pen, paper and trust. Keeping survivors' semen testing and safer-sex advice in circulation after the outbreak ends.

The monoclonals and the vaccine cannot be improvised, and the vaccine's −60 °C to −80 °C requirement makes it one of the least deployable products in existence outside an organised response. The minimum chain is mammalian cell culture under high containment, sterile fill-finish, an ultra-cold chain, an international stockpile, and an emergency response able to reach a village within days.

But the historical record is that Ebola outbreaks were stopped, repeatedly, before any vaccine or drug existed — by isolation, barrier precautions, safe burial and contact tracing. Those remain the measures that end outbreaks, and they are largely simple.

**Gaps. WHO gives no case or death counts on the Ebola fact sheet** — not even for the 2014–2016 West African epidemic. **No efficacy figures with confidence intervals are published by WHO for Ervebo, ansuvimab or REGN-EB3** , and the Ça Suffit and PALM trial figures could not be retrieved. **No figures at all are asserted for Marburg, Lassa, Crimean-Congo haemorrhagic fever, Rift Valley fever, yellow fever or hantaviruses** , all of which belong in this chapter; Lassa fever and yellow fever in particular carry substantial burden and need their own entries. The reservoir is not definitively confirmed. The 25 to 90 per cent case fatality range is unexplained, and the source does not disaggregate it by species or by care availability. No specific treatment or vaccine exists for Sudan or Bundibugyo virus, and the 2026 Bundibugyo outbreak had no published figures on the retrieved page. Post-Ebola syndrome and survivor viral persistence are poorly quantified.

---

## Antimicrobial resistance (cross-cutting)

**What it is.** Not a disease but a property that infections acquire: the organism stops responding to the drugs that used to kill it. It converts curable conditions into uncurable ones, which is why it appears in almost every entry in this chapter. It arises wherever antimicrobials are used.

This entry takes the eight sections of a condition because the book's form is uniform, and because the questions the form asks — what prevents it, what treats it, what can be done with simple means — all have answers here. It is not a condition, and the CURE STATUS section says so.

**Measured.** Two sources, and they are the same family of estimates at different vintages.

GBD 2021 bacterial AMR analysis, IHME, published in the *Lancet* in 2024:

- 2021 deaths *associated with* bacterial AMR: 4.71 million (95 per cent UI 4.23–5.19 million)
- 2021 deaths *attributable to* bacterial AMR: 1.14 million (95 per cent UI 1.00–1.28 million)
- 2050 forecast, attributable: 1.91 million (95 per cent UI 1.56–2.26 million)

- 2050 forecast, associated: 8.22 million (95 per cent UI 6.85–9.65 million)

Age pattern, 1990 to 2021: deaths in children under five fell by more than 50 per cent, while deaths in people aged 70 and over rose by more than 80 per cent. Under-five AMR mortality fell in every super-region, and mortality in those aged five and over rose in all super-regions. By 2050, people aged 70 and over are forecast to account for 65.9 per cent (95 per cent UI 61.2–69.8) of all-age attributable deaths.

WHO fact sheet on antimicrobial resistance, 16 July 2026:

- more than 4.7 million deaths associated with bacterial AMR in 2021, consistent with the GBD figure above
- about one in six, roughly 17 per cent, of laboratory-confirmed common bacterial infections were resistant in 2023; one in three reported infections were resistant in the WHO South-East Asia and Eastern Mediterranean Regions
- resistance rose in over 40 per cent of monitored pathogen-antibiotic combinations between 2018 and 2023, at an average annual increase of 5 to 15 per cent
- gonorrhoea: 75 per cent ciprofloxacin resistance
- tuberculosis: 3.2 per cent of new episodes drug-resistant, 16 per cent of previously treated episodes
- antibiotic use in 2022: Access group about 53 per cent of global human use; Watch group about 45 per cent, exceeding 70 per cent of total use in nearly one-third of countries; the target is at least 70 per cent Access by 2030
- economic projection: US$412 billion a year in treatment costs through 2035, plus US$443 billion a year in productivity losses
- target: a 10 per cent reduction in bacterial AMR-associated deaths by 2030, set at the 2024 UN General Assembly

Earlier figures, for comparison, from the WHO sepsis fact sheet of 3 May 2024 citing 2019 data: 4.95 million deaths associated with AMR, 1.27 million directly attributable. The figures move between sources and years and are not always labelled.

**The two 2050 projections in circulation do not agree, and this book prints both.**

| Projection | Source | 2050 figure |
|---|---|---|
| Deaths per year attributable to AMR | O’Neill review, 2016 | **10 million** |
| Deaths per year attributable to bacterial AMR | GBD 2021 forecast, published 2024 | **1.91 million** (95 per cent UI 1.56–2.26 million) |
| Deaths per year associated with bacterial AMR | GBD 2021 forecast, published 2024 | **8.22 million** (95 per cent UI 6.85–9.65 million) |

The ten-million figure, from the 2016 review chaired by Jim O’Neill, is the number in public circulation. It rests on methodology that the GBD authors’ own forecast does not reproduce. The GBD attributable forecast is about one fifth of it. The GBD *associated* forecast, 8.22 million, is within the same order of magnitude as the O’Neill figure. That is how the two can appear to agree in a summary that does not say which measure it is quoting. It is precisely the error to avoid. The discrepancy is methodological and unresolved. Both numbers are in circulation and they are not to be presented as agreeing.

**Where it starts.** Selection. Antimicrobial exposure kills susceptible organisms and leaves resistant ones to multiply; resistance genes then spread between bacteria on mobile genetic elements, including across species. This is settled evolutionary biology, not hypothesis.

The established drivers:

- antimicrobial use and misuse in human medicine, including treatment of viral illness, incomplete courses, and substandard and falsified medicines
- use in animal agriculture for growth promotion and prophylaxis, which accounts for a large share of global antimicrobial consumption by volume
- absence of diagnostics, which forces empirical broad-spectrum treatment. The chlamydia entry shows the mechanism exactly: the drug costs cents, the test costs more, so people are treated blind
- poor infection prevention and control, which spreads resistant organisms between patients; 15 per 1,000 hospitalised patients acquire sepsis as a complication of care

- inadequate water, sanitation and hygiene, which increases infection incidence and therefore antimicrobial use
- environmental contamination from pharmaceutical manufacturing effluent and from human and animal waste

Not known, and this is the central measurement problem: the attributable-against-associated distinction. The two figures differ by a factor of about four — 1.14 million against 4.71 million in 2021 — and they answer different questions. "Attributable" asks how many deaths would be averted if resistant infections became susceptible. "Associated" counts deaths in people who had a resistant infection. Which is the right number depends on the question, and both are legitimate. They are routinely quoted interchangeably, which is wrong.

The relative contribution of agricultural against human antimicrobial use to resistance in human pathogens is genuinely contested, with good sources differing substantially, and it is the most politically consequential open question in the field. Whether resistance is reversible at population level when antimicrobial pressure is withdrawn is partly established for some drug-organism pairs and unknown for others.

Read in the net: the one rule is that only what returns in phase persists. Antimicrobial exposure is a test applied to a population of forms, and the forms that fit remain. Resistance is not a response to the drug; it is what the drug selects from what was already there. This is a reading, not a mechanism — and in this case the standing account says the same thing, which is why no reading is needed to understand it. It is included because the rest of the chapter's readings are of the same shape.

**Cure status.** Not applicable as a condition. AMR is not itself curable, controllable or self-limiting. It is a property that reclassifies other conditions, and the classification that belongs here is a statement of how it moves them down the scale.

| Condition | Without resistance | With resistance |
|---|---|---|
| Gonorrhoea | CURABLE | Credible prospect of untreatable. Ciprofloxacin at 75 per cent resistance is already lost; ceftriaxone is the last reliable single agent |
| Typhoid | CURABLE | XDR strains have exhausted chloramphenicol, ampicillin, co-trimoxazole, fluoroquinolones and third-generation cephalosporins, leaving azithromycin and carbapenems, with azithromycin resistance now appearing |
| Tuberculosis | CURABLE with a cheap four-drug six-month regimen | MDR and RR-TB require six months of BPaLM at many times the cost, and only two in five of those affected access treatment |
| Shigellosis | CURABLE | Fluoroquinolone-resistant and XDR *S. sonnei* circulating internationally |
| Malaria | CURABLE | Partial artemisinin resistance confirmed in four African countries |
| HIV | CONTROLLABLE | Resistance follows treatment interruption, which is why supply continuity matters as much as supply |
| Neonatal sepsis, bacterial meningitis | CURABLE if treated early | First-line empirical regimens failing where resistance is high and alternatives unavailable |
| Cholera, leprosy, syphilis, chlamydia | CURABLE | So far substantially spared. No established penicillin resistance in *T. pallidum* after eighty years, and no clinically significant resistance in *C. trachomatis* |

Those last exceptions are real and worth stating. The evidence for the reclassification is WHO's own: resistance rising in over 40 per cent of monitored pathogen-antibiotic combinations, one in six common infections resistant, one in three in two WHO regions.

**Prevention.**

Infection prevention and control, and hand hygiene in health facilities: STRONG. Preventing the infection removes the need for the antimicrobial.

Vaccination: STRONG, and under-recognised as an AMR measure. Every vaccine in this chapter prevents antimicrobial use. The Gambian PCV trial reduced all-cause mortality by 16 per cent (95 per cent CI 3–28). It reduced radiological pneumonia by 37 per cent per protocol (95 per cent CI 27–45), or 36 per cent by intention to treat (95 per cent CI 27–43). Each prevented pneumonia is an antibiotic course not given. Typhoid conjugate vaccine is the principal countermeasure to extensively drug-resistant typhoid.

Water, sanitation and hygiene: STRONG. Handwashing with soap where soap is provided gives a community risk ratio of 0.66 (95 per cent CI 0.58–0.75) for diarrhoea, Cochrane CD004265 — about a third fewer episodes — and most of that diarrhoea would otherwise attract antibiotics.

Diagnostics to direct treatment: STRONG in principle, limited in practice by cost, which is the binding constraint identified above.

Antimicrobial stewardship: STRONG. WHO's Access, Watch and Reserve framework carries a target of at least 70 per cent Access by 2030; Watch antibiotics exceed 70 per cent of use in nearly a third of countries, so the gap is large and measurable.

Completing prescribed courses, and not using antibiotics for viral illness: STRONG.

Reducing agricultural antimicrobial use, especially for growth promotion: STRONG on principle and on settled biology; CONTESTED in its quantitative contribution to human resistance. Both positions belong in print. The biological mechanism is not in doubt. The magnitude of the human health benefit from agricultural restriction is disputed, and **no effect size is asserted for it** .

Controlling pharmaceutical manufacturing effluent: MODERATE.

New antimicrobial development: STRONG in necessity, failing in practice. The commercial model does not reward drugs intended to be used sparingly, which is why zoliflodacin for gonorrhoea and the newer tuberculosis regimens have come through non-profit partnerships — GARDP, the TB Alliance, DNDi — rather than through ordinary commercial development.

**Treatment.** There is no treatment for antimicrobial resistance itself. What exists is treatment for resistant infections, which is uniformly more expensive, more toxic, longer and less effective than the first-line agents it replaces.

The pattern across this chapter, with the prices as sourced in the individual entries:

| First-line: cheap, off-patent, on the EML | Resistant alternative | Cost and burden consequence |
|---|---|---|
| RHZE first-line TB, US$66.04 per 672-tablet pack, GDF Q3-2025 | BPaLM: bedaquiline US$44.44 per 100, pretomanid US$123.08 per 100, linezolid US$16.00 per 100, levofloxacin US$4.61 per 100, GDF Q3-2025 | Per tablet, RHZE is about 9.8 US cents and pretomanid about US$1.23 — roughly 12.5 times as much for one component of a multi-drug regimen; and only two in five of those needing the regimen are treated |
| Ciprofloxacin for gonorrhoea, cents | Ceftriaxone injection, low dollars | 75 per cent ciprofloxacin resistance; the cheap oral option is gone, and the replacement needs a syringe and an injector |
| Chloramphenicol, ampicillin or co-trimoxazole for typhoid, cents | Azithromycin, then meropenem | XDR typhoid requires hospital-administered carbapenems |
| Ampicillin with gentamicin for neonatal sepsis, cents | Ceftriaxone, then carbapenems | Escalation in exactly the settings least able to supply it |

Reserve-group antibiotics — carbapenems, colistin, ceftazidime-avibactam and others — are on the EML in the Reserve category. The older agents are mostly off-patent and the newer ones patented, and they cost from low dollars to hundreds of US dollars per course. **No primary prices were confirmed.**

**Simple means.** Unusually large, because AMR is driven by infection incidence and by drug use, and simple means reduce both.

Handwashing with soap: fewer infections, fewer antibiotic courses, less selection pressure. Soap is producible from fat and ash. Clean water by boiling, filtration, chlorination or solar disinfection, which cuts the diarrhoeal disease that drives much inappropriate antibiotic use. Latrines and safe faeces disposal. Not taking antibiotics for colds, influenza and most diarrhoea — a decision costing nothing that directly reduces selection pressure; most episodes in this chapter's diarrhoeal entries need salt, sugar and water, not antibiotics. Completing a course once started, and not sharing or saving leftover antibiotics. Oral rehydration, which substitutes for antibiotics in the majority of diarrhoeal illness. Breastfeeding, which reduces infant infection and therefore antibiotic exposure. Clean birth practice: handwashing, a clean blade, clean cord care, nothing applied to the stump — which prevents the neonatal sepsis for which resistant organisms are now a leading problem. Isolating the infectious,

and ventilating rooms. Wound care: cleaning with clean water and soap, keeping wounds covered and dry, which prevents the skin infections that attract antibiotics. Keeping animals out of sleeping and cooking areas.

What cannot be done without an industrial chain is treating a resistant infection. The minimum chain for second-line therapy is substantial and rises with each step of resistance: injectable cephalosporins, then carbapenems requiring hospital administration, plus the laboratory capacity to identify the resistance in the first place.

The honest statement is that simple means can slow the generation of resistance considerably but can do nothing for the person already infected with a resistant organism. That person's survival depends on exactly the long chains that are least available where resistance is highest, and that is the structural shape of the problem.

**Gaps. The attributable-against-associated distinction is the central measurement problem**: 1.14 million against 4.71 million for 2021, a factor of about four, routinely conflated in public discussion. **The two most-cited 2050 projections disagree** — the O'Neill review's ten million a year against GBD's 1.91 million attributable and 8.22 million associated; the discrepancy is methodological and unresolved, and both figures are printed above. WHO's 2026 fact sheet cites 2021 GBD figures for deaths and 2023 figures for resistance proportions, while the sepsis fact sheet cites 2019 figures of 4.95 million and 1.27 million; the figures move between sources and years and are not always labelled. **The agricultural-against-human-use contribution is genuinely contested** and is the most consequential open question. Surveillance is weakest where resistance is highest: the one-in-six figure rests on laboratory-confirmed infections, and most infections in high-burden settings are never cultured, so the true proportion is unknown. **Fungal, viral and parasitic resistance is barely quantified**; WHO's 2026 fact sheet gives no figures for *Candidozyma auris*, *Aspergillus*, HIV, influenza, hepatitis or malaria resistance, despite naming them. Whether resistance reverses when drug pressure is withdrawn is established for some drug-organism pairs and unknown for others. The economic projections of US$412 billion and US$443 billion a year are modelled and carry no published uncertainty interval in the source.

# Chapter 02 — Neoplasms

This chapter covers the cancers and the benign tumours that carry clinical weight. The burden figures are GLOBOCAN 2022, with GLOBOCAN 2024 beside them, and the stage-specific survival figures are from the United States SEER programme. Where a WHO page or a retrieval of the Essential Medicines List closed a figure, that figure was read off its source and the figure it replaces is named.

**A cure status without a stage is false at one end.** For almost no other group of conditions in this book does one label mislead so completely. Colorectal cancer caught in the bowel wall has a five-year relative survival of 91.3 per cent; the same disease with liver and lung deposits has 16.9 per cent. One word cannot cover both. So nearly every entry in this chapter splits its cure status by stage, and each label names its stratum and carries the survival figure that supports it wherever the entry has one. The reader who wants the single answer should take the stage distribution with it: half of all lung cancer in the United States presents as distant disease, which is why the lung entry reads CURABLE at stage I to II, CONTROLLABLE at stage III and RELIEF ONLY at stage IV without a targetable driver.

**The reservoir of cancer that never surfaces predicts how much screening will overdiagnose.** The measurement comes from people who died of something else and whose organs were then examined. In men over 79, incidental prostate cancer is found at autopsy in 59 per cent, interval 48 to 71; screen-detected prostate cancer is judged overdiagnosed in 20 to 50 per cent of cases. On whole-gland examination, occult differentiated thyroid cancer is found in 11.2 per cent, interval 6.7 to 16.1; in South Korea, where ultrasound was added to routine health checks, incidence rose roughly fifteenfold with mortality flat, and the overdiagnosed fraction of screen-detected thyroid cancer in that setting approaches 90 per cent or more. Occult *invasive* breast cancer at autopsy is found in only 0.85 per cent, and breast overdiagnosis is correspondingly the most contested figure in cancer screening — 19 per cent against 30 per cent. The occult reservoir of ductal carcinoma in situ, at 8.9 per cent, is ten times the invasive reservoir, and that is where the breast dispute sits.

**Nasopharyngeal carcinoma is the control case that proves the rule.** No autopsy series shows occult nasopharyngeal carcinoma at any meaningful prevalence. Screening for it with plasma Epstein-Barr virus DNA in an endemic population shifts stage sharply. Roughly 70 per cent of screen-detected cancers were stage I or II against roughly 20 per cent in an unscreened comparison, and three-year progression-free survival was about 97 per cent against about 70. Those figures come from the Hong Kong prospective study published in the *New England Journal of Medicine* in 2017. No overdiagnosis percentage has been published for it, and the absence of an indolent reservoir is the reason the question does not arise. A cheap blood test, a defined high-risk population, a large stage shift and no overdiagnosis penalty: that combination appears once in this chapter. Read in the net: the test finds what is there to be found, and the size of what is there is a property of the organ, not of the test. This is a reading, not a mechanism.

**A short list of cancers is curable at early stage with nothing on patent.** Basal cell and squamous cell carcinoma of the skin, cured above 95 and above 90 per cent respectively by excision under local anaesthetic†. Localized melanoma, five-year relative survival 100.0 per cent, treated by wide excision with a scalpel and sutures. Localized endometrial cancer, 94.9 per cent, by hysterectomy with bilateral salpingo-oophorectomy. Localized thyroid cancer, 99.9 per cent, by lobectomy plus levothyroxine at a few dollars a year. Localized colorectal cancer, 91.3 per cent, by colectomy. Localized cervical cancer, 91.8 per cent, and its precursor cured by thermal ablation in one visit. Localized breast cancer, 100.0 per cent,

by mastectomy plus tamoxifen at US$80 to 250 for five years at generic international prices, 2024, against US$785 to 1,241 for the same five years at one tablet a day, for orientation only, at the United States cash price of 43 to 68 cents a tablet, October 2026. Stage I testicular cancer, by inguinal orchidectomy. Localized kidney cancer, 93.6 per cent, by nephrectomy. Intraocular retinoblastoma, above 95 per cent, found with a torch and cured by enucleation†. Wilms tumour, above 95 per cent localized, by nephrectomy plus two drugs costing tens of dollars.

**Four metastatic cancers are cured with Essential Medicines alone, and one cancer is cured by antibiotics.** Widely metastatic testicular cancer is cured in roughly 90 to 95 per cent of good-risk and the majority of poor-risk patients by bleomycin, etoposide and cisplatin, all off-patent, at a drug cost of a few hundred dollars. Stage IV Hodgkin lymphoma has a five-year relative survival of 82.8 per cent, and ABVD is four off-patent listed medicines. Acute promyelocytic leukaemia is cured in over 90 per cent by all-trans retinoic acid and arsenic trioxide, with no conventional chemotherapy at all in non-high-risk disease. Childhood acute lymphoblastic leukaemia is cured in roughly 90 to 94 per cent in high-income settings by a protocol built entirely from off-patent listed medicines. And early-stage gastric mucosa-associated lymphoid tissue lymphoma is cleared in roughly 60 to 80 per cent of cases by one to two weeks of generic antibiotics costing a few dollars. That is a very cheap cancer cure. Against it, the same Essential Medicines List now carries pembrolizumab and blinatumomab. The price range across the products in section F spans many orders of magnitude, and section F sets it out.

---

# The entries

## 1. Lung cancer

**What it is.** A malignant tumour of the cells lining the airways or of the lung tissue itself. Two classes: non-small-cell, about 85 per cent of cases, including adenocarcinoma and squamous carcinoma; and small-cell, about 15 per cent, faster growing†. It is the most commonly diagnosed cancer in the world and the largest single cause of cancer death.

**Measured.** WHO gives 2.6 million new cases and 1.86 million deaths for 2024. GLOBOCAN 2022 gives 2,480,675 cases, 12.4 per cent of all cancers, and 1,817,469 deaths, 18.7 per cent of all cancer deaths; GLOBOCAN 2024 gives 2,637,005 cases and 1,861,839 deaths. Five-year relative survival in the United States is 29.5 per cent overall, and by stage: localized 65.5, regional 38.2, distant 10.5, unknown 17.5 per cent. Median age at diagnosis 71. Stage at diagnosis: localized 24, regional 21, distant 51, unknown 4 per cent. United States incidence is falling 1.9 per cent a year over 2014 to 2023 and the death rate 4.1 per cent a year over 2015 to 2024. The highest age-standardised incidence is Hungary, 61.8 per 100,000 in men. The decline tracks falling smoking prevalence at a lag of decades, so it has not begun where smoking peaked later.

**Where it starts.** Current smokers carry about twenty times the risk of never-smokers; smoking is estimated to cause about 85 per cent of lung cancer deaths, and tobacco about 90 per cent of lung cancers in men and 78 per cent in women. Ten years of abstinence lowers lung cancer mortality risk by 30 to 60 per cent relative to continuing, and never to never-smoker level. Second-hand smoke raises risk about 20 per cent. Radon is the attributable cause of a median 26 per cent of lung cancer deaths in lifelong non-smokers, range 13 to 50, and 10 per cent in ever-smokers. High occupational exposure to asbestos, arsenic, beryllium, cadmium, chromium or nickel raises risk more than fivefold, and occupational exposures together account for 9 to 15 per cent of lung cancer deaths. Outdoor fine-particle pollution raises risk about 40 per cent at the highest against the lowest exposure. Smoking-associated lung tumours sit well above the adult pan-cancer reference mutation rate of 1.8 mutations per megabase. Not known: why most heavy smokers never develop it; the cause of adenocarcinoma in never-smokers, a rising share of cases; the shape of the dose-response at low radon and low particulate levels.

**Cure status.** Localized, stage I to II: CURABLE — five-year relative survival 65.5 per cent. Regional, stage III: CONTROLLABLE — 38.2 per cent. Distant, stage IV, without a targetable

driver: RELIEF ONLY — 10.5 per cent. Distant with a targetable driver mutation or high PD-L1 expression: CONTROLLABLE. Small-cell, extensive stage: RELIEF ONLY.

**Prevention.** Not starting, and cessation — STRONG. Twentyfold risk, 85 per cent attributable fraction, 30 to 60 per cent mortality reduction after ten years. Radon remediation — MODERATE: the attributable fraction is solid and no trial shows that remediation lowers incidence. Occupational exposure control — STRONG for asbestos. Beta-carotene supplementation — harmful, on strong evidence: lung cancer relative risk 1.18, interval 1.03 to 1.36, in the ATBC trial and 1.28, interval 1.04 to 1.57, in CARET, which was stopped early. Vitamin E — no effect, summary odds ratio 0.97, interval 0.87 to 1.08. Low-dose CT screening — STRONG for mortality reduction in heavy smokers. NLST reported a 20 per cent reduction in lung cancer deaths against chest radiography. NELSON, at ten years or more, reported a lung cancer mortality rate ratio of 0.76 in men and 0.67 in women. The harms, with figures: NELSON gave a false-positive rate of 1.2 per cent across all rounds, a positive predictive value of 43.5 per cent, and an overdiagnosis upper threshold of 8.9 per cent. Secondary analyses of NLST put overdiagnosis substantially higher. The two trials used different intervals — NLST strictly annual, NELSON at one, two and two and a half years — and the literature has not reconciled them. Both are printed.

**Treatment.** Surgical lobectomy for stage I to II is the intervention with the clearest curative effect. Platinum doublet chemotherapy follows: cisplatin, carboplatin, etoposide, gemcitabine, paclitaxel, docetaxel and vinorelbine are all listed medicines and all off-patent, at generic prices in the tens to low hundreds of dollars a vial, so a full doublet course is achievable for a low-hundreds-of-dollars drug cost. Radiotherapy, definitive or palliative, requires a linear accelerator, which is the binding constraint in most of the world. Pembrolizumab is a selected medicine on the list, for metastatic non-small-cell lung cancer with oncogene-driver wildtype status and PD-L1 expression of 50 per cent or more, as monotherapy; it is not off-patent. Atezolizumab and cemiplimab are listed as therapeutic alternatives for that indication and nivolumab as a therapeutic equivalent to pembrolizumab, which is a weaker status than selection. Objective response as first-line monotherapy in PD-L1-high disease is in the region of 40 to 45 per cent in the registrational trials†, and the figure moves with the PD-L1 threshold, so it does not transfer across populations. Erlotinib, gefitinib and afatinib are listed; erlotinib and gefitinib are off-patent. Osimertinib is not listed and not off-patent, with a United States list price in the order of US$150,000 a year†. Objective response to EGFR inhibitors in mutation-positive disease is roughly 60 to 80 per cent†, in a minority subgroup that is far commoner in East Asian and never-smoker populations. ALK, ROS1 and KRAS G12C inhibitors are not listed and are all on patent.

**Simple means.** Very little works here without an industrial chain, and that should be said first. No dietary or low-technology intervention changes the course of established lung cancer, and lobectomy needs thoracic surgery, anaesthesia and chest drainage. What is available simply: tobacco cessation, which needs no technology and is the highest-yield action available; oral morphine for pain and breathlessness, listed, off-patent, cents per dose; thoracentesis for a malignant pleural effusion with a needle and a drainage set, which relieves breathlessness at once and needs no imaging if the effusion is large; nutritional support; oxygen where it exists. Nearly all of the simple-means benefit in lung cancer sits in palliative care.

**Gaps.** Overdiagnosis in low-dose CT screening is unsettled between NELSON's ceiling of 8.9 per cent and higher NLST-derived estimates. Checkpoint response rates are reported against varying PD-L1 thresholds and cross-trial comparison is unreliable. Never-smoker lung cancer has a rising incidence and no established dominant cause. Survival figures are United States figures; five-year survival in low-income settings is substantially lower and comparable site-specific data are sparse.

## 2. Colorectal cancer

**What it is.** Cancer of the colon or rectum, in the great majority of cases developing over years from a benign adenomatous polyp. The slow precursor stage is what makes it screenable.

**Measured.** WHO gives 2.0 million new cases and 918,000 deaths for 2024. GLOBOCAN 2022 gives 1,926,425 cases, 9.6 per cent of all cancers, and 9.3 per cent of cancer deaths;

GLOBOCAN 2024 gives 2,041,007 cases and 917,895 deaths. Five-year relative survival in the United States is 65.4 per cent overall: localized 91.3, regional 75.2, distant 16.9, unknown 49.7 per cent. Median age 66. Stage at diagnosis: localized 34, regional 37, distant 23, unknown 6 per cent. Incidence is falling about 0.5 per cent a year and deaths 1.3 per cent a year in the United States, and the fall masks a rise in adults under 50 that is one of the clearest unexplained trends in oncology.

**Where it starts.** Physical activity is protective, relative risk 0.76, interval 0.72 to 0.81. Obesity raises colon cancer risk, relative risk 1.45, interval 1.02 to 2.07, in women above a body mass index of 29, with mortality relative risk 1.47 at 30 to 34.9. Smoking: incidence relative risk 1.18, mortality 1.25. Alcohol above 45 grams a day: 1.41, interval 1.16 to 1.72. Aspirin: colorectal cancer incidence hazard ratio 0.60, interval 0.47 to 0.76, at ten to nineteen years after starting, against 0.99 within the first ten years, with a twenty-year death hazard ratio of 0.67; the harm is major gastrointestinal bleeding, odds ratio 1.58, and about fourteen extra bleeds per thousand people over ten years at very low doses. Lynch syndrome carries a lifetime colorectal cancer risk of about 80 per cent, and aspirin in Lynch syndrome gave a hazard ratio of 0.65, interval 0.43 to 0.97, in CAPP2. On meat the authorities do not agree. NCI PDQ gives no relative risk and states there is no reliable evidence that a low-fat, low-meat, high-fibre diet reduces colorectal cancer risk by a clinically important degree. IARC classified processed meat as Group 1 and red meat as Group 2A in 2015, with a reported 18 per cent increase in risk per 50 grams a day of processed meat. Both positions are printed. Mutation burden splits the disease: microsatellite-stable tumours sit near the adult reference of 1.8 per megabase, and hypermutated microsatellite-unstable or POLE-mutant tumours one to two orders of magnitude above it. The hypermutated group is the group that responds to checkpoint blockade. Not known: the cause of the early-onset rise; whether the diet relation is causal and through which component.

**Cure status.** Precursor adenoma: CURABLE by polypectomy. Localized, stage I to II: CURABLE — five-year relative survival 91.3 per cent. Regional, stage III: CURABLE in 75.2 per cent (five-year relative survival). Distant with resectable liver-only or lung-only metastases: CURABLE in roughly 20 to 40 per cent (long-term survival after metastasectomy in selected series). Distant otherwise: CONTROLLABLE — 16.9 per cent.

**Prevention.** Screening — STRONG, and the randomised evidence is now complete at the colonoscopy end. Flexible sigmoidoscopy: four randomised trials pooled, 458,002 people, colorectal cancer mortality rate ratio 0.74, interval 0.68 to 0.80, over eleven to seventeen years. Guaiac faecal occult blood testing over two to nine biennial rounds: relative risk 0.78, interval 0.65 to 0.93, to 0.91, interval 0.84 to 0.98, at eleven to thirty years. Faecal immunochemical testing has no randomised trial; a Taiwanese cohort of 5,417,699 people gave an adjusted relative risk of 0.90, interval 0.84 to 0.95, at six years. Colonoscopy: the NordICC randomised trial reported ten-year colorectal cancer risk of 0.98 per cent in those invited against 1.20 per cent in usual care, an 18 per cent reduction, risk ratio 0.82, interval 0.70 to 0.93. Death from colorectal cancer was 0.28 against 0.31 per cent, risk ratio 0.90, interval 0.64 to 1.16, which is not significant. All-cause death was 11.03 against 11.04 per cent. The number needed to invite to prevent one colorectal cancer was 455, interval 270 to 1,429. Uptake was 11,843 of 28,220 invited, 42.0 per cent. An adjusted analysis estimating the effect had all invited been screened gives incidence 1.22 to 0.84 per cent and colorectal cancer death 0.30 to 0.15 per cent, without intervals; recomputed here, the adjusted incidence reduction is 31.1 per cent. Recommended ages: 50 to 75, Grade A; 45 to 49, Grade B; 76 to 85 selectively, Grade C; stop at 86. Harms, with figures: colonoscopy after a positive stool test gives about 17.5 serious bleeds and 5.4 perforations per 10,000 procedures; screening colonoscopy 14.6 bleeds and 3.1 perforations; flexible sigmoidoscopy 0.5 and 0.2; colonoscopy after abnormal sigmoidoscopy 20.7 and 12.0. Lifetime complications for screening from 45 to 75 are 10 to 16 per 1,000 adults screened. Overdiagnosis of colorectal *cancer* is not the principal harm; overdetection and removal of adenomas that would never have progressed is, and no percentage has ever been published for it. The underlying ratio is about twenty polypectomies for each cancer prevented, and entry 35 sets it out. Physical activity — MODERATE. Aspirin — MODERATE on the cancer effect and CONTESTED on net benefit: hazard ratio 0.60 against fourteen extra bleeds per thousand over ten years. Tobacco and heavy alcohol — MODERATE. Low-fat, high-fibre diet — CONTESTED, with both positions above.

**Treatment.** Surgical resection is curative for stages I to III and for resectable oligometastatic disease, and needs laparotomy capability rather than high technology. Polypectomy at colonoscopy is both preventive and curative for the precursor. Fluoropyrimidine-based adjuvant chemotherapy follows: fluorouracil, capecitabine, calcium folinate, oxaliplatin and irinotecan are all listed and all off-patent, and fluorouracil and calcium folinate are among the cheapest cytotoxics in use, so three to six months of FOLFOX or CAPOX is achievable at a drug cost in the low hundreds of dollars. Cetuximab and panitumumab for RAS-wild-type disease are not listed, with originator costs in the tens of thousands of dollars a year; they are inactive and may be harmful in RAS-mutant disease. Bevacizumab is not listed for colorectal cancer; biosimilars have cut its price substantially. Pembrolizumab is a selected medicine for metastatic colorectal cancer, as monotherapy, restricted to mismatch-repair-deficient or microsatellite-instability-high tumours; it is not off-patent. Objective response in that subgroup in the first-line setting is in the region of 45 per cent with a substantial durable fraction†, and the subgroup is only about 4 to 5 per cent of metastatic colorectal cancer†, so the population effect is small.

**Simple means.** Colectomy and the formation of a stoma are achievable in a district hospital with a general surgeon, anaesthesia and basic instruments, and for localized disease that alone is curative in about 90 per cent of cases†. This is one of the highest-yield simple interventions in the chapter. A diverting colostomy relieves obstruction and is life-saving with no advanced equipment. Oral morphine is listed, off-patent and costs cents a dose. Iron treats the chronic blood-loss anaemia that often presents first, and the corollary matters: iron-deficiency anaemia in an adult requires investigation of the bowel, not iron alone. What has no simple substitute is the screening colonoscopy itself, which needs an endoscope, a reprocessing chain and a trained operator, and infusional chemotherapy, although oral capecitabine is far simpler to deliver than infusional fluorouracil.

**Gaps.** PDQ and IARC disagree on meat and on diet. The early-onset incidence rise is unexplained and its magnitude by country inconsistently reported. Faecal immunochemical testing has no randomised mortality evidence. NordICC's per-protocol and adjusted figures come from a secondary source and carry no intervals.

## 3. Stomach cancer

**What it is.** Cancer of the stomach lining, mostly adenocarcinoma, divided into non-cardia disease, the great majority, which is tied to *Helicobacter pylori* infection, and cardia disease, which behaves more like oesophageal adenocarcinoma. It is the clearest case of a common cancer with a treatable infectious cause.

**Measured.** WHO gives 1.0 million new cases and 642,000 deaths for 2024. GLOBOCAN 2022 gives 968,784 cases, 4.9 per cent of all cancers, and 6.8 per cent of cancer deaths; GLOBOCAN 2024 gives 980,286 cases and 641,554 deaths. Five-year relative survival in the United States is 39.8 per cent overall: localized 78.1, regional 39.0, distant 8.1, unknown 33.6 per cent. Japan and South Korea report far better stage-specific and overall survival, because population endoscopic screening shifts the stage at diagnosis, so the United States figure understates what is achievable. Median age 68. Stage at diagnosis: localized 32, regional 23, distant 35, unknown 9 per cent. Incidence is concentrated in East Asia, parts of Latin America and Eastern Europe, following *H. pylori* prevalence and strain virulence. United States incidence is rising about 1.1 per cent a year against the global trend, while the death rate falls 2.0 per cent a year.

**Where it starts.** *H. pylori* is an IARC Group 1 carcinogen for non-cardia gastric carcinoma and for gastric MALT lymphoma, and about half the world's population is infected. de Martel and colleagues, in *The Lancet Global Health* in 2020, attributed about 810,000 cancer cases worldwide in 2018 to *H. pylori*, at an age-standardised incidence of 8.7 per 100,000, the largest single infectious cause of cancer. Against roughly a million annual gastric cases, the implied attributable fraction for non-cardia disease is in the region of 75 to 90 per cent†; that is an inference from two sources rather than a published figure, and is marked as one. Eradication lowers incidence: a pooled meta-analysis of 24 studies gave an incidence rate ratio of 0.53, interval 0.44 to 0.64. Ford and colleagues, in the *BMJ* in 2014, pooled six randomised trials in 6,497 asymptomatic infected adults: gastric cancer occurred in 51 of 3,294 treated, 1.6 per cent, against 76 of 3,203 controls, 2.4 per cent, relative risk 0.66, interval 0.46 to 0.95. The number needed to treat was 124, interval 78 to 843, falling to

about 15 for Chinese men and rising to about 245 for United States women if lifetime benefit is assumed. A Chinese trial in first-degree relatives gave a hazard ratio of 0.45, interval 0.21 to 0.94, at 9.2 years. Smoking: about 60 per cent higher risk in male smokers and 20 per cent in female. Excessive salt intake is associated with increased risk on correlational and case-control evidence, of a magnitude PDQ describes as small and difficult to determine. Epstein-Barr virus marks a recognised molecular subtype, roughly 9 per cent of gastric cancers in TCGA. Not known: why only a small minority of the infected develop cancer, and how much of that is strain, host or co-factor; whether population-wide eradication would do net good or harm.

**Cure status.** Infection with pre-malignant change: CURABLE — one week of oral antibiotics eradicates the organism and lowers subsequent cancer incidence by a third to a half, relative risk 0.53 to 0.66. Early cancer confined to the mucosa: CURABLE by endoscopic resection, with survival approaching that of the general population in Japanese and Korean series. Localized: CURABLE — five-year survival 78.1 per cent. Regional: CURABLE in 39.0 per cent (five-year relative survival). Distant: RELIEF ONLY — 8.1 per cent.

**Prevention.** *H. pylori* eradication — STRONG on the mechanism, MODERATE as population policy. Relative risk 0.53 to 0.66; number needed to treat 124 overall and about 15 in the highest-risk group. The limitation both PDQ and Ford state is that the trials are almost all Asian. Salt reduction — WEAK, on correlational evidence of uncertain magnitude. Tobacco cessation — MODERATE. Endoscopic screening — STRONG in high-incidence countries, not justified in low-incidence countries. Japan and South Korea run population endoscopic programmes and the measured effect is a large stage shift and substantially better survival; there is no randomised mortality trial of endoscopic gastric screening anywhere. The harms are the procedural risk of endoscopy and the overdiagnosis of indolent early lesions, and **overdiagnosis has never been quantified for gastric screening**, in a disease whose occult reservoir is not small. That is an evidence gap, not evidence of absence. Fruit and vegetable intake — CONTESTED: the association holds, causation is not established, and the benefit of change is unknown.

**Treatment.** Gastrectomy with D2 lymphadenectomy is curative for localized and regional disease. Endoscopic mucosal or submucosal resection cures intramucosal early cancer with the organ preserved. The eradication regimen is the cheapest cancer-preventive drug regimen in the chapter: amoxicillin, clarithromycin, metronidazole and a proton-pump inhibitor, with bismuth and tetracycline in quadruple regimens, all available as generics for a few dollars a course. Amoxicillin is a listed Access-group antibiotic and clarithromycin and metronidazole are listed, though the list's own first-choice indications for amoxicillin do not include *H. pylori* eradication. Perioperative chemotherapy uses fluorouracil, capecitabine, cisplatin, oxaliplatin and docetaxel, all listed and off-patent; epirubicin is not listed and doxorubicin is. Trastuzumab for HER2-positive disease, roughly 15 to 20 per cent of cases, is listed; the originator is off-patent in most markets with biosimilars available, and a precise current per-course figure could not be retrieved. Pembrolizumab is a selected medicine on the list, for other listed indications. Nivolumab's listing for this cancer needs checking against the 24th List (2025)†. Neither is off-patent. Benefit concentrates in PD-L1-high and microsatellite-unstable disease and is small in PD-L1-low disease†.

**Simple means.** Test and treat for *H. pylori* is the outstanding simple intervention in this chapter. A urea breath test or a stool antigen test, then one week of generic antibiotics costing a few dollars: no cold chain, no infusion, no imaging. Serology is simpler still, and less specific after treatment. Gastrectomy with a hand-sewn anastomosis is a general-surgical operation and does not require stapling devices. Gastrojejunostomy bypasses an obstructing unresectable tumour, stops vomiting and allows eating, for a large return in quality of life. Oral morphine is listed and costs cents a dose. Reducing salt-preserved food and increasing fresh food needs no industrial chain, though the evidence grade for the cancer effect is weak. Endoscopy, for diagnosis and for early-lesion resection, has no simple substitute.

**Gaps.** The eradication trials are overwhelmingly Asian and both PDQ and Ford decline to generalise from them. No randomised mortality trial of endoscopic screening exists despite decades of national programmes. Overdiagnosis from gastric screening is unquantified. The attributable fraction for gastric cancer specifically is given differently across sources, and the 75 to 90 per cent range above is an inference.

## 4. Liver cancer

**What it is.** Cancer arising in the liver, most often hepatocellular carcinoma on a background of cirrhosis. The dominant causes are chronic hepatitis B and C infection, alcohol and, increasingly, fatty liver disease. It is one of the few cancers that a vaccine given in infancy prevents decades later.

**Measured.** WHO gives 732,000 deaths for 2024. GLOBOCAN 2022 gives 866,136 cases and 7.8 per cent of all cancer deaths; GLOBOCAN 2024 gives 843,045 cases and 732,489 deaths. Liver cancer is third among causes of cancer death and sixth or seventh in incidence, and that gap is the measure of the outcome. Five-year relative survival in the United States is 21.9 per cent overall: localized 37.4, regional 13.4, distant 3.6, unknown 11.6 per cent. Median age 68. Stage at diagnosis: localized 45, regional 23, distant 21, unknown 10 per cent. Rates are highest in East and Southeast Asia and sub-Saharan Africa, tracking hepatitis B prevalence and aflatoxin exposure. United States incidence is falling about 0.7 per cent a year as the hepatitis C birth-cohort bulge is treated, while the death rate is stable.

**Where it starts.** Chronic hepatitis B or C is the critical agent in at least 80 per cent of hepatocellular carcinoma worldwide. The relative risk for hepatitis B is at least fivefold on average, with some prospective studies above 50; for hepatitis C it is at least fifteenfold; with heavy alcohol the combinations reach about fiftyfold and about a hundredfold respectively. de Martel and colleagues, 2020, attribute about 360,000 cancer cases worldwide to hepatitis B and about 160,000 to hepatitis C, nearly all liver cancer. Cirrhosis of any cause is present in 80 to 90 per cent of those who die of hepatocellular carcinoma, and the five-year risk in established cirrhosis is 5 to 30 per cent. Aflatoxin B1 with chronic hepatitis B raises risk about sixtyfold and without it about fourfold, with population attributable risks of 20 per cent in the Western Pacific, 27 in Southeast Asia and 40 in Africa; replacing heavily contaminated food reduced liver cancer mortality by more than 50 per cent. Alcohol: relative risk 1.19 at 25 grams a day, 1.40 at 50 and 1.81 at 100. Obesity: summary relative risk 1.83, interval 1.59 to 2.11. Type 2 diabetes: 2.18, interval 1.58 to 3.01. Current smoking: 1.51, interval 1.37 to 1.67. Untreated hereditary haemochromatosis: at least twentyfold. Aflatoxin leaves a specific mutational signature, AFB1 with the R249S *TP53* change, which is among the clearest environmental fingerprints in tumour DNA. Not known: why most people with cirrhosis never develop it; the quantitative contribution of fatty liver disease without cirrhosis.

**Cure status.** Chronic hepatitis B: CONTROLLABLE — nucleos(t)ide analogues suppress the virus indefinitely and cut hepatocellular carcinoma incidence by about 50 per cent, and do not remove the integrated virus. Chronic hepatitis C: CURABLE — direct-acting antivirals achieve sustained virological response in over 95 per cent, which lowers subsequent risk by about 75 per cent, hazard ratio 0.31 with cirrhosis and 0.18 without. Localized small tumour in preserved liver function: CURABLE by resection, ablation or transplantation — selected transplant series report five-year survival above 70 per cent†, against a population-level localized figure of 37.4 per cent, because most localized disease arises in a liver that limits what can be done. Regional: RELIEF ONLY — 13.4 per cent. Distant: RELIEF ONLY — 3.6 per cent.

**Prevention.** Hepatitis B vaccination — STRONG, and with human papillomavirus vaccination the best-evidenced cancer vaccine effect in existence. Neonatal or early-childhood vaccination cut incidence in young adults by at least 50 per cent in immunised cohorts, and universal neonatal immunisation is predicted to prevent 70 to 85 per cent of global cases. Hepatitis B antiviral treatment — STRONG, about 50 per cent lower incidence. Hepatitis C direct-acting antivirals — STRONG on effect size, rated fair by PDQ on the cancer endpoint: about 75 per cent lower risk after sustained response. Aflatoxin-free food — STRONG: more than 50 per cent lower mortality, achieved by drying and storage practice rather than by industrial processing. Alcohol reduction — STRONG, on the dose-response above. Statins in viral hepatitis — CONTESTED, rated fair but inadequate. Six-monthly ultrasound and alpha-fetoprotein surveillance of cirrhotic patients — MODERATE: widely recommended, with one Chinese randomised trial behind it, and a debated effect on mortality in Western cirrhotic populations. The harms are false positives leading to biopsy and to futile investigation in patients with little liver reserve, and **overdiagnosis has never been quantified for hepatocellular carcinoma surveillance**.

**Treatment.** Hepatitis B vaccination is listed, off-patent and costs well under a dollar a dose at UNICEF and Gavi prices: the highest-value intervention in this entry by a wide margin. Resection, radiofrequency or microwave ablation and transplantation are the curative options; transplantation is the most effective and the least available. Tenofovir and entecavir are listed and off-patent, and generic tenofovir costs in the region of US$30 to 60 a year in generic-supplied markets† — a global procurement figure, not comparable with the United States cash prices elsewhere in this chapter. Sofosbuvir, daclatasvir, velpatasvir and ledipasvir are listed. The originator launch price of sofosbuvir was US$84,000 for a twelve-week course in 2013 to 2014; a curative course now costs under US$50 in many low- and middle-income countries, according to the WHO fact sheet printed 28 July 2026. That is the largest originator-to-generic ratio in this chapter, of more than 1,680-fold. Transarterial chemoembolisation serves intermediate-stage disease and requires interventional radiology. Sorafenib and lenvatinib are not listed; sorafenib is off-patent with generics, and the measured benefit in the registrational trial was a median overall survival gain of under three months, with response rates in the single digits to low teens. Atezolizumab, listed for non-small-cell lung cancer, with bevacizumab gave the first clear survival improvement over sorafenib, with objective response in the region of 30 per cent†.

**Simple means.** Hepatitis B vaccination at birth is a single intramuscular injection under a dollar, with no cold-chain problem beyond routine immunisation, preventing 70 to 85 per cent of global cases if universal. This is the clearest case in the chapter of a simple means with a very large measured effect. Grain drying and storage to prevent aflatoxin needs no industrial chain at all and the measured mortality reduction exceeds 50 per cent. Alcohol reduction needs no technology. Oral morphine is listed and cheap. Large-volume paracentesis with a needle and a drainage set relieves ascitic distension at once and needs no imaging. For established disease, nothing simple is curative: resection requires hepatic surgery and blood, ablation requires imaging guidance, transplantation requires a national system. The simple means in liver cancer are almost entirely preventive.

**Gaps.** The randomised evidence for cirrhosis surveillance is thin and dominated by one trial. PDQ rates the obesity and diabetes associations as fair but inadequate to act on, while clinical guidance increasingly treats them as actionable. Overdiagnosis in surveillance is unquantified. The generic antiviral prices quoted come from global procurement and are not like-for-like with the United States cash prices used elsewhere here.

## 5. Breast cancer

**What it is.** Cancer of the breast tissue, in the great majority of cases arising in the milk ducts or lobules. Oestrogen-receptor-positive disease, HER2-positive disease and triple-negative disease behave differently enough to be treated as different diseases. It is the most commonly diagnosed cancer in women.

**Measured.** WHO gives 2.4 million new cases and 694,000 deaths for 2024. GLOBOCAN 2022 gives 2,296,840 female cases, 11.6 per cent of all cancers, and 6.9 per cent of cancer deaths; GLOBOCAN 2024 gives 2,434,087 cases and 693,660 deaths. Five-year relative survival in United States women is 91.9 per cent overall: localized 100.0, regional 87.5, distant 33.8, unknown 70.6 per cent. Median age 64. Stage at diagnosis: localized 64, regional 27, distant 6, unknown 2 per cent. Incidence is highest in high-income countries and the mortality-to-incidence ratio is highest in low-income countries: that gap is a treatment-access gap, not a biology gap. United States incidence is rising about 0.7 per cent a year and the death rate falling 1.2 per cent a year.

**Where it starts.** Lifetime risk is 55 to 65 per cent in BRCA1 carriers and 45 to 47 per cent in BRCA2 carriers, against 13 per cent in the general population. Alcohol at about four drinks a day: relative risk 1.32, interval 1.19 to 1.45, rising about 7 per cent per additional drink a day. Obesity in postmenopausal women never using hormone therapy, heaviest against lightest: 2.85, interval 1.81 to 4.49. Menopausal oestrogen-progesterone therapy: 1.60 in years one to four and 2.08 in years five to fourteen; oestrogen alone 1.17 and 1.33; combination therapy raises invasive breast cancer about 26 per cent, number needed to harm 237. Physical activity is protective at about 20 per cent, summary relative risk 0.88 across 38 prospective studies. Ionising radiation, breast density, early menarche, late menopause, nulliparity, late first pregnancy and absence of breastfeeding are all rated solid. Mutation burden sits at or somewhat below the adult reference of 1.8 per megabase, with higher

burdens and homologous-recombination-deficiency signatures in triple-negative and BRCA-deficient tumours. Not known: the cause of the large majority of cases — the established risk factors together account for only a minority, and most women diagnosed have no identifiable cause; why incidence is rising; the mechanism linking density to risk.

**Cure status.** Ductal carcinoma in situ: CURABLE — and this is where the overdiagnosis problem sits, because an unknown but substantial proportion would never have progressed to invasive cancer in the woman's lifetime, and almost all of it is treated. Localized, stage I: CURABLE — five-year relative survival 100.0 per cent, meaning survival indistinguishable from the general population at five years; twenty-year figures are lower, because relapse in receptor-positive disease continues for decades. Regional, stage II to III: CURABLE in 87.5 per cent (five-year relative survival). Distant, stage IV: CONTROLLABLE — 33.8 per cent. Within distant disease, receptor-positive cancer is often controlled for years with endocrine therapy, HER2-positive cancer now has median survival approaching five years, and triple-negative cancer has median survival of about 12 to 18 months†.

**Prevention.** Tamoxifen in high-risk women — STRONG. The Breast Cancer Prevention Trial gave 49 per cent lower incidence at four years, 85 against 154 invasive cases; pooled high-risk data give a 30 to 50 per cent reduction in receptor-positive cancer and ductal carcinoma in situ over five years of treatment, lasting at least sixteen years from starting. No overall mortality benefit has been demonstrated: relative risk 1.10, interval 0.85 to 1.43, at seven years. The harms are endometrial cancer, hazard ratio 2.18, interval 1.39 to 3.42, and venous thromboembolism, 1.73, interval 1.47 to 2.05. Raloxifene — STRONG for incidence reduction in postmenopausal women, with no endometrial excess, hazard ratio 1.09, interval 0.74 to 1.62, and an increase in thromboembolism. Aromatase inhibitors — STRONG. Exemestane in MAP.3 gave invasive cancer hazard ratio 0.35, interval 0.18 to 0.70, about 65 per cent, with 21 cancers avoided among 2,280 participants over 35 months and a number needed to treat of about 100; anastrozole in IBIS-II gave 53 per cent, persisting at eleven years. Risk-reducing bilateral mastectomy — STRONG for risk, reducing it by as much as 90 per cent, and unproven for survival, where reported benefits are generally attributed to selection bias. Risk-reducing salpingo-oophorectomy in BRCA carriers — STRONG. Physical activity — MODERATE. Alcohol reduction — STRONG on the dose-response. Mammographic screening — the mortality reduction is real and the overdiagnosis figure is genuinely contested, and both are printed. The UK Independent Breast Screening Review of 2012 gave a relative mortality reduction of 20 per cent, relative risk 0.80, interval 0.73 to 0.89; one death prevented per 235 women invited, equal to 43 deaths prevented per 10,000 women aged 50 invited over 20 years; and overdiagnosis of 19 per cent of breast cancers diagnosed in invited women, equal to 129 per 10,000. The implied ratio of about three overdiagnosed cancers per death prevented is an arithmetic inference from those two per-10,000 figures, which may not share an identical time frame, and the panel did not state it. The Cochrane review of 2013 gave breast cancer mortality at thirteen years as relative risk 0.90, interval 0.79 to 1.02, not significant, in the three adequately randomised trials, against 0.75, interval 0.67 to 0.83, in the four suboptimally randomised ones; it assumes a 15 per cent mortality reduction and 30 per cent overdiagnosis, and summarises that per 2,000 women invited over ten years about one woman avoids dying of breast cancer, about ten healthy women are treated unnecessarily, and more than 200 experience important psychological distress from false-positive findings. The disagreement is substantive. The two groups differ on which trials are adequately randomised and on the denominator for the overdiagnosis percentage. WHO recommends mammographic screening for women aged 50 to 69 where health systems are strong.

**Treatment.** Breast-conserving surgery with radiotherapy and mastectomy give equivalent survival, with curative intent for stages I to III. Endocrine therapy follows for receptor-positive disease. Tamoxifen is a listed medicine, for early-stage and for metastatic breast cancer, and off-patent: United States cash prices are US$0.43 to 0.68 per 20 mg tablet, US$20.48 for 30 and US$430.56 for 1,000, so five years of treatment at one tablet a day, for orientation only, costs US$785 to 1,241 at those United States cash prices, October 2026, against US$80 to 250 at generic international prices, 2024, and it reduces recurrence by about half and breast cancer mortality by about a third in receptor-positive disease. Anastrozole is listed and off-patent and also costs a few cents a tablet generically. Doxorubicin, cyclophosphamide, paclitaxel, docetaxel, fluorouracil, methotrexate and carboplatin are all listed and all off-patent, at tens to low hundreds of dollars a vial. Trastuzumab for HER2-

positive disease is listed; the originator is off-patent in most markets and biosimilars have cut the price by a reported 50 to 75 per cent in several markets†. A precise current per-course figure could not be retrieved; the originator price for a year of adjuvant treatment was historically in the region of US$50,000 to 70,000 at United States list. Pertuzumab, trastuzumab emtansine and trastuzumab deruxtecan are not listed and all on patent, at annual costs in the region of US$100,000 to 200,000 and above at United States list†; trastuzumab deruxtecan has the highest measured response rates in the class, above 50 per cent in the registrational trials†. Palbociclib, ribociclib and abemaciclib are not listed and on patent at US$150,000 a year and above at United States list†; they roughly double progression-free survival added to endocrine therapy, and the overall survival benefit is not uniform across the class. Olaparib and talazoparib are not listed. Pembrolizumab is listed, for other indications, and used in triple-negative disease. Radiotherapy reduces local recurrence after conserving surgery and improves survival in node-positive disease, and requires a linear accelerator.

**Simple means.** Simple mastectomy with axillary clearance is achievable with basic instruments, anaesthesia and a general surgeon. For a woman with operable disease and no access to radiotherapy, mastectomy rather than conservation is the correct simple-means choice, because conservation depends on the radiotherapy. Tamoxifen is the most important simple means in this entry: oral, off-patent, pennies a day, no cold chain, no monitoring beyond clinical review, and for receptor-positive disease it delivers a large fraction of the total available survival benefit. Clinical breast examination and breast awareness need no equipment; the evidence that they reduce mortality is weak, and the measured effect is a stage shift. Oral morphine serves bone-metastasis pain, and single-fraction palliative radiotherapy is highly effective for it in one visit where a machine exists. HER2-positive and triple-negative disease have no simple-means answer: trastuzumab needs a cold chain and intravenous infusion, and without it HER2-positive disease is substantially worse. The gap between simple means and the full chain is wider in breast cancer than in cervical or gastric cancer.

**Gaps.** Mammography overdiagnosis is the most contested figure in cancer screening, and the dispute — 19 against 30 per cent, and a 20 per cent mortality reduction against a non-significant one — is unresolved. Tamoxifen prevention reduces incidence with no demonstrated mortality benefit. Risk-reducing mastectomy has no demonstrated survival benefit. Trastuzumab and biosimilar pricing could not be retrieved and the figures given are historical. The established risk factors explain only a minority of cases.

## 6. Cervical cancer

**What it is.** Cancer of the neck of the womb, caused in virtually every case by persistent infection with a high-risk human papillomavirus. It develops through a long pre-cancerous stage that can be detected and treated. It is the most preventable of the common cancers and the one where the gap between what is possible and what is delivered is widest.

**Measured.** GLOBOCAN 2022 gives 662,301 cases at an age-standardised rate of 14.1 per 100,000 and 348,874 deaths; GLOBOCAN 2024 gives 604,196 cases and 279,583 deaths. The WHO sexually transmitted infections fact sheet gives over 311,000 cervical cancer deaths a year, and WHO records cervical cancer as the most common cancer among women in 26 countries. Five-year relative survival in the United States is 68.8 per cent overall: localized 91.8, regional 64.0, distant 20.5, unknown 62.3 per cent. Median age at diagnosis 50, which is why the burden in disability-adjusted life years exceeds what the case count suggests. Stage at diagnosis: localized 41, regional 37, distant 16, unknown 6 per cent. The geographical gradient is a screening and HIV gradient: the highest age-standardised incidences are Eswatini 95.9, Zambia 71.5, Malawi 70.9, Zimbabwe 68.2 and Tanzania 64.8, against 6.3 in the United States — a fifteenfold range. In countries with organised cytology screening, incidence fell by 60 to 80 per cent over the decades after the programme started†.

**Where it starts.** Persistent infection with certain high-risk human papillomavirus types causes about 95 per cent of cervical cancers, and types 16 and 18 cause around 76 per cent. It is the clearest single-cause cancer in this chapter. de Martel and colleagues, 2020, attribute about 690,000 cancer cases worldwide across all sites to human papillomavirus, at an age-standardised incidence of 8.0 per 100,000, the majority cervical, and the attributable rate rises as income falls, from 6.9 in high-income countries to 16.1 in low-income countries. Women living with HIV are six times more likely to develop cervical cancer, and about 5 per cent of all cases are attributable to HIV. Among infected women, current and former smokers

have about two to three times the incidence of high-grade intraepithelial neoplasia or invasive cancer. Six or more lifetime sexual partners against one: relative risk 2.98 for squamous carcinoma. First intercourse at 17 or younger against 21 or older: 2.24. Oral contraceptives in infected women: odds ratio 0.73 under five years, not significant, 2.82 at five to nine years and 4.03 at ten years or more, returning to baseline about ten years after stopping. Diethylstilboestrol exposure in utero: about one in a thousand exposed daughters develop clear cell adenocarcinoma, and grade II or higher intraepithelial neoplasia occurred in 6.9 against 3.4 per cent, hazard ratio 2.28. The driving event is viral oncoprotein expression inactivating p53 and Rb rather than an accumulation of point mutations, so mutation burden is a poor description of this cancer. Not known: why only a small minority of infections persist and progress, most clearing within two years, and what determines persistence.

**Cure status.** Human papillomavirus infection: SELF-LIMITING — most infections clear spontaneously within one to two years with no treatment. This is the one place in the chapter where SELF-LIMITING is the right label for a precursor state. High-grade intraepithelial neoplasia, CIN2 or CIN3: CURABLE — cryotherapy, thermal ablation or large-loop excision cures the great majority in a single outpatient visit. Localized invasive, stage I: CURABLE — five-year relative survival 91.8 per cent. Regional, stage II to III: CURABLE in 64.0 per cent (five-year relative survival), with cisplatin chemoradiation. Distant, stage IV: CONTROLLABLE — 20.5 per cent.

**Prevention.** Human papillomavirus vaccination — STRONG, with efficacy figures among the highest in preventive medicine. Against incident and persistent infection: 91.6 per cent, interval 64.5 to 98.0, for type 16, and 100 per cent, interval 45 to 100, for type 18. The bivalent vaccine gave 100 per cent, interval 81.8 to 100, against persistent type 16 or 18 infection per protocol, and 100 per cent, interval 51.3 to 100, against CIN2 or worse in the total vaccinated cohort, neither analysis being intention-to-treat. The quadrivalent trials gave 100 per cent, interval 90.5 to 100, against CIN3 in the virus-naive, against 45.3 per cent, interval 29.8 to 57.6, by intention to treat: that gap is the measure of how much depends on vaccinating before exposure. Against invasive cancer, the endpoint that matters, the Swedish national cohort published in the *New England Journal of Medicine* in 2020 gave an incidence rate ratio of 0.51, interval 0.32 to 0.82, adjusted for age alone. After full adjustment, vaccination before age 17 gave an incidence rate ratio of 0.12, interval 0.00 to 0.34: an 88 per cent reduction. A Scottish cohort vaccinated at age 12 to 13 gave an 87 per cent relative reduction in cervical cancer, interval 72 to 94, and 97 per cent in CIN3. One dose is non-inferior to two for protection against the targeted types, which has large consequences for programme cost. WHO projects that widespread vaccination could cut incidence worldwide by as much as 90 per cent. Global first-dose coverage in girls reached 33 per cent in 2025, up from 17 per cent in 2019, against a 90 per cent target for 2030. Screening — STRONG. WHO recommends a high-performance human papillomavirus test every five to ten years from age 30, and every three to five years from age 25 for women with HIV, and states that self-collection is as reliable as provider collection. The elimination targets for 2030 are 90 per cent of girls fully vaccinated by age 15, 70 per cent of women screened with a high-performance test by 35 and again by 45, and 90 per cent of women with pre-cancer or invasive cancer treated appropriately. Barrier contraception — MODERATE, relative risk 0.4, interval 0.2 to 0.9. Smoking cessation — MODERATE. The harms of screening are over-treatment of low-grade lesions that would have regressed, and excisional treatment carries a measurable increase in subsequent preterm birth, which is the most important harm in young women. **Overdiagnosis percentages comparable to the breast and prostate figures have never been published for cervical intraepithelial neoplasia**, partly because the treated entity is a precursor rather than a cancer. That is a gap in the literature, not evidence of no harm.

**Treatment.** Ablation or excision of high-grade pre-cancer — thermal ablation, cryotherapy or loop excision — is an outpatient, single-visit, curative procedure in the great majority. Radical hysterectomy with pelvic lymphadenectomy treats early invasive disease. Chemoradiation with cisplatin is the single most important curative treatment for stage II to III; cisplatin is a listed medicine, with cervical cancer among its listed indications, off-patent, at a drug cost of tens of dollars a course. The binding constraint is the machine, not the drug, and brachytherapy in particular is essential for cure in locally advanced disease and unavailable across much of sub-Saharan Africa. Carboplatin and paclitaxel are both listed and off-patent. Bevacizumab is not listed for this indication. Pembrolizumab is a selected medicine on the list for metastatic cervical cancer with PD-L1 expression of 1 per cent or more, in combina-

tion with platinum-based chemotherapy; it is not off-patent, at a United States cash price of US$1,530.35 per 4 mL (100 mg) unit and US$6,121.41 per four-unit pack at the United States cash price, October 2026, which is about US$53,000 a year at 200 mg every three weeks, against US$150,000 to 200,000 a year at United States list price. A drug at that price being listed as essential for a cancer that is 95 per cent preventable by a vaccine costing under ten dollars a dose is the sharpest cost contrast in this chapter.

**Simple means.** This is the entry where simple means do the most work in the chapter. Visual inspection with acetic acid needs a speculum, a light source and a trained nurse or midwife: no laboratory, no pathologist, no electricity beyond a torch, and the result is immediate, so the woman can be treated at the same visit. WHO's current position has moved on: its cervical cancer guidance now recommends a high-performance human papillomavirus test as the primary screen and describes acetic acid application as the examination used after a positive screen to locate lesions. Where testing is genuinely unavailable, visual inspection with same-visit thermal ablation remains the only screen-and-treat approach that works with no industrial chain. Thermal ablation uses a hand-held battery or mains probe costing a few hundred dollars, with no gas cylinder and no cold chain, and cure rates for CIN2 and CIN3 comparable to cryotherapy†. Cryotherapy with a carbon dioxide or nitrous oxide cylinder needs no electricity, and the cylinder logistics are a real constraint. Self-collection removes the speculum, the clinic visit and much of the cultural barrier. Vaccination is one or two intramuscular doses in a girl aged 9 to 14, within the routine immunisation cold chain. Oral morphine matters disproportionately here, because so many women present with advanced disease, are young and have dependent children. What has no simple substitute is brachytherapy. Cure of locally advanced cervical cancer requires it and there is no low-technology equivalent: the prevention and the pre-cancer treatment are simple, and the treatment of established locally advanced disease is not.

**Gaps.** The Osmanabad cluster-randomised trials of visual inspection and human papillomavirus screening in India — the key randomised evidence that a no-laboratory screen reduces cervical cancer mortality — could not be retrieved, so no hazard ratio is quoted here. Over-treatment of intraepithelial neoplasia has no published percentage. WHO's downgrading of visual inspection from primary screen to triage is not always reflected in secondary sources, and programmes still run it as a primary screen. GLOBOCAN 2022 and 2024 give materially different figures — 662,301 against 604,196 cases and 348,874 against 279,583 deaths. A 20 per cent fall in deaths over two years is larger than any plausible real change and most likely reflects a methodological revision. It should not be read as a trend.

## 7. Prostate cancer

**What it is.** Cancer of the prostate gland. Most of it grows so slowly that it never causes symptoms or death, and a minority is aggressive and lethal. The central clinical problem is telling the two apart, and the central epidemiological fact is that very large numbers of men have prostate cancer without ever knowing it.

**Measured.** WHO gives 1.5 million new cases for 2024. GLOBOCAN 2022 gives 1,467,854 cases, 7.3 per cent of all cancers; GLOBOCAN 2024 gives 1,546,112 cases and 419,849 deaths. Five-year relative survival in the United States is 98.2 per cent overall: localized 100.0, regional 100.0, distant 40.1, unknown 94.1 per cent. The two 100 per cent figures mean five-year survival indistinguishable from the general male population, and they are the strongest single piece of evidence that much of what is diagnosed would never have caused harm. Median age 68. Stage at diagnosis: localized 69, regional 14, distant 9, unknown 8 per cent. Incidence is highest in high-income countries with prostate-specific antigen testing and in men of African ancestry everywhere, and the mortality-to-incidence ratio is far higher in sub-Saharan Africa and the Caribbean. United States incidence is rising 2.7 per cent a year, the steepest rise of any common cancer here, while the death rate falls 0.8 per cent a year.

**Where it starts.** Age dominates. Incidental prostate cancer is found at autopsy in 5 per cent of men under 30, interval 3 to 8, and 59 per cent of men over 79, interval 48 to 71, across 29 autopsy studies dated 1948 to 2013, rising about 1.7-fold per decade. About 15 per cent of men with prostate cancer have a first-degree relative with the disease against about 8 per cent of the United States population, and about 9 per cent of cases may result from heritable susceptibility genes. Risk of developing and of dying from it is highest in Black men,

intermediate in White men and lowest in native Japanese men, and the incidence difference is not explained by access to care. PDQ's prevention summary does not mention BRCA2, although BRCA2 is established elsewhere as conferring elevated risk of aggressive disease; that is a gap in the source. Primary prostate adenocarcinoma has one of the lowest point-mutation burdens of any adult carcinoma, well below the adult reference of 1.8 per megabase, and is driven instead by structural rearrangement, most characteristically the TMPRSS2-ERG fusion present in roughly half of cases. The low burden is the leading explanation for its poor response to checkpoint blockade. Not known: what distinguishes the indolent majority from the lethal minority at diagnosis, reliably enough to act on; why incidence and mortality are so much higher in men of African ancestry. **No modifiable risk factor for prostate cancer has been established with the confidence that smoking is established for lung cancer**, and that is the largest void in the chapter for a cancer of this size.

**Cure status.** Indolent localized, Gleason 6 and low-volume: CONTROLLABLE by surveillance — the ProtecT randomised trial found no difference in prostate-cancer mortality between surgery, radiotherapy and active monitoring at ten and at fifteen years, with monitoring producing more metastases. Treatment is not indicated, and applying CURABLE to this stratum would mislead. Localized clinically significant, Gleason 7 and above: CURABLE — five-year relative survival 100.0 per cent. Regional: CURABLE — five-year relative survival 100.0 per cent, which understates the long-term relapse rate. Distant, metastatic: CONTROLLABLE — 40.1 per cent. Androgen deprivation with an androgen-receptor-pathway inhibitor or docetaxel now gives median survival in the region of five years in hormone-sensitive metastatic disease; castration-resistant disease remains uniformly fatal.

**Prevention.** There is no established means of primary prevention, and that is the honest summary. 5-alpha reductase inhibitors — CONTESTED, and the two findings point in opposite directions. The Prostate Cancer Prevention Trial gave finasteride incidence of 18.4 against 24.4 per cent, a relative reduction of 24.8 per cent, interval 18.6 to 30.6; REDUCE gave dutasteride an absolute reduction of 5.1 per cent at four years, relative 22.8 per cent, interval 15.2 to 29.8. Against that, finasteride produced high-grade cancers, Gleason 7 to 10, in 6.4 against 5.1 per cent, relative risk 1.27, interval 1.07 to 1.50, a statistically significant excess; dutasteride showed no significant difference in Gleason 8 to 10 over years one to four, 29 against 19 cases. Mortality: finasteride hazard ratio 0.75, interval 0.50 to 1.12, not significant, and PDQ states the evidence is inadequate to determine whether either drug reduces prostate cancer mortality. Screening with prostate-specific antigen — the mortality benefit is small, the overdiagnosis is large, and the trials disagree. Both sides are printed, from the USPSTF evidence review of 2018. ERSPC, in men aged 55 to 69, gave prostate cancer mortality at thirteen years of 4.3 against 5.4 deaths per 10,000 person-years, rate ratio 0.79, interval 0.69 to 0.91. The number needed to screen was 781, interval 490 to 1,929, to prevent one prostate cancer death over thirteen years, an absolute reduction of about 1.28 deaths per 1,000 men screened. The metastatic-cancer rate ratio at twelve years was 0.70, an absolute reduction of 3.1 metastatic cases per 1,000 men. There was no reduction in all-cause mortality. PLCO gave prostate cancer mortality at a median of 14.8 years with a rate ratio of 1.04, interval 0.87 to 1.24, no significant difference, in a trial whose control group had about 78 per cent prostate-specific antigen testing, so it is better described as a trial of organised against opportunistic screening. CAP, a single invitation in the United Kingdom, gave a rate ratio of 0.99, interval 0.94 to 1.03, at a median of ten years, with only 34 per cent of invited men having a valid test. **Overdiagnosis: 20 to 50 per cent of screen-detected cancers.** About 21 per cent of screen-detected cancers in PLCO and about 50 per cent in ERSPC were judged overdiagnosed, and CISNET decision models estimated 22 to 42 per cent for United States screen-detected cancers from 1988 to 2000. That is a more-than-twofold disagreement between the two main trials, and both ends are printed. The USPSTF recommendation is grade C, an individual decision, for men 55 to 69, and grade D, against, for men 70 and older. Beyond overdiagnosis the harms are biopsy complications — infection, bleeding, sepsis — and the treatment harms that follow overdiagnosis: erectile dysfunction and urinary incontinence after prostatectomy, bowel and urinary toxicity after radiotherapy. Those harms fall on men whose cancer would never have hurt them.

**Treatment.** Active surveillance is the correct treatment for a large fraction of localized disease, and it is free. Radical prostatectomy and radical radiotherapy give equivalent survival for clinically significant localized disease. Androgen deprivation follows: goserelin, leuprorelin and triptorelin are all listed and off-patent with generics in many markets, and

bicalutamide, flutamide and nilutamide are all listed, off-patent and cheap. Docetaxel added to androgen deprivation in metastatic hormone-sensitive disease is listed and off-patent at tens to low hundreds of dollars a vial. Abiraterone is listed and has been off-patent in most markets since about 2018 to 2019, with generics at a small fraction of the originator price†. That originator price was in the region of US$9,000 to 10,000 a month at United States list, and generics have fallen to the low hundreds of dollars a month in competitive markets. Enzalutamide is listed; its patent status is market-dependent and it remains expensive in most, in the region of US$10,000 a month and above at United States list†. Radium-223 and lutetium-177-PSMA are not listed and require a radiopharmacy. Olaparib is not listed. Checkpoint inhibitors are essentially inactive outside the rare microsatellite-unstable subset, with response rates in the single digits in unselected castration-resistant disease, consistent with the low mutation burden.

**Simple means.** Bilateral orchidectomy is the outstanding simple means in this entry. It is a short operation under local or spinal anaesthesia with basic instruments, it achieves castrate testosterone permanently in one sitting, it costs almost nothing, and it is therapeutically equivalent to lifelong agonist injections for metastatic disease. Where drug supply is unreliable it is the correct treatment rather than a compromise. Its disadvantages are irreversibility and psychological cost. Transurethral resection or a suprapubic catheter relieves retention from local disease at once. Oral morphine serves the bone pain that dominates advanced prostate cancer, and single-fraction palliative radiotherapy to a painful bone metastasis is one of the highest-value single interventions in oncology where a machine exists. Digital rectal examination needs no equipment; its sensitivity for early cancer is poor and it is not a screening test, and it detects locally advanced disease. Nothing simple prevents prostate cancer, and nothing simple distinguishes the indolent from the lethal: diagnosis requires biopsy and histopathology. The simple means here are all about controlling established disease, and orchidectomy is a genuinely large one.

**Gaps.** Overdiagnosis ranges from 20 to 50 per cent across sources, with PLCO at 21 and ERSPC at 50, and the disagreement is unresolved. ERSPC, PLCO and CAP give materially different mortality answers, attributed to control-group contamination and compliance, and the true effect size is not settled. The 5-alpha reductase question has not been resolved in two decades. No modifiable risk factor is established, so prevention has nothing to offer. PDQ's prevention summary does not address BRCA2. The excess burden in men of African ancestry is unexplained. SEER's 100 per cent five-year figures are uninformative about long-term outcome, and ten- and fifteen-year stage-specific figures are not published on the Stat Facts page. The intermediate age-group autopsy prevalences, between 5 and 59 per cent, are not in the retrievable abstract of Bell and colleagues.

## 8. Pancreatic cancer

**What it is.** Cancer of the pancreas, almost always ductal adenocarcinoma. It produces no symptoms until it is advanced, it spreads early, and it resists almost all drug treatment. Its incidence and its death rate are nearly the same number, which is the shortest description of the problem.

**Measured.** GLOBOCAN 2022 gives 510,992 cases; GLOBOCAN 2024 gives 531,318 cases and 490,786 deaths, so deaths are 92 per cent of incidence. No other major cancer comes this close. Five-year relative survival in the United States is 13.7 per cent overall: localized 43.6, regional 17.0, distant 3.4, unknown 12.5 per cent. Median age 71. Stage at diagnosis: localized 15, regional 28, distant 51, unknown 5 per cent. It is 3.2 per cent of United States cancer cases and 8.4 per cent of United States cancer deaths, and in several high-income countries it has overtaken breast cancer as the third leading cause of cancer death. United States incidence is rising about 0.9 per cent a year and the death rate is stable.

**Where it starts.** The NCI PDQ prevention summary for pancreatic cancer could not be retrieved, so the effect sizes here carry no evidence grade, which is an asymmetry against the rest of the chapter. Smoking is the best-established modifiable cause, with a relative risk for current smokers generally reported in the region of 1.7 to 2.2 and an attributable fraction of roughly 20 to 25 per cent of cases†. Obesity is reported at a relative risk in the region of 1.5 for a body mass index of 30 or more†. Type 2 diabetes is associated with roughly 1.5- to twofold risk†, with a large interpretive problem: new-onset diabetes is frequently an early manifestation of the cancer rather than a cause of it, so reverse causation confounds this

association more than any other in the chapter. Hereditary pancreatitis confers a lifetime risk reported in the region of 40 per cent†. BRCA2, BRCA1, PALB2, ATM, CDKN2A, STK11, Lynch syndrome and hereditary pancreatitis together account for roughly 10 per cent of cases†. Mutation burden is low to moderate, around or below the adult reference of 1.8 per megabase, and the disease is dominated by four drivers — KRAS, mutated in roughly 90 to 95 per cent of cases, with TP53, CDKN2A and SMAD4. KRAS was undruggable for forty years, and the G12C inhibitors now entering use address a small minority of pancreatic KRAS mutations. Not known: why it is silent until advanced; whether the diabetes association is cause or consequence and in what proportion; why the dense stromal reaction makes it so resistant to drugs. **There is no validated early-detection test**, and that is the single largest unmet need here.

**Cure status.** Localized and resectable, about 15 to 20 per cent at presentation: CURABLE in roughly 30 to 50 per cent of patients who complete resection and adjuvant chemotherapy (five-year survival in trial populations); five-year relative survival for localized disease is 43.6 per cent. Borderline resectable and locally advanced: CONTROLLABLE — 17.0 per cent. Metastatic: RELIEF ONLY — 3.4 per cent. Median survival with FOLFIRINOX in fit patients is in the region of eleven months and with gemcitabine monotherapy in less fit patients about six. Pancreatic cancer belongs on the short list of cancers that are not reliably curable even when caught early, because early by current detection methods still usually means systemically disseminated.

**Prevention.** Smoking cessation — MODERATE on the measured pancreatic effect, with the figures above unverified. Weight control — WEAK. There is no screening programme in the general population and no basis for one: prevalence is too low and no test has adequate performance. Surveillance of high-risk individuals with defined germline mutations or a strong family history, using magnetic resonance imaging and endoscopic ultrasound, is offered in specialist centres and detects some resectable lesions; whether it reduces mortality has not been established in a randomised trial. The harms include a high rate of investigation of cystic lesions that would never have progressed, and pancreatic surgery carries a mortality of 1 to 3 per cent even in high-volume centres†, so an unnecessary resection is a serious harm. Population screening is not recommended, on no evidence of benefit. Pancreatic cancer is the major cancer with the least to offer in prevention: no vaccine, no eradicable infection, no dominant modifiable exposure of the kind smoking is for lung, and no effective screen.

**Treatment.** Surgical resection — pancreaticoduodenectomy or distal pancreatectomy — is the only curative modality, with 1 to 3 per cent mortality in high-volume centres and considerably higher elsewhere; the volume-outcome relationship is one of the strongest in surgery. Modified FOLFIRINOX is the standard adjuvant regimen for fit patients after resection and produced the largest survival gain of any adjuvant regimen in this disease, a median overall survival of roughly 54 against 35 months in PRODIGE-24†. **Fluorouracil, calcium folinate, irinotecan and oxaliplatin are all listed and all off-patent**, at a drug cost in the low hundreds of dollars for a full adjuvant course. That is the most important fact in this section: the best adjuvant regimen for pancreatic cancer is made entirely of off-patent listed medicines. Gemcitabine, alone or with capecitabine, serves patients unfit for FOLFIRINOX; both are listed, off-patent and cheap. Nab-paclitaxel is not listed and is not the same agent as the off-patent paclitaxel that is. Erlotinib added to gemcitabine is listed and off-patent, and the measured survival gain was about two weeks, which is worth stating as a calibration point on what statistical significance has meant in this disease. Olaparib maintenance in BRCA-mutant metastatic disease is not listed and benefits a few per cent of patients. Checkpoint inhibitors are inactive outside the roughly 1 per cent that is microsatellite-unstable, with response rates near zero in unselected disease: the clearest negative result for immunotherapy among the major cancers, consistent with the low mutation burden and the immunosuppressive stroma. Biliary stenting for obstructive jaundice is not a cancer treatment and is among the most valuable interventions available.

**Simple means.** Where endoscopic stenting is unavailable, a surgical double bypass — choledochojejunostomy or cholecystojejunostomy with gastrojejunostomy — relieves jaundice and duodenal obstruction with basic instruments and a general surgeon. It is a major but entirely conventional operation and it transforms the final months. Oral morphine in adequate dose matters more here than almost anywhere: coeliac plexus infiltration causes a boring epigastric and back pain that responds poorly to small doses. A coeliac plexus block with alcohol or

phenol can be performed percutaneously using anatomical landmarks, and intraoperatively under direct vision during a bypass laparotomy at no extra cost, which is a genuinely simple and underused means. Oral pancreatin replaces the exocrine failure that causes steatorrhoea and weight loss; it is cheap, oral, off-patent and listed, for cystic fibrosis, and widely omitted. Nutritional support, antiemetics and dexamethasone, listed and off-patent at a United States-equivalent indicative price of 24 cents a 4 mg tablet in the UNICEF Supply Catalogue, October 2026, serve anorexia and duodenal oedema. For the cancer itself nothing simple exists: no simple prevention, no simple detection and no simple cure. The whole of the simple-means contribution in pancreatic cancer is palliative, and it is substantial on its own terms without extending life.

**Gaps.** The PDQ pancreatic prevention summary could not be retrieved, so the risk-factor effect sizes carry no evidence grade. The diabetes association is confounded by reverse causation to an extent that is acknowledged and not quantified. High-risk surveillance has no randomised mortality evidence. No early-detection test exists, and the biomarker claims in this field have not been validated.

## 9. Oesophageal cancer

**What it is.** Cancer of the gullet, in two forms with different causes and geography. Squamous cell carcinoma is tied to tobacco, alcohol and hot drinks and dominates in Asia and Africa; adenocarcinoma is tied to reflux, obesity and Barrett's oesophagus and dominates and is rising in Western countries. Both present late, because swallowing only becomes difficult when the lumen is already badly narrowed.

**Measured.** GLOBOCAN 2022 gives 511,054 cases; GLOBOCAN 2024 gives 494,320 cases and 441,994 deaths, so deaths are about 89 per cent of incidence. Five-year relative survival in the United States is 22.2 per cent overall: localized 48.6, regional 29.1, distant 5.3, unknown 15.9 per cent. Median age 69. Stage at diagnosis: localized 19, regional 32, distant 39, unknown 10 per cent. Squamous carcinoma was over 90 per cent of oesophageal tumours in the 1960s, and adenocarcinoma is now more prevalent than squamous in the United States and Western Europe; globally squamous remains the majority. The highest squamous rates run in a belt from northern Iran through Central Asia to north-central China, with eastern and southern Africa also high. United States incidence is falling about 0.6 per cent a year and the death rate 1.1 per cent a year, a fall that combines falling squamous with rising adenocarcinoma incidence.

**Where it starts.** For squamous carcinoma: tobacco, relative risk 2.4, with a population attributable risk of 54.2 per cent, interval 3.0 to 76.2 — an interval so wide as to be nearly uninformative, and PDQ reports it without comment. Alcohol, in a multicentre case-control study of 221 cases and 695 controls, gave a population attributable risk of 72.4 per cent, interval 53.3 to 85.8, with ever-smoking at 56.9 per cent and the two combined at 89.4 per cent; cohort studies adjusted for tobacco give a two- to sevenfold increase for alcohol addiction. On hot beverages the sources disagree by omission: the PDQ oesophageal page does not address them, while IARC's 2016 evaluation classified drinking very hot beverages, above about 65 degrees Celsius, as probably carcinogenic to humans, Group 2A, largely on studies from South America, Iran and China. Both positions are noted. Achalasia, caustic stricture, Plummer-Vinson syndrome, tylosis, low fruit and vegetable intake and nutritional deficiency are established and not quantified on the PDQ page. For adenocarcinoma: PDQ gives no relative risks for smoking or alcohol, a notable asymmetry since both are established at smaller effect sizes. Recurrent reflux symptoms give an odds ratio of 7.7 in a Swedish study, long-standing severe symptoms 43.5, interval 18.3 to 103.5, and daily heartburn with regurgitation 8.0, interval 4.5 to 14.0. Barrett's oesophagus gives adenocarcinoma at about 1.2 cases per 1,000 person-years in a Swedish cohort, roughly 11.3 times the general-population rate, and PDQ adds that the absolute risk is still not high and that over half of adenocarcinoma cases are not linked to reflux symptoms. Obesity is named by PDQ with no risk estimate; elsewhere central obesity is established, with relative risks in the region of 2 to 3 for the highest body mass index categories†. PDQ's grade for reflux and adenocarcinoma is fair evidence of unknown magnitude, and it states that whether eliminating reflux reduces risk is unknown. Both forms carry high mutation burdens, and oesophageal adenocarcinoma is among the most heavily mutated of all tumours, with a very high rate of structural rearrangement and TP53 mutation in the large majority. Not known: why reflux progresses to

Barrett's in a minority and Barrett's to cancer in a small minority of those; why over half of adenocarcinomas arise without reflux symptoms; the mechanism of the hot-beverage effect, where thermal injury is assumed rather than demonstrated.

**Cure status.** Barrett's oesophagus with high-grade dysplasia: CURABLE by radiofrequency ablation or endoscopic resection — one randomised trial with good internal validity, and PDQ states that the effect on cancer mortality is not known. Localized, stage I and mucosal: CURABLE — five-year survival 48.6 per cent for localized disease overall, by endoscopic resection for T1a and oesophagectomy for deeper lesions. Regional, stage II to III: CURABLE in 29.1 per cent (five-year relative survival), with neoadjuvant chemoradiation then oesophagectomy. Distant: RELIEF ONLY — 5.3 per cent. Oesophageal cancer is also one of the cancers where the curative treatment is itself dangerous: oesophagectomy carries an operative mortality of 2 to 5 per cent in high-volume centres and considerably more elsewhere, with major morbidity in a third of patients.

**Prevention.** Tobacco and alcohol avoidance — STRONG for squamous carcinoma. The combined population attributable risk is 89.4 per cent, one of the highest attributable fractions in the chapter, and it is addressable with no technology at all. Alcohol cessation specifically — CONTESTED: PDQ rates the cessation evidence inadequate, with odds ratios of 0.45 for oral cavity and 0.69 for larynx at twenty years or more after cessation and no support for an oesophageal reduction. Never starting is STRONG; stopping is contested. That asymmetry is real and is printed as PDQ states it. Avoiding very hot drinks — WEAK, on an IARC Group 2A classification with no intervention trial. Aspirin and other non-steroidal anti-inflammatory drugs — CONTESTED on net benefit: PDQ gives fair evidence of a small positive effect for squamous carcinoma against solid harms, an upper gastrointestinal excess of 4 to 5 events per 1,000 people a year and serious cardiovascular events up 50 to 60 per cent. Treating reflux to prevent adenocarcinoma — CONTESTED: PDQ states explicitly that it is unknown whether eliminating reflux reduces risk. Radiofrequency ablation of dysplastic Barrett's — MODERATE, one good randomised trial, effect on cancer mortality not known. Weight control — WEAK for adenocarcinoma, with no estimate given. There is no population screening programme outside high-incidence regions of China, where endoscopic screening with Lugol's iodine chromoendoscopy has been deployed and reported to reduce mortality in cluster-randomised and cohort studies; **harms and overdiagnosis from that programme have not been published as percentages**. Barrett's surveillance in Western countries is widely practised with no randomised evidence that it reduces mortality.

**Treatment.** Endoscopic mucosal or submucosal resection cures T1a disease with the organ preserved. Neoadjuvant chemoradiotherapy then oesophagectomy treats resectable locally advanced disease; the CROSS regimen is carboplatin and paclitaxel with radiotherapy, and both drugs are listed and off-patent at a low drug cost. The radiotherapy and the surgery are the expensive and scarce components. Definitive chemoradiotherapy without surgery uses cisplatin and fluorouracil, both listed and off-patent at a trivial drug cost, and for squamous carcinoma it is a legitimate curative alternative to surgery. Palliative chemotherapy for metastatic disease is platinum with a fluoropyrimidine and taxanes second line, all listed and off-patent. Trastuzumab serves HER2-positive oesophagogastric adenocarcinoma and is listed, with the originator off-patent and biosimilars available. Pembrolizumab is a selected medicine on the list, for other listed indications. Nivolumab's listing for this cancer needs checking against the 24th List (2025)†. Neither is off-patent, and pembrolizumab costs US$1,530.35 per 4 mL (100 mg) unit at the United States cash price, October 2026, which is about US$53,000 a year at 200 mg every three weeks, against US$150,000 to 200,000 a year at United States list price. Objective response as monotherapy in pre-treated oesophageal squamous carcinoma is in the region of 15 to 20 per cent†. A self-expanding metal stent is the single most effective palliative intervention, restoring swallowing in one endoscopic session.

**Simple means.** Avoiding tobacco and alcohol, with a combined population attributable risk of 89.4 per cent for squamous carcinoma, is the highest-yield no-technology intervention available for any cancer in this chapter other than lung. A feeding gastrostomy or jejunostomy placed surgically through the abdominal wall, with basic instruments and local or general anaesthesia, allows a patient with complete obstruction to eat. It does not treat the cancer and does not restore swallowing, and it prevents death by starvation and dehydration, which is otherwise how oesophageal cancer kills. Where endoscopic stenting is unavailable this is the intervention that matters most. Oral morphine has a specific limitation here: a

patient who cannot swallow cannot take it, so sublingual, rectal or subcutaneous administration is required, and the rectal route needs no equipment at all. Dilatation of a malignant stricture with bougies or a balloon over a guidewire gives temporary relief and needs no fluoroscopy if done carefully, with a real perforation risk. The curative treatment has no simple-means version: oesophagectomy is one of the largest operations in general surgery and chemoradiation requires a linear accelerator. Simple means here are prevention, which is very large, and palliation of obstruction, which is very valuable, and nothing in between.

**Gaps.** PDQ gives smoking and alcohol relative risks for squamous carcinoma and none for adenocarcinoma, and gives no obesity estimate at all: an asymmetry in the source rather than in the evidence. PDQ does not address hot beverages while IARC classifies them Group 2A. Barrett's surveillance has no randomised mortality evidence. The Chinese endoscopic screening programme's mortality effect and harms are not reported in a form comparable with the Western screening literature. The tobacco attributable-risk interval, 3.0 to 76.2 per cent, is nearly uninformative.

## 10. Bladder cancer

**What it is.** Cancer of the bladder lining, almost always urothelial carcinoma. It divides sharply into non-muscle-invasive disease, which recurs repeatedly and rarely kills, and muscle-invasive disease, which does. Painless blood in the urine is the usual first sign. In parts of Africa and the Middle East a squamous form caused by schistosomiasis predominates instead.

**Measured.** GLOBOCAN 2022 gives 614,298 cases; GLOBOCAN 2024 gives 635,264 cases and 227,626 deaths. Five-year relative survival in the United States is 79.1 per cent overall: in situ 98.0, localized 73.0, regional 41.8, distant 9.6, unknown 50.8 per cent. Median age at diagnosis 73, the oldest in this chapter. Stage at diagnosis: in situ 50, localized 34, regional 7, distant 6, unknown 3 per cent. Half of all United States bladder cancer is diagnosed in situ, which is why the overall survival figure is high and why it conceals a lethal minority. United States incidence is falling about 1.6 per cent a year, tracking the decline in smoking, and the death rate 1.3 per cent a year. Schistosomal squamous bladder cancer is concentrated in Egypt, Sudan and parts of sub-Saharan Africa, where schistosomiasis control has substantially reduced it.

**Where it starts.** The PDQ bladder prevention summary could not be retrieved, so the figures here carry no evidence grade. Smoking is the dominant cause, with a relative risk for current smokers generally reported in the region of 3 to 4 and an attributable fraction of roughly 50 per cent in men and 35 to 50 per cent in women in high-income countries†. Occupational aromatic amines — benzidine, 2-naphthylamine, 4-aminobiphenyl — in dye, rubber, leather, textile and painting work account for roughly 5 to 10 per cent of cases†; this was one of the first occupational cancers ever identified, in 1895. Arsenic in drinking water is an established dose-dependent cause, with the clearest evidence from Taiwan, Chile and Bangladesh. *Schistosoma haematobium* is an IARC Group 1 carcinogen causing squamous bladder carcinoma; de Martel and colleagues, 2020, include it among infectious causes of cancer, and the retrieved summary gave case counts for four agents only, which did not include it. In high-endemic areas schistosomal squamous carcinoma has historically been the majority of bladder cancer, and the attributable fraction there is high and not well quantified in any single source. Cyclophosphamide, itself a cancer drug, and pelvic radiotherapy are established iatrogenic causes, and chronic indwelling catheterisation with chronic infection causes squamous carcinoma in paraplegia. Urothelial carcinoma has one of the highest mutation burdens of any cancer, well above the adult reference of 1.8 per megabase, with prominent APOBEC and tobacco signatures, and that high burden is the explanation for its unusually good response to checkpoint blockade: it was one of the first solid tumours where these drugs were approved. Not known: why some non-muscle-invasive tumours progress to muscle invasion and most do not; why intravesical bacille Calmette-Guérin works, after forty years of use; the quantitative contribution of arsenic at the low concentrations found in many water supplies.

**Cure status.** Non-muscle-invasive disease — Ta, T1, carcinoma in situ: CONTROLLABLE — in situ five-year relative survival 98.0 per cent and localized 73.0 per cent. The qualification is recurrence: up to 50 to 70 per cent recur and 10 to 20 per cent progress to muscle invasion†, so lifelong cystoscopic surveillance is required and the disease is survived rather

than eliminated in many patients. Muscle-invasive, non-metastatic: CURABLE in 41.8 per cent (regional five-year survival), by radical cystectomy with neoadjuvant cisplatin-based chemotherapy or by chemoradiation for bladder preservation. Metastatic with a durable checkpoint-inhibitor response, a minority: CONTROLLABLE. Metastatic otherwise: RELIEF ONLY — five-year survival 9.6 per cent.

**Prevention.** Smoking cessation — STRONG, against an attributable fraction around half. Occupational exposure control — STRONG: aromatic amines are among the best-established occupational carcinogens and their control is a demonstrated success, with bladder cancer rates in exposed trades falling after regulation. Arsenic removal from drinking water — STRONG on the causal evidence, and achievable by simple means. Schistosomiasis control — STRONG. Mass praziquantel administration and snail control have cut *S. haematobium* prevalence substantially, with a corresponding fall in squamous bladder cancer; WHO records at least 253.7 million people requiring preventive treatment for schistosomiasis in 2024, of whom more than 100.5 million were reported treated, a coverage of 39.6 per cent, and a fall of almost 60 per cent in prevalence among school-aged children in sub-Saharan Africa over the past ten years. Praziquantel is a listed medicine, off-patent, and costs under a dollar a treatment: one of the cheapest cancer-preventive interventions that exists. There is no population screening programme for bladder cancer and no recommendation for one. Haematuria dipstick screening detects cancers and has never been shown to reduce mortality, and its false-positive rate leads to large numbers of unnecessary cystoscopies. **Overdiagnosis has never been quantified, because no programme exists to quantify it in**, in a disease where half of all diagnoses are already in situ. Surveillance after treated non-muscle-invasive disease is surveillance of known disease rather than screening, and its intensity rests on recurrence risk rather than on randomised mortality evidence.

**Treatment.** Transurethral resection is both diagnostic and therapeutic for non-muscle-invasive disease and requires a resectoscope and cystoscopy capability. Intravesical bacille Calmette-Guérin is the most effective agent for reducing recurrence and progression in high-risk non-muscle-invasive disease. The vaccine is on the Essential Medicines List as a vaccine, and the intravesical therapeutic preparation is off-patent and inexpensive; global supply has been chronically short for over a decade because few manufacturers make it. That is a supply failure rather than a price failure, and a genuine clinical problem. Intravesical mitomycin C or gemcitabine are alternatives; gemcitabine is listed and off-patent, mitomycin is off-patent, and a single post-operative instillation reduces recurrence cheaply. Radical cystectomy with urinary diversion is the curative surgery for muscle-invasive disease. Neoadjuvant cisplatin-based combination chemotherapy before cystectomy improves survival by about 5 to 8 percentage points absolute†; cisplatin, gemcitabine, methotrexate, vinblastine and doxorubicin are all listed and all off-patent at low generic cost. Chemoradiotherapy for bladder preservation gives comparable survival in selected patients. Pembrolizumab is a selected medicine on the list, for other listed indications. The listing of nivolumab and atezolizumab for this cancer needs checking against the 24th List (2025)†. None is off-patent, and pembrolizumab costs US$1,530.35 per 4 mL (100 mg) unit at the United States cash price, October 2026, which is about US$53,000 a year at 200 mg every three weeks, against US$150,000 to 200,000 a year at United States list price. Objective response in platinum-refractory metastatic urothelial carcinoma is in the region of 15 to 25 per cent as monotherapy, with a long tail of durable responders† — the characteristic pattern of checkpoint blockade here. Enfortumab vedotin with pembrolizumab is not listed and is on patent; the combination produced objective response above 65 per cent and the largest overall survival gain yet seen in metastatic urothelial carcinoma, at an annual cost at United States list well above US$300,000†. Erdafitinib is not listed.

**Simple means.** Praziquantel for schistosomiasis is a single oral dose, listed, off-patent and under a dollar, and it prevents the squamous bladder cancer that follows chronic infection. That is the clearest simple-means cancer prevention available in the settings where schistosomal bladder cancer occurs. Arsenic removal from drinking water — switching to a deep tubewell, rainwater harvesting, or simple iron-based filtration — requires no industrial chain in its simplest versions. Smoking cessation needs no technology. Urinary catheterisation and suprapubic cystostomy relieve outflow obstruction or intractable bleeding immediately. Bladder irrigation through a three-way catheter for clot retention needs only saline and a catheter and stops a patient dying of retention and clot. Formalin or alum bladder instillation for intractable haemorrhagic cystitis from tumour is crude and painful and effective,

requiring nothing beyond the chemical and a catheter where no radiotherapy or embolisation exists. Oral morphine serves pain and transfusion the chronic anaemia of recurrent haematuria. Against that, resection and cystectomy require urological equipment and training, and non-muscle-invasive disease cannot be managed without cystoscopy, for which there is no simple substitute. Bladder cancer is a disease where the prevention has excellent simple means and the treatment has almost none.

**Gaps.** The PDQ bladder prevention summary could not be retrieved, so the risk-factor effect sizes carry no evidence grade. The *S. haematobium*-attributable case count was not obtainable from the retrieved de Martel summary, which gave figures for four agents only. The mechanism of bacille Calmette-Guérin is unknown and the global supply shortage is unresolved. Haematuria screening has never been tested for mortality. Overdiagnosis is unquantified because no screening programme exists.

## 11. Kidney cancer

**What it is.** Cancer of the kidney, mostly renal cell carcinoma arising from the tubules, with clear cell the commonest subtype. A large and rising proportion is found by accident on scans done for other reasons, before it causes any symptom. It responds to immune treatment and is almost entirely resistant to conventional chemotherapy.

**Measured.** GLOBOCAN 2022 gives 434,840 cases; GLOBOCAN 2024 gives 442,570 cases and 144,871 deaths. Five-year relative survival in the United States is 79.2 per cent overall: localized 93.6, regional 77.6, distant 20.3, unknown 55.2 per cent. Median age 65. Stage at diagnosis: localized 66, regional 17, distant 15, unknown 3 per cent. United States incidence is rising about 0.7 per cent a year while the death rate falls 1.1 per cent a year. **That combination is the signature of incidental detection**: more small tumours are being found, and many of them would never have caused harm. Incidence is highest in Europe, particularly Czechia and Lithuania, and North America, and lowest in Africa and Asia.

**Where it starts.** The PDQ kidney prevention summary could not be retrieved, so the figures here carry no evidence grade. Smoking is an established dose-dependent cause with a relative risk generally reported in the region of 1.3 to 1.6 for current smokers, reversible with cessation†. Obesity is one of the strongest obesity-cancer associations, commonly reported at a relative risk in the region of 1.7 to 1.8 for a body mass index of 30 or more, with a clear dose-response†. Hypertension is an established independent risk factor at a reported relative risk in the region of 1.5 to 2†. Chronic kidney disease and end-stage renal failure on dialysis carry substantially elevated risk, partly through acquired cystic disease. Occupational trichloroethylene is IARC Group 1 for kidney cancer. Von Hippel-Lindau disease, hereditary papillary renal carcinoma, Birt-Hogg-Dubé syndrome, hereditary leiomyomatosis and renal cell cancer, succinate dehydrogenase deficiency and tuberous sclerosis together account for roughly 5 per cent of cases†. Von Hippel-Lindau is the key one, because the sporadic clear cell tumours use the same pathway: loss of VHL with constitutive hypoxia-inducible factor activation is near-universal in clear cell disease. Renal clear cell carcinoma has a low point-mutation burden, below the adult reference of 1.8 per megabase, which is a genuine anomaly: it responds well to checkpoint inhibitors despite that, which contradicts the general rule that burden predicts response, and no explanation is established. Not known: why a low-burden tumour is immunotherapy-responsive; why small renal masses behave so variably, some growing indolently for years and others metastasising early; the late and unpredictable relapse pattern, which can run a decade or more after nephrectomy; whether any of the rising incidence is real rather than detection-driven.

**Cure status.** Small renal mass under 4 cm, T1a: CURABLE by partial nephrectomy or ablation — localized five-year relative survival 93.6 per cent. Active surveillance is now an accepted option for small masses in older or comorbid patients, which is an implicit acknowledgement of overdetection. Localized larger, T1b to T2: CURABLE by radical or partial nephrectomy — 93.6 per cent. Regional, T3 to T4 or node-positive: CURABLE in 77.6 per cent at five years — with the proviso that late relapse is characteristic, so five-year figures overstate cure. Metastatic, in the small minority achieving a complete response that persists off treatment: CURABLE. Metastatic otherwise: CONTROLLABLE — five-year survival 20.3 per cent. Combination checkpoint-inhibitor therapy produces complete responses in roughly 10 per cent of patients, some of whom remain disease-free off treatment, which is one of the few settings where a genuinely metastatic solid tumour is sometimes cured by drug therapy;

cytoreductive nephrectomy with metastasectomy can also render selected patients disease-free.

**Prevention.** Smoking cessation — MODERATE. Weight control — MODERATE on the association, with no trial showing that weight loss reduces incidence. Blood pressure control — MODERATE on the association, with no trial evidence on the cancer endpoint. Occupational trichloroethylene control — STRONG, on an IARC Group 1 classification. There is no screening programme and no recommendation for one: the disease is too uncommon and the great majority of what imaging the general population would find would be clinically unimportant. The overdetection is nonetheless already happening, through computed tomography and ultrasound performed for unrelated reasons. **That is unintended screening at scale, with no evidence base and no measurement of its net effect, and no published overdiagnosis percentage exists for kidney cancer comparable to the breast, prostate or thyroid figures.** The rising-incidence and falling-mortality pattern is the best available quantification of it. Kidney cancer has no established effective prevention beyond the general measures, and no screening.

**Treatment.** Partial or radical nephrectomy is the curative treatment, with partial nephrectomy preferred for smaller tumours because it preserves renal function. Thermal ablation serves small masses in unfit patients and is image-guided. Active surveillance is free. Checkpoint-inhibitor combinations are now first-line for metastatic disease: pembrolizumab is a selected medicine, for other listed indications; nivolumab's listing for this cancer needs checking against the 24th List (2025)†; neither off-patent, and ipilimumab is not listed and is on patent. Objective response in first-line metastatic clear cell disease is in the region of 40 to 60 per cent for the combinations, with complete response in roughly 8 to 12 per cent†, at an annual cost at United States list above US$250,000†. Sunitinib, pazopanib, axitinib, cabozantinib and lenvatinib are not listed; everolimus is listed and is now largely superseded in kidney cancer. Sunitinib and pazopanib are off-patent with generics available, which brings a VEGF-directed inhibitor within reach at a few hundred dollars a month in generic markets, against originator prices historically in the region of tens of thousands of US dollars a month and above; sunitinib's response rate as first-line monotherapy was about 30 to 47 per cent in the registrational trials†. For a setting without checkpoint inhibitors, a generic VEGF inhibitor is the realistic option and delivers a real though smaller benefit. Conventional cytotoxic chemotherapy is ineffective in renal cell carcinoma, which is worth stating plainly: the entire off-patent listed cytotoxic armamentarium that serves breast, colorectal and gastric cancer has nothing to offer here. Palliative radiotherapy is effective for bone and brain metastases.

**Simple means.** Radical nephrectomy is a conventional open operation that a general surgeon can perform with basic instruments, anaesthesia and blood availability, and for localized disease it is curative in over 90 per cent of cases†. That is a substantial simple-means cure for a cancer of this size, and it is the main one here. Oral morphine serves bone-metastasis pain and single-fraction palliative radiotherapy serves it better where a machine exists. Transfusion and iron treat the anaemia that is common at presentation. For metastatic kidney cancer nothing simple exists: chemotherapy does not work, so the off-patent cytotoxics are useless, and the effective drugs are either on patent or require a reliable oral supply chain and monitoring. A generic VEGF inhibitor is the lowest rung that still does something, and it is not simple in the sense of needing no industrial chain. There is no simple prevention either.

**Gaps.** The PDQ kidney prevention summary could not be retrieved, so the risk-factor effect sizes carry no evidence grade. Overdetection of small renal masses through incidental imaging is substantial and unquantified. The mechanism by which a low-burden tumour responds to checkpoint blockade is unexplained, and it undermines the general use of mutation burden as a predictor. Late relapse makes five-year survival an unreliable proxy for cure, and SEER does not publish longer-horizon stage-specific figures.

## 12. Ovarian cancer

**What it is.** Cancer arising in the ovary, the fallopian tube or the peritoneum, now understood as largely one disease, with most high-grade serous carcinoma originating in the fallopian tube rather than the ovary. It produces vague abdominal symptoms and is usually widespread in the abdomen by the time it is diagnosed. It is the most lethal of the gynaecological cancers.

**Measured.** GLOBOCAN 2022 gives 324,603 cases; GLOBOCAN 2024 gives 330,731 cases and 203,850 deaths. Five-year relative survival in the United States is 52.0 per cent overall: localized 91.9, regional 70.1, distant 31.5, unknown 38.5 per cent. Median age 63. Stage at diagnosis: localized 22, regional 18, distant 54, unknown 6 per cent. More than half present with disease already spread through the abdomen, and that single fact determines the outcome. Lifetime risk of developing it is 1.12 per cent and of dying from it 0.71 per cent. United States incidence is falling about 1.4 per cent a year, one of the few clear falls in this chapter, attributed substantially to oral contraceptive use and to falling hormone therapy use, and the death rate is falling 2.9 per cent a year.

**Where it starts.** Oral contraceptives are protective and the effect is large and dose-dependent on duration. A collaborative reanalysis of 45 studies gave relative risks against non-users of 0.78 at one to four years, 0.64 at five to nine, 0.56 at ten to fourteen and 0.42 at fifteen years or more. A Danish cohort gave 0.58 for current users and 0.77 for former users, with no benefit from progesterone-only products. Parity is protective: parous against never-parous relative risk 0.69, one child 0.82, four or more 0.58, so parous women carry about 30 per cent lower risk. Breastfeeding is protective. Tubal ligation gives a meta-analytic relative risk of 0.66 and a pooled odds ratio across thirteen studies of 0.71, about a 30 per cent reduction after adjusting for other contraception. Salpingectomy gives about a 50 per cent reduction: meta-analytic odds ratio 0.51, interval 0.35 to 0.71, a Swedish hazard ratio of 0.65 and a Danish bilateral odds ratio of 0.46 against 0.73 for unilateral, which is the clinical expression of the fallopian-tube origin. Menopausal hormone therapy is harmful: a meta-analysis of 52 studies gave a relative risk of 1.37, interval 1.29 to 1.46, for current or recent use in prospective studies. PDQ's ovarian prevention summary does not give a BRCA-specific lifetime risk, referring instead to its genetics summary, and rates family history and BRCA mutations as solid evidence of increased risk; elsewhere BRCA1 lifetime ovarian cancer risk is generally given as roughly 40 to 45 per cent and BRCA2 as roughly 15 to 20 per cent†. Endometriosis carries fair evidence of increased risk. On perineal talc the sources genuinely conflict and both are printed. Case-control meta-analysis gives a relative risk of 1.33, interval 1.16 to 1.45, with no dose-response, and the Ovarian Cancer Association Consortium pooled odds ratio is 1.24, interval 1.15 to 1.33, with no significant trend by number of applications. The two large prospective cohorts find nothing: the Nurses' Health Study relative risk 1.09, interval 0.86 to 1.37, and the Women's Health Initiative hazard ratio 1.06, interval 0.87 to 1.28. PDQ's conclusion is that the results are inconsistent and the data inadequate to show an association. The absence of dose-response in the positive studies is the strongest argument against causation. Dietary factors and aspirin carry inadequate evidence, and ovarian hyperstimulation for infertility treatment is rated uncertain on poor evidence. High-grade serous carcinoma has a moderate point-mutation burden with near-universal TP53 mutation, above 95 per cent, and extensive copy-number alteration; roughly half have homologous recombination deficiency, which is what PARP inhibitors exploit. Not known: why it is silent until advanced; the proportion arising in tube against ovary against peritoneum; whether talc matters at all.

**Cure status.** Localized, stage I: CURABLE — five-year relative survival 91.9 per cent. Regional, stage II: CURABLE in 70.1 per cent (five-year relative survival). Distant, stage III to IV, the majority: CONTROLLABLE — 31.5 per cent. Advanced ovarian cancer responds very well to initial platinum-based chemotherapy, with complete clinical remission in a large majority, and then relapses in most; the pattern is repeated response with progressively shorter intervals, over years. A minority, perhaps 10 to 15 per cent of stage III patients with complete surgical cytoreduction, remain disease-free long term and can be considered cured.

**Prevention.** Oral contraceptive use — STRONG, and among the largest preventive drug effects in this chapter: relative risk 0.42, interval 0.36 to 0.49, at fifteen years or more of use, a 58 per cent reduction, with a meta-analytic estimate of 185 women treated for five years to prevent one case. The harm is venous thromboembolism at about three per 10,000 woman-years, higher with smoking. Bilateral salpingectomy at the time of other pelvic surgery — MODERATE, and increasingly standard: about a 50 per cent reduction, odds ratio 0.46 to 0.51. Done opportunistically at hysterectomy or sterilisation it adds minutes to an operation already under way and removes the organ where the cancer starts. Tubal ligation — MODERATE, relative risk 0.66, with major morbidity at about 1.0 per 100 procedures and minor at about 6.0. Risk-reducing salpingo-oophorectomy in BRCA carriers — STRONG, about a

90 per cent reduction. The harm is large and must be set against it: menopausal symptoms, reduced sexual function, and with early menopause an increased cardiovascular disease risk at a relative risk of 4.55, interval 2.56 to 9.01, which is why the timing of the operation matters. Breastfeeding and parity — MODERATE, not policy-actionable. Avoiding menopausal hormone therapy — MODERATE. Screening does not work, and this is an unusually clear negative result. The PLCO trial of CA-125 and transvaginal ultrasound found no reduction in ovarian cancer mortality, with substantial harm from false positives leading to unnecessary oophorectomy and surgical complications; UKCTOCS, in over 200,000 women with long follow-up, likewise did not demonstrate a significant reduction in its final analysis despite achieving a stage shift. Neither trial could be retrieved in primary form, so no hazard ratios are quoted here. The qualitative conclusion is firm and is the basis of every guideline: ovarian cancer screening is not recommended in the general population, including in most guidelines for BRCA carriers, for whom risk-reducing surgery is recommended instead.

**Treatment.** Cytoreductive surgery aims at complete removal of all visible disease, and the completeness of cytoreduction is the strongest modifiable prognostic factor in advanced disease; it is extensive abdominal surgery, often including bowel resection and peritoneal stripping. Platinum-taxane chemotherapy follows: carboplatin and paclitaxel are both listed and both off-patent, as is cisplatin, whose listed indications include ovarian germ cell tumours. That regimen produces complete clinical remission in the majority of advanced cases and costs a few hundred dollars at generic prices, and it is the single most important treatment in this entry. Other off-patent cytotoxics active in relapse are pegylated liposomal doxorubicin, gemcitabine and etoposide, all listed, and topotecan, which is not. Bevacizumab is not listed for this indication; biosimilars are available and off-patent in many markets. Olaparib, niraparib and rucaparib are not listed and all on patent. In BRCA-mutant advanced disease, olaparib maintenance after first-line chemotherapy produced the largest progression-free survival gain seen in this disease: in SOLO-1, median progression-free survival was not reached against 13.8 months, with a substantial fraction progression-free at seven years†. The annual cost at United States list is in the region of US$150,000 to 200,000†. Objective response as treatment rather than maintenance in BRCA-mutant platinum-sensitive relapse is in the region of 60 to 80 per cent†. Checkpoint inhibitors have been largely unsuccessful here, with response rates in the region of 10 per cent or below as monotherapy and no benefit in the randomised trials: ovarian cancer is one of the clear immunotherapy failures. Hyperthermic intraperitoneal chemotherapy has one positive randomised trial at interval debulking and is not widely adopted.

**Simple means.** Opportunistic salpingectomy at any pelvic operation, and risk-reducing salpingo-oophorectomy in a known mutation carrier, are straightforward operations needing basic instruments: prevention achievable in a district hospital with a measured 50 to 90 per cent risk reduction. Oral contraceptives are oral, off-patent, pennies a cycle and listed as contraceptives, for a 58 per cent risk reduction with long use, with no cold chain and no monitoring. Paracentesis is the single most valuable palliative procedure in ovarian cancer and requires almost nothing: a needle and a drainage set relieve massive abdominal distension, breathlessness and anorexia within an hour, and it can be repeated indefinitely. Removal of a large ovarian mass is a conventional operation; complete cytoreduction of miliary peritoneal disease is not, and the difference matters prognostically. Oral morphine, nasogastric drainage or a venting gastrostomy for malignant bowel obstruction, dexamethasone, listed and off-patent, and hyoscine butylbromide manage the obstruction that is how most patients with ovarian cancer die, and it can be managed medically without surgery. The chemotherapy that produces most of the benefit is off-patent and listed, and it still requires intravenous infusion, antiemetics, blood-count monitoring and safe handling: a modest but real industrial chain. PARP inhibitors, which deliver the largest recent gain, have no simple-means equivalent.

**Gaps.** The PLCO and UKCTOCS screening figures could not be retrieved, so the conclusion that screening does not reduce mortality is stated qualitatively without hazard ratios. PDQ's ovarian prevention summary gives no BRCA lifetime risks and does not cover screening. On perineal talc the case-control meta-analyses find an effect, the two large prospective cohorts find nothing, and there is no dose-response; PDQ calls the evidence inadequate and both sides are printed. Ovarian hyperstimulation is rated poor evidence and uncertain.

## 13. Endometrial cancer

**What it is.** Cancer of the lining of the womb. Most of it is driven by unopposed oestrogen, from obesity, from oestrogen-only hormone therapy or from tamoxifen, and most of it announces itself early with abnormal bleeding, which is why it is usually caught at a curable stage. It is the one common cancer whose incidence is rising mainly because of obesity.

**Measured.** GLOBOCAN 2022 gives 420,368 cases; GLOBOCAN 2024 gives 434,620 cases and 100,680 deaths. Five-year relative survival in the United States is 80.9 per cent overall: localized 94.9, regional 70.1, distant 19.9, unknown 58.3 per cent. Median age 64. Stage at diagnosis: localized 67, regional 18, distant 11, unknown 4 per cent. United States incidence is rising about 0.7 per cent a year and the death rate about 1.3 per cent a year. It is one of very few cancers in this chapter with a rising death rate, attributed to obesity and to a rising share of aggressive non-endometrioid histologies. Incidence is highest in North America and Europe, tracking obesity prevalence.

**Where it starts.** Obesity raises risk about 1.5-fold per 5 kg/m² of body mass index, and obesity-associated relative risks range from 2 to 10, rated solid with good internal validity, consistency and external validity: the strongest obesity-cancer relationship of any cancer in this chapter. Unopposed oestrogen gives at least twofold higher risk with five years or more of use, rising with duration, and older studies reported ten- to thirtyfold risk at five years or more; adding a progestogen abolishes most of that excess, which is why combined preparations replaced oestrogen-only therapy in women with a uterus. Tamoxifen used more than two years gives a relative risk of 2.3 to 7.5, the principal harm of tamoxifen in breast cancer prevention and treatment, corresponding to the hazard ratio of 2.18 in entry 5. Oral contraceptives are protective at a relative risk of 0.76 per five years of use, interval 0.73 to 0.78, a 24 per cent reduction per five years, with protection persisting more than thirty years after last use, from a meta-analysis of 36 studies covering 27,276 women; a separate United Kingdom cohort gave an incidence rate ratio of 0.66, interval 0.48 to 0.89, for ever-users. Lynch syndrome carries a lifetime endometrial cancer risk of up to 60 per cent, and in Lynch syndrome endometrial cancer is often the sentinel cancer, preceding colorectal cancer. Nulliparity, early menarche, late menopause, polycystic ovary syndrome, diabetes and oestrogen-secreting tumours all operate through the same unopposed-oestrogen route. Mutation burden splits the disease into four molecular groups and the split matters more here than almost anywhere. POLE-ultramutated tumours carry among the highest burdens ever measured in human cancer, often above 100 mutations per megabase, and have an excellent prognosis; microsatellite-hypermutated tumours are also high-burden; copy-number-low endometrioid tumours are moderate; and copy-number-high serous-like tumours are lower-burden with near-universal TP53 mutation and the worst prognosis. Against an adult reference of 1.8 per megabase, a single figure for endometrial cancer would be meaningless, and the extremes differ by more than two orders of magnitude. Not known: why POLE-ultramutated tumours, with the heaviest mutation load, have the best outcome; why the share of aggressive serous-like disease is rising; why obesity acts so much more strongly here than on any other organ.

**Cure status.** Atypical endometrial hyperplasia, the precursor: CURABLE by hysterectomy, and in women wanting fertility often reversible with progestogen therapy — a levonorgestrel intrauterine system or an oral progestogen produces regression in a majority. This is one of the few pre-cancers treatable with a cheap off-patent drug rather than an operation. Localized, stage I: CURABLE — five-year relative survival 94.9 per cent, with hysterectomy and bilateral salpingo-oophorectomy alone curative for most. Regional, stage II to III: CURABLE in 70.1 per cent (five-year relative survival). Distant, stage IV, mismatch-repair-proficient: RELIEF ONLY — 19.9 per cent. Distant, mismatch-repair-deficient or microsatellite-unstable: CONTROLLABLE. That subgroup is roughly 25 to 30 per cent of endometrial cancers, the highest proportion of any common cancer, and it responds to checkpoint blockade better than almost any other solid tumour.

**Prevention.** Weight control — STRONG on the association, 1.5-fold per 5 kg/m² and relative risks of 2 to 10, with no randomised trial showing that weight loss reduces incidence; bariatric surgery cohorts show reduced incidence and are observational. Combined oral contraceptives — STRONG: relative risk 0.76 per five years, interval 0.73 to 0.78, with protection lasting over thirty years after stopping, so a woman who used the combined pill for ten years has roughly half the lifetime risk, permanently. Adding a progestogen to oestrogen therapy — STRONG, abolishing most of the two- to thirtyfold excess, and settled practice. The

levonorgestrel intrauterine system — MODERATE for preventing and reversing hyperplasia, including in obese and tamoxifen-exposed women. Raloxifene instead of tamoxifen where breast cancer prevention is the aim — a real and measurable trade-off: raloxifene's endometrial cancer hazard ratio is 1.09, interval 0.74 to 1.62, against tamoxifen's 2.18, interval 1.39 to 3.42. Hysterectomy is definitively preventive and is appropriate as risk-reducing surgery in Lynch syndrome, where lifetime risk reaches 60 per cent. There is no population screening programme and no recommendation for one. Transvaginal ultrasound and endometrial sampling have not been shown to reduce mortality in asymptomatic women, and the false-positive rate leads to unnecessary instrumentation. Prompt investigation of postmenopausal bleeding is not screening and functions as the de facto early-detection system, and it works — hence the 67 per cent localized rate. That is graded STRONG. Annual endometrial surveillance is recommended in Lynch syndrome in most guidelines, on the strength of the risk rather than on randomised mortality evidence. **Overdiagnosis has never been quantified for endometrial cancer, because no screening programme exists.**

**Treatment.** Total hysterectomy with bilateral salpingo-oophorectomy is curative for the large majority, with sentinel node sampling or lymphadenectomy for staging. Progestogen therapy — medroxyprogesterone, megestrol, or a levonorgestrel intrauterine system — treats hyperplasia, allows fertility-sparing management of grade 1 stage IA cancer, and palliates advanced hormone-receptor-positive disease at response rates in the region of 15 to 25 per cent†. Medroxyprogesterone is off-patent and cheap and is not in the antineoplastic section of the Essential Medicines List, though progestogens appear elsewhere on it. Adjuvant radiotherapy, by vaginal brachytherapy or external beam, reduces local recurrence in intermediate- and high-risk localized disease. Carboplatin and paclitaxel are the standard regimen for advanced or high-risk disease, both listed, both off-patent, at low generic cost. Pembrolizumab is listed for other indications and is on patent at US$1,530.35 per 4 mL (100 mg) unit at the United States cash price, October 2026, which is about US$53,000 a year at 200 mg every three weeks, against US$150,000 to 200,000 a year at United States list price; dostarlimab is not listed and is on patent. In mismatch-repair-deficient advanced disease the measured effect is among the largest for any checkpoint inhibitor in any solid tumour: objective response above 40 per cent as monotherapy in pre-treated disease, and randomised first-line trials adding a PD-1 inhibitor to carboplatin-paclitaxel showed hazard ratios for progression in the region of 0.3 in that subgroup†. In mismatch-repair-proficient disease the benefit is much smaller. Pembrolizumab with lenvatinib serves mismatch-repair-proficient advanced disease; lenvatinib is not listed, and the combination is expensive and toxic, with objective response around 30 per cent†. Trastuzumab serves HER2-positive uterine serous carcinoma and is listed, with the originator off-patent and biosimilars available.

**Simple means.** Abdominal total hysterectomy with bilateral salpingo-oophorectomy is a standard operation performable in a district hospital with basic instruments, anaesthesia and blood availability. For stage I disease, two-thirds of all cases, that single operation is curative in roughly 95 per cent of patients, with no drugs, no radiotherapy and no pathology beyond a confirmatory specimen. **Endometrial cancer is therefore the common cancer most completely curable by simple means in this chapter.** Endometrial biopsy with a suction curette or by dilatation and curettage is all that diagnosis of postmenopausal bleeding requires, plus a histopathologist; where no histopathology exists the diagnostic step fails, and that is the binding constraint. Oral progestogens or a levonorgestrel intrauterine system are oral or a single device insertion, off-patent, cheap and need no cold chain, and they treat hyperplasia, control bleeding and palliate advanced hormone-sensitive disease. Oral morphine, and vaginal packing or tranexamic acid, listed and off-patent, serve bleeding from advanced local disease. Weight reduction needs no technology and addresses the dominant cause. Advanced and serous-like disease has no simple-means answer, and the checkpoint inhibitors that transformed mismatch-repair-deficient disease are among the most expensive drugs in this chapter. But because two-thirds of the disease is localized and surgically curable, the simple-means fraction of the total achievable benefit is higher here than anywhere else in the chapter.

**Gaps.** No randomised evidence that weight loss reduces incidence, despite the strongest obesity association of any cancer. No randomised mortality evidence for Lynch syndrome endometrial surveillance, which is nonetheless recommended. Overdiagnosis is unquantified, as no screening programme exists. The rise in United States mortality is attributed to obesity and to a histology shift, and the relative contribution of each is not established.

## 14. Thyroid cancer

**What it is.** Cancer of the thyroid gland, overwhelmingly the differentiated papillary and follicular types, which grow slowly and rarely kill. A small minority — medullary and anaplastic — behave entirely differently, and anaplastic thyroid cancer is among the most lethal of all human cancers. Thyroid cancer is the clearest case in medicine of an epidemic of diagnosis rather than an epidemic of disease.

**Measured.** GLOBOCAN 2022 gives 821,214 cases; GLOBOCAN 2024 gives 959,281 cases and 48,070 deaths, making it the seventh most commonly diagnosed cancer in the world, with deaths at 5 per cent of incidence — the lowest ratio of any cancer in this chapter by a wide margin. Five-year relative survival in the United States is 98.3 per cent overall: localized 99.9, regional 98.1, distant 48.3, unknown 91.9 per cent. Median age 51, and it is one of the commonest cancers of young adults and about three times commoner in women. Stage at diagnosis: localized 63, regional 31, distant 3, unknown 3 per cent. United States incidence and the death rate are both stable now, and that stability follows a roughly threefold rise in United States incidence between 1975 and about 2014 with a completely flat mortality rate throughout. **Incidence tripling with mortality unchanged is the definitive signature of overdiagnosis**, and it is the most-cited example of the phenomenon in oncology. The South Korean experience is the canonical case: after ultrasound screening was added opportunistically to national health checks, incidence rose roughly fifteenfold between 1993 and 2011 while mortality remained flat, and incidence fell sharply after public concern reduced screening uptake.

**Where it starts.** Ionising radiation to the neck, particularly in childhood, is the only well-established environmental cause. The evidence base is the atomic bomb survivor cohorts, childhood therapeutic irradiation cohorts, and the Chernobyl accident, after which childhood thyroid cancer incidence in the contaminated regions of Belarus, Ukraine and Russia rose by a large multiple, caused by radioiodine in milk. Risk is strongly inversely related to age at exposure, and exposure in adulthood carries much less. A pooled relative risk per unit dose could not be retrieved. Iodine deficiency is associated with follicular and anaplastic histology, and iodine sufficiency shifts the mix towards papillary; whether total incidence is affected is unclear. Medullary thyroid carcinoma occurs in multiple endocrine neoplasia type 2 with germline RET mutation, where penetrance approaches 100 per cent and prophylactic thyroidectomy in childhood is standard†; papillary carcinoma occurs in familial adenomatous polyposis, Cowden syndrome and Carney complex. Obesity shows a consistent positive association at relative risks generally in the region of 1.2 to 1.5 for a body mass index of 30 or more†, with confounding by increased medical contact, and hence more neck imaging, a serious and unresolved problem in interpreting it. Papillary thyroid carcinoma has one of the lowest point-mutation burdens of any adult cancer, far below the adult reference of 1.8 per megabase. It is driven by single dominant events: BRAF V600E in roughly 60 per cent of papillary carcinomas, RAS mutations in follicular variants, and RET or NTRK fusions, the latter characteristic of radiation-induced and paediatric cases. Anaplastic carcinoma carries a high burden with TP53 and TERT promoter mutations, consistent with its behaviour. Not known: what fraction of detected papillary microcarcinomas would ever progress — the autopsy reservoir bears directly on this; why the female preponderance; whether the obesity association is causal or a detection artefact; the cause of the great majority of sporadic papillary thyroid cancer, since most patients have had no radiation exposure. **For a cancer with nearly a million annual diagnoses the aetiology is strikingly unexplained.**

**Cure status.** Papillary microcarcinoma, 1 cm or less, incidentally found: CONTROLLABLE by active surveillance, and most of these need no treatment at all. Japanese active-surveillance cohorts followed over a thousand patients with low-risk papillary microcarcinoma for a decade or more: a small minority grew by 3 mm or more, a small minority developed node metastases, and none died of thyroid cancer. Labelling this stratum CURABLE would be technically true and practically misleading. Localized differentiated: CURABLE — five-year relative survival 99.9 per cent, by lobectomy or total thyroidectomy. Regional differentiated: CURABLE — 98.1 per cent; nodal spread barely affects survival in differentiated thyroid cancer, which is unlike almost every other cancer here. Distant differentiated, radioiodine-avid in a young patient: CURABLE. Distant differentiated otherwise: CONTROLLABLE — 48.3 per cent. Radioiodine-avid lung metastases from papillary carcinoma in a young patient can be eradicated by radioiodine; bone metastases and radioiodine-refractory

disease cannot. Medullary carcinoma, confined: CURABLE by surgery, which is the only cure, since it does not take up radioiodine. Medullary carcinoma, metastatic: CONTROLLABLE with RET-directed inhibitors. Anaplastic carcinoma: RELIEF ONLY — median survival 3 to 6 months†, one of the most lethal cancers known. The exception is genuine and recent: BRAF V600E-mutant anaplastic carcinoma, roughly 40 per cent of cases, responds to dabrafenib with trametinib at objective response above 50 per cent, and a minority achieve prolonged survival†. From a baseline of near-universal death within six months, that is a large proportional improvement.

**Prevention.** Avoiding unnecessary medical radiation to the neck, particularly in children — STRONG, and the only established primary prevention. Potassium iodide prophylaxis after a nuclear accident — STRONG: saturating the thyroid with stable iodine blocks radioiodine uptake, and it must be given within hours. Potassium iodide is listed, off-patent and costs a few cents a tablet. The failure to distribute it promptly after Chernobyl is the reason for the childhood thyroid cancer epidemic that followed, and it is the clearest avoidable cancer epidemic in the historical record. Universal salt iodisation — MODERATE, justified by the prevention of goitre and cretinism rather than of cancer, with an unclear effect on total incidence and a shift of histology towards the more favourable papillary type. Prophylactic thyroidectomy in RET mutation carriers — STRONG: near-complete penetrance makes this one of the few places where removing a healthy organ in a child is unambiguously correct. Screening — recommend against, and this is one of the few places in cancer screening where the recommendation rests on demonstrated harm rather than on absence of benefit. The USPSTF recommends against screening asymptomatic adults, grade D. The quantified harm: in South Korea, a roughly fifteenfold rise in incidence with flat mortality means essentially all of the additional diagnosed cancer was overdiagnosis, and the overdiagnosed fraction of screen-detected thyroid cancer in that setting approaches 90 per cent or more. IARC's 2016 analysis estimated that over twenty years more than half a million people in twelve high-income countries — about 470,000 women and 90,000 men — were overdiagnosed with thyroid cancer, the great majority then receiving thyroidectomy, lifelong hormone replacement and in many cases radioiodine. The harms are concrete and permanent: lifelong levothyroxine dependence, a 2 to 6 per cent rate of permanent hypoparathyroidism and a 1 to 2 per cent rate of permanent recurrent laryngeal nerve injury after total thyroidectomy, and the second-cancer risk from radioiodine. One respect is contested: those who defend case-finding argue that some of the mortality stability reflects effective treatment of detected disease rather than harmlessness of it, and that a small number of aggressive cancers are caught. The counter-argument is that mortality was flat before, during and after the incidence rise, which leaves little room for a treatment effect. The weight of evidence sits heavily on the overdiagnosis side, and this is the most settled of the overdiagnosis controversies in this chapter, unlike breast and prostate, where the dispute remains open. The autopsy reservoir explains why: occult differentiated thyroid cancer is found in 11.2 per cent of whole glands examined, interval 6.7 to 16.1, and 4.1 per cent on partial examination, interval 3.0 to 5.4, across 35 studies and 12,834 autopsies conducted between 1949 and 2007.

**Treatment.** The proportion of radioiodine-avid distant disease in a young patient that is eradicated is not given. Active surveillance for low-risk papillary microcarcinoma is free and increasingly the correct choice. Lobectomy or total thyroidectomy is the curative treatment, and lobectomy is now preferred for low-risk tumours up to 4 cm, because it avoids lifelong hormone replacement and halves the risk of parathyroid and nerve injury: one of the clearest recent reversals in surgical oncology. Levothyroxine is a listed medicine for hypothyroidism, off-patent, and costs a few dollars a year generically — one of the cheapest lifelong medications in existence. Radioiodine is uniquely effective in differentiated thyroid cancer, because the tumour keeps the iodine-uptake machinery of normal thyroid, and it requires a nuclear medicine facility and radiation protection; its use in low-risk disease has been substantially reduced over the past decade, as trials showed no benefit. Lenvatinib and sorafenib for radioiodine-refractory differentiated disease are not listed; sorafenib is off-patent and lenvatinib is not, and lenvatinib's objective response rate in radioiodine-refractory disease was about 65 per cent in the registrational trial, the highest of its class, at an annual cost in the region of US$150,000 to 200,000 at United States list†. Selpercatinib and pralsetinib for RET-altered disease are not listed and on patent, at objective response rates above 60 to 70 per cent, among the highest for any targeted agent in any cancer†. Larotrectinib and entrectinib for NTRK-fusion disease are not listed, at response rates around 70 per cent and above†.

Dabrafenib with trametinib for BRAF V600E-mutant anaplastic carcinoma is not listed and both are on patent, at objective response above 50 per cent in a disease with median survival of 3 to 6 months†. External beam radiotherapy serves anaplastic carcinoma and unresectable local disease.

**Simple means.** Doing nothing comes first, deliberately. For low-risk papillary microcarcinoma, active surveillance is legitimate evidence-based management requiring no industrial chain at all, and for a large fraction of diagnosed thyroid cancer it is both the simplest and the best available option. Thyroid lobectomy and total thyroidectomy are classical operations requiring basic instruments, good lighting, meticulous technique and anaesthesia; energy devices and nerve monitors reduce complications and are not necessary. For localized differentiated disease — 94 per cent of cases are localized or regional — the operation is curative in over 98 per cent. That makes thyroid cancer the second most complete simple-means cure in this chapter after endometrial cancer. Levothyroxine is a single daily tablet, off-patent, listed, a few dollars a year, needing no cold chain and only a periodic measurement of thyroid-stimulating hormone, and in practice manageable on clinical grounds where no assay exists. Potassium iodide after a radiological accident costs cents, is listed, and is the only prophylaxis that works. Iodised salt needs no industrial chain beyond the salt supply. Tracheostomy prevents death by asphyxiation from anaplastic carcinoma or bulky local disease and is a basic operation. Oral morphine serves the pain of advanced local disease. Radioiodine has no simple-means equivalent, and for radioiodine-refractory and anaplastic disease the effective drugs are all on patent and expensive. Because almost all thyroid cancer is localized differentiated disease curable by an operation and a cheap tablet, thyroid cancer has one of the best simple-means profiles in the chapter, and its biggest problem is not undertreatment but overtreatment.

**Gaps.** A pooled relative risk for radiation-induced thyroid cancer per unit dose could not be retrieved. The obesity association may be a detection artefact, and that is unresolved. The aetiology of sporadic papillary thyroid cancer is largely unknown. The proportion of papillary microcarcinomas that would ever progress is unknown; the Japanese surveillance cohorts give an upper bound over a decade and not over a lifetime. The precise overdiagnosis percentage depends entirely on the screening intensity of the population described, so no single number can be given: the figures above are setting-specific. The confidence intervals for the thyroid autopsy meta-analysis are given as two subgroup estimates rather than one pooled figure, and the difference between them — 4.1 against 11.2 per cent — is itself the point, because how much cancer is found depends on how hard the pathologist looks.

## 15. Melanoma of the skin

**What it is.** Cancer of the pigment-producing cells of the skin. It is far less common than the other skin cancers and causes the great majority of skin cancer deaths, because it metastasises while still small. It is the cancer most clearly caused by a single avoidable exposure, and the cancer where immunotherapy first demonstrated that metastatic disease can be cured by a drug.

**Measured.** GLOBOCAN 2022 gives 331,722 cases; GLOBOCAN 2024 gives 337,969 cases and 58,398 deaths. GBD 2023 gives 66,600 deaths from malignant skin melanoma in 2023, interval 59,900 to 75,200. Five-year relative survival in the United States is 94.7 per cent overall: localized 100.0, regional 76.0, distant 34.0, unknown 95.4 per cent. Median age 67, and melanoma is also one of the commonest cancers in young adults, and in several countries the commonest cancer in people aged 20 to 39. Stage at diagnosis: localized 77, regional 10, distant 5, unknown 9 per cent. NCI PDQ gives about 104,960 United States diagnoses and 8,430 deaths for 2025, and states that melanoma is about 2 per cent of skin cancers and causes more than 80 per cent of skin cancer deaths. United States incidence is rising about 1.1 per cent a year and the death rate falling about 2.2 per cent a year. **That falling mortality is the clearest population-level signal of checkpoint-inhibitor efficacy anywhere in oncology**: the decline begins around 2013, the year the first PD-1 inhibitors and ipilimumab came into use, after decades of flat or rising mortality. Part of the rising incidence is detection-driven. Australia and New Zealand have by far the world's highest rates, a consequence of fair-skinned populations at low latitudes; rates are low in Asia and Africa, where melanoma when it occurs is more often acral or mucosal, unrelated to ultraviolet exposure, and carries a worse prognosis.

**Where it starts.** Total sun exposure in childhood gives an odds ratio of 1.81 to 4.4, and intermittent exposure with sunburn is the characteristic melanoma pattern, as distinct from the cumulative-exposure pattern that causes keratinocyte carcinomas; PDQ rates this fair evidence of unknown magnitude, with fair internal validity and consistency and poor external validity. Fair skin that burns easily carries about twofold risk against skin that never burns, and natural red or blond hair roughly twofold to fourfold. On indoor tanning PDQ cites studies and gives no relative risk; IARC classified ultraviolet-emitting tanning devices as Group 1 in 2009, and the commonly cited meta-analytic figure is a relative risk of roughly 1.2 for any use, rising to about 1.6 to 1.8 for first use before age 35†. PDQ's silence on this is itself notable. Naevus count, atypical naevi and family history are all established, with risk rising steeply with naevus count. CDKN2A germline mutation is the principal high-penetrance melanoma gene and MC1R variants the common low-penetrance ones. Immunosuppression raises risk. Cutaneous melanoma has the highest point-mutation burden of any common human cancer, an order of magnitude or more above the adult reference of 1.8 per megabase, dominated by the C-to-T transitions at dipyrimidine sites that are the direct chemical fingerprint of ultraviolet damage. BRAF V600E or V600K is present in roughly 40 to 50 per cent and NRAS in roughly 20 per cent. The high ultraviolet-induced burden is the accepted explanation for melanoma's exceptional responsiveness to checkpoint blockade: the mutations generate neoantigens the immune system can see. Acral and mucosal melanomas, which are not ultraviolet-driven, carry much lower burdens and respond far less well, which is strong internal evidence for that reading. Not known: why intermittent rather than cumulative exposure drives melanoma while the reverse holds for keratinocyte cancers; why some thin melanomas metastasise and most do not; the magnitude of the sunscreen effect; why acral melanoma occurs at similar rates across all skin colours with no ultraviolet involvement.

**Cure status.** Melanoma in situ: CURABLE by excision. Localized thin melanoma, 1 mm or less: CURABLE — five-year relative survival 100.0 per cent for localized disease. Wide local excision with a 1 to 2 cm margin is the entire treatment, and it is curative in the great majority: no drugs, no radiotherapy, no imaging. Localized thick melanoma, over 4 mm and ulcerated: CURABLE. Regional, node-positive stage III: CURABLE in 76.0 per cent (five-year relative survival). Distant, stage IV, in the substantial minority with a sustained complete response to combination checkpoint blockade: CURABLE. Distant, stage IV, otherwise: CONTROLLABLE — 34.0 per cent at five years in the 2016 to 2022 SEER cohort, a figure still catching up with practice. In the long-term follow-up of nivolumab with ipilimumab in advanced melanoma, roughly half of patients were alive at five years, and a substantial fraction were alive and off all treatment with no evidence of disease. Before 2011, median survival in metastatic melanoma was 6 to 9 months and five-year survival was under 10 per cent†.

**Prevention.** Sun avoidance, shade, clothing and hats — STRONG for the causal relationship, with the honest caveat that the intervention evidence is weaker than the aetiological evidence. PDQ rates sun exposure and keratinocyte carcinoma as solid evidence with good internal validity, consistency and external validity, and intermittent sun exposure with sunburn and melanoma as fair evidence of unknown magnitude. Sunscreen — CONTESTED, and the figures are genuinely weak. PDQ states there is inadequate evidence to assess magnitude, with poor internal and external validity and inconsistent results; randomised trials showed inconsistent benefit for squamous cell carcinoma and no benefit for melanoma, and an eight-year post-trial follow-up showed reductions in squamous cancers and melanomas with very wide confidence intervals. The trial in question is the Nambour, Queensland randomised trial, whose ten-year follow-up reported roughly a halving of invasive melanoma incidence in the daily-sunscreen group, on 11 against 22 melanomas† — a result based on very few events and wholly consistent with PDQ's assessment that the magnitude cannot be assessed. Both positions are printed: sunscreen is universally recommended, and its randomised evidence base for melanoma prevention rests on a single trial with 33 events in total. The possibility that sunscreen enables longer exposure, offsetting its protective effect, has never been excluded. Avoiding indoor tanning — STRONG on IARC's Group 1 classification, with no effect size from PDQ. Avoiding sunburn in childhood — MODERATE, odds ratio 1.81 to 4.4. Topical fluorouracil on sun-damaged skin — one good-quality randomised trial with moderate net benefit for preventing squamous cell carcinoma requiring surgery, which concerns keratinocyte carcinoma rather than melanoma. Screening — CONTESTED: the USPSTF position is that the evidence is insufficient, grade I, for visual skin examination in asymptomatic adults, and there is no randomised trial showing that skin cancer screening

reduces melanoma mortality. The German SCREEN project in Schleswig-Holstein reported a fall in melanoma mortality after a population programme, which was then not sustained when the programme was extended nationally — an inconsistent result cited on both sides. Overdiagnosis of melanoma is real and quantified in the same way as thyroid: a roughly six-fold rise in United States incidence since the 1970s with a far smaller change in mortality†. Estimates of the overdiagnosed fraction in high-screening populations range from around 15 per cent to as high as 60 per cent depending on method and country, with the higher end from Australian analyses. Both ends are printed; the figure is contested and the method — incidence-mortality divergence against modelling — drives the difference. The principal harm is excision of lesions that would never have progressed, plus the anxiety and insurance consequences of a cancer diagnosis. Melanoma excision is a small operation, so the harm per overdiagnosed case is lower than for thyroid or prostate overdiagnosis.

**Treatment.** The proportion of localized thick ulcerated melanoma that is cured is not given. Most are cured, the relapse risk is substantial, and adjuvant checkpoint-inhibitor or BRAF-directed therapy reduces it. Wide local excision is the curative treatment for localized disease, which is 77 per cent of cases, with margins of 1 to 2 cm depending on thickness. Sentinel lymph node biopsy is staging rather than therapeutic, and completion lymphadenectomy for a positive sentinel node was shown by randomised trials not to improve survival and has largely been abandoned. Checkpoint inhibitors are the transformative treatment, and melanoma is where they were first proven. Pembrolizumab is a selected medicine on the list for melanoma of the skin as monotherapy, and nivolumab is listed as a therapeutic equivalent to it for that same indication; neither is off-patent. Ipilimumab is not listed and is on patent. Objective response in advanced melanoma is in the region of 35 to 45 per cent for pembrolizumab or nivolumab monotherapy, and 55 to 60 per cent for nivolumab with ipilimumab, with complete response in roughly 20 per cent†; five-year survival with the combination is roughly 50 per cent in the registrational trial against under 10 per cent before 2011†. Pembrolizumab costs US$1,530.35 per 4 mL (100 mg) unit, US$6,121.41 per four-unit pack and US$12,234.94 for eight units at the United States cash price, October 2026, which is about US$53,000 a year at 200 mg every three weeks, against US$150,000 to 200,000 a year at United States list price, and the combination costs substantially more. Adjuvant checkpoint therapy after resection of stage III and high-risk stage II melanoma roughly halves the recurrence rate. BRAF with MEK inhibitors for BRAF V600-mutant disease — dabrafenib-trametinib, vemurafenib-cobimetinib, encorafenib-binimetinib — are none of them listed and all on patent, at objective response rates of roughly 65 to 70 per cent, faster-acting than immunotherapy with a shorter median duration, and roughly a third of patients have durable long-term benefit. Dacarbazine is listed and off-patent and cheap, and almost inactive: objective response in advanced melanoma is in the region of 10 per cent with no demonstrated survival benefit†. That matters for the simple-means question, because the only melanoma drug on the list that is off-patent and affordable barely works, and it is the honest baseline against which the expensive drugs should be read. Interleukin-2, talimogene laherparepvec and tumour-infiltrating lymphocyte therapy are not listed and require cell-processing facilities. Radiotherapy serves brain metastases and palliation, and melanoma is relatively radioresistant.

**Simple means.** Sun avoidance — shade, long sleeves, a wide-brimmed hat, and staying indoors in the middle of the day — needs no industrial chain, costs nothing and addresses the dominant cause. It is the highest-yield simple means in this entry, and clothing and shade have better evidence than sunscreen and cost less. Excision of a suspicious pigmented lesion under local anaesthetic with a scalpel and sutures is the single most important point here: for 77 per cent of melanoma, a curative operation can be performed in an outpatient room with a blade, local anaesthetic, sutures and a histopathologist, at a five-year relative survival of 100 per cent. Melanoma is, alongside endometrial, thyroid and keratinocyte skin cancer, among the most completely curable-by-simple-means cancers in this chapter, provided the lesion is recognised and excised. Naked-eye examination of the skin, with or without a dermatoscope that costs a few hundred dollars and needs no power beyond a battery, is possible because melanoma is one of very few cancers visible from outside the body, which is an enormous practical advantage and the reason awareness matters so much; the asymmetry, border, colour, diameter and evolution rule requires no equipment. Oral morphine serves pain, and dexamethasone, listed and off-patent, relieves the symptoms of brain metastases, which are common in melanoma, within hours. For metastatic melanoma nothing simple exists, and

the gap is stark: the off-patent listed drug has a response rate around 10 per cent† and no survival benefit, and the drugs that cure a third to a half of metastatic melanoma cost over US$150,000 a year at United States list, and are all on patent. Melanoma therefore shows the widest divergence in this chapter between what simple means achieve for early disease, which is essentially complete cure, and for advanced disease, which is essentially nothing.

**Gaps.** Sunscreen's randomised evidence for melanoma prevention rests on one trial with very few events; PDQ calls the evidence inadequate while public health guidance recommends it universally, and that is a genuine disagreement between the evidence appraisal and the recommendation. PDQ gives no relative risk for indoor tanning despite IARC's Group 1 classification. Melanoma overdiagnosis estimates range from roughly 15 to 60 per cent depending on method and country, and the disagreement is unresolved. No randomised trial of skin cancer screening has mortality as an outcome, and the German SCREEN result was not reproduced. SEER's distant-stage five-year survival lags current practice, because the cohort partly predates routine combination immunotherapy, so the true current figure is higher.

## 16. Keratinocyte skin cancer — basal cell and squamous cell carcinoma

**What it is.** The two common cancers of the ordinary skin cells: basal cell carcinoma, which invades locally and almost never spreads, and cutaneous squamous cell carcinoma, which can spread to lymph nodes and occasionally kills. Together they are the most common cancers in human beings by a very wide margin, and they are so rarely fatal that most cancer registries do not count them.

**Measured.** This is the one entry in this chapter where the incidence figures are fundamentally unreliable, and the reason matters: keratinocyte carcinomas are not notifiable in most registries, people often have several, and registries that do count them count lesions rather than patients inconsistently. GLOBOCAN 2022 gives 19,976,499 cases including non-melanoma skin cancer and 18,741,966 excluding it, implying a non-melanoma skin cancer total of about 1,234,533; GLOBOCAN 2024 gives about 20.6 million including and 19.5 million excluding, implying roughly 1.1 million. The WHO cancer fact sheet gives non-melanoma skin cancer as 1.1 million cases in 2024, making it the fifth commonest cancer in the world on that count. These figures are certainly large underestimates. NCI PDQ estimated keratinocyte carcinomas combined at about 3 million diagnoses in the United States alone in 2012, from Medicare extrapolation, and states explicitly that exact figures are unavailable because these cases are not required to be registry-reported. The true global figure is plausibly several times the GLOBOCAN number. SEER publishes no Cancer Stat Facts page for basal or squamous cell carcinoma of the skin, for the same reason, so no stage-specific five-year relative survival table comparable to the other entries in this chapter exists. GBD 2023 gives 63,900 deaths from non-melanoma skin cancer in 2023, interval 54,400 to 71,600. Against that, PDQ's statement that melanoma is about 2 per cent of skin cancers and causes more than 80 per cent of skin cancer deaths implies keratinocyte carcinoma deaths in the order of 10,000 to 15,000 globally, almost all from squamous cell carcinoma and from neglected or immunosuppressed cases; that is an inference from PDQ's ratio rather than a published count, and the GBD figure of 63,900 is four to six times higher, so the two do not agree. Both are printed. Incidence is strongly age-dependent, rising steeply after 50 and reflecting cumulative lifetime ultraviolet dose, and basal cell carcinoma is roughly four times commoner than squamous. Australia has the highest rates in the world, with a majority of fair-skinned Australians developing at least one keratinocyte carcinoma in their lifetime. Rates are low in darkly pigmented populations.

**Where it starts.** PDQ rates sun and ultraviolet exposure in keratinocyte carcinoma as solid evidence with good internal validity, consistency and external validity — a stronger grade than it gives for melanoma — and gives no risk ratio. The pattern differs from melanoma: cumulative lifetime exposure drives keratinocyte carcinoma and intermittent exposure with sunburn drives melanoma, which is why keratinocyte carcinomas appear on the face, ears, scalp, forearms and hands and why they are an occupational disease of outdoor workers. People who tan poorly or burn easily are particularly susceptible. Immunosuppression is the strongest single risk amplifier known for any cancer in this chapter: organ transplant recipients have cutaneous squamous cell carcinoma rates reported at roughly 65 to 250 times

the general population, with basal cell carcinoma raised about tenfold, and in transplant recipients the normal four-to-one basal-to-squamous ratio inverts. Squamous cell carcinoma in transplant recipients is also far more aggressive and does metastasise. Ionising radiation, arsenic, chronic scarring and chronic ulceration, chronic inflammation, and beta-genus human papillomavirus — particularly in the immunosuppressed and in epidermodysplasia verruciformis — are all established. Basal cell naevus syndrome, from PTCH1 mutation in the hedgehog pathway, xeroderma pigmentosum, albinism and epidermodysplasia verruciformis are the genetic syndromes. Cutaneous squamous cell carcinoma and basal cell carcinoma carry the highest mutation burdens ever measured in human tumours, higher even than melanoma, frequently tens to over a hundred mutations per megabase against an adult reference of 1.8, and overwhelmingly the ultraviolet-signature C-to-T transition. Basal cell carcinoma is driven by hedgehog pathway activation, PTCH1 loss or SMO mutation in the great majority: a single-pathway disease sitting inside an extremely high mutation background. That is the molecular basis both for hedgehog inhibitors and for the striking checkpoint-inhibitor responses in both tumours. Not known: why basal cell carcinoma, with one of the highest mutation burdens in oncology, essentially never metastasises — a genuine and unexplained anomaly; the quantitative contribution of beta-genus human papillomavirus; why the basal-to-squamous ratio inverts under immunosuppression.

**Cure status.** Basal cell carcinoma, localized and locally advanced but operable: CURABLE — excision with clear margins cures over 95 per cent, and Mohs micrographic surgery exceeds 98 per cent for high-risk sites†. Metastatic basal cell carcinoma is so rare, well under 0.1 per cent, that it is reportable†. The harm basal cell carcinoma causes when neglected is local destruction of the eyelid, nose or ear, not death. Basal cell carcinoma, inoperable after long neglect: CONTROLLABLE with hedgehog inhibitors or a checkpoint inhibitor. Cutaneous squamous cell carcinoma, localized: CURABLE — excision cures over 90 to 95 per cent of ordinary lesions†. Cutaneous squamous cell carcinoma, high-risk or node-positive: CURABLE, with surgery plus radiotherapy. Metastatic cutaneous squamous cell carcinoma: CONTROLLABLE — cemiplimab produces objective responses in roughly 45 to 50 per cent†, among the highest checkpoint-inhibitor response rates in any cancer, consistent with the very high mutation burden.

**Prevention.** Sun avoidance — STRONG. PDQ's grade for sun and ultraviolet exposure in keratinocyte carcinoma is solid evidence with good internal validity, consistency and external validity, its strongest grading in the skin cancer summary. Shade, clothing, hats and avoiding midday exposure. Occupational sun protection for outdoor workers is the measure with the largest population effect and the least implementation. Sunscreen — CONTESTED, leaning positive for squamous cell carcinoma: the evidence is better here than for melanoma and PDQ still rates it inadequate to assess magnitude, with poor internal and external validity and inconsistent randomised results. The Nambour trial reported a reduction in squamous cell carcinoma incidence with daily sunscreen, and that is the most positive randomised sunscreen result that exists. Topical fluorouracil on sun-damaged skin — MODERATE: one good-quality randomised trial with moderate net benefit for preventing squamous cell carcinoma requiring surgery. Fluorouracil is listed and off-patent, and the topical 5 per cent cream is inexpensive. That makes it one of the few pharmacological cancer preventives in this chapter that is both proven in a randomised trial and cheap. Avoiding indoor tanning — STRONG on IARC Group 1, with no figure from PDQ. Reducing immunosuppression intensity, and switching transplant recipients from calcineurin inhibitors to sirolimus-based regimens — MODERATE, with randomised evidence of reduced squamous cell carcinoma incidence in transplant recipients. Nicotinamide — MODERATE: the ONTRAC randomised trial in patients with prior keratinocyte carcinoma reported roughly a 23 per cent reduction in new keratinocyte carcinomas over twelve months, and the effect ceases when the supplement stops. Screening — insufficient evidence, USPSTF grade I, as for melanoma. For a cancer that essentially never kills, mortality is the wrong endpoint, and no trial has used morbidity endpoints. Overdiagnosis in the usual sense is not the main issue here, and the conceptual point matters: a basal cell carcinoma left alone will grow and destroy tissue, so detecting and treating it is beneficial even though it would not have been fatal. The overdiagnosis framing that applies to thyroid, prostate and breast does not transfer, because the harm prevented is disfigurement rather than death. Overtreatment does occur, in the form of aggressive surgery for small lesions in very elderly patients with limited life expectancy, where observation or topical treatment would suffice.

**Treatment.** The proportion of high-risk or node-positive cutaneous squamous cell carcinoma cured by surgery plus radiotherapy is not given. Most are cured. Recurrence and nodal spread are real risks in large, deep, perineural, immunosuppressed or head-and-neck lesions. Simple surgical excision with clear margins under local anaesthetic is the standard curative treatment for both tumours, at a cure rate over 95 per cent for basal cell carcinoma and over 90 per cent for squamous†. Curettage and cautery, cryotherapy or shave excision serve small, low-risk, superficial basal cell carcinomas: faster, cheaper, no sutures, slightly higher recurrence. Mohs micrographic surgery serves high-risk sites — nose, eyelid, ear, lip — and recurrent lesions, at the highest cure rate, tissue-sparing, requiring on-site frozen-section pathology. Radiotherapy is a curative alternative where surgery would be disfiguring or the patient is unfit. For superficial basal cell carcinoma and in-situ squamous cell carcinoma, topical fluorouracil 5 per cent is listed, off-patent and inexpensive; imiquimod is not listed and is off-patent; photodynamic therapy requires a light source and a photosensitiser. Vismodegib and sonidegib for locally advanced or metastatic basal cell carcinoma are neither listed and both on patent, at objective response rates of roughly 45 to 60 per cent in locally advanced disease and an annual cost at United States list in the region of US$100,000 and above†. Their toxicity — muscle cramps, taste loss, alopecia — causes frequent discontinuation. Cemiplimab is on the list, as a therapeutic alternative for metastatic non-small-cell lung cancer rather than for its original approval in advanced cutaneous squamous cell carcinoma, and is on patent, at objective response in advanced cutaneous squamous cell carcinoma of roughly 45 to 50 per cent†; it is also active in hedgehog-inhibitor-refractory basal cell carcinoma at response rates around 30 per cent. Prices as for the class, US$150,000 to 200,000 a year at United States list†. Pembrolizumab is also active. Cisplatin and carboplatin are listed, off-patent and cheap for advanced squamous cell carcinoma; responses occur and are not durable, and checkpoint inhibitors have displaced chemotherapy where available.

**Simple means.** This entry has the strongest simple-means profile in the chapter. Excision under local anaesthetic with a scalpel and sutures cures over 95 per cent of basal cell carcinomas and over 90 per cent of squamous cell carcinomas†: no imaging, no staging, no drugs, no radiotherapy, no cold chain, no electricity beyond a light. A trained general practitioner, clinical officer or nurse can do it. Set beside the fact that these are the most common cancers in the world, that makes minor skin surgery arguably the highest-volume curative cancer intervention available by simple means anywhere. Curettage and cautery, or cryotherapy with liquid nitrogen in a hand-held flask, is simpler still for small superficial lesions: no sutures, minutes per lesion. Sun avoidance for outdoor workers is clothing rather than technology, and PDQ's grading for cumulative ultraviolet exposure here is its strongest in the skin summary. Topical fluorouracil 5 per cent cream is listed, off-patent, cheap and applied by the patient at home, with randomised evidence of reduced squamous cell carcinoma requiring surgery, and needs no clinic visit for the treatment itself. Nicotinamide is an inexpensive vitamin, associated with a roughly 23 per cent reduction in new keratinocyte carcinomas in the ONTRAC trial. Its dose and use are for a clinician and are not given here. Naked-eye diagnosis is possible: these cancers are visible and have characteristic appearances, so diagnosis is substantially clinical with histology confirming, and this is the only cancer group in the chapter where competent management is possible with essentially no diagnostic technology. Where nothing simple exists: neglected, deeply invasive facial basal cell carcinoma that has destroyed the orbit or the nasal skeleton requires major reconstructive surgery or a hedgehog inhibitor, and metastatic cutaneous squamous cell carcinoma requires cemiplimab, whose listing for this cancer was not checked and needs checking against the 24th List (2025)†, and which costs over US$150,000 a year. And for the xeroderma pigmentosum and albinism populations, who develop these cancers continuously from childhood, simple excision cannot keep pace: in several African countries albinism carries a high rate of fatal squamous cell carcinoma by early adulthood, and the simple answer — rigorous lifelong sun protection from infancy — is known and not delivered.

**Gaps.** The incidence data are the weakest in this chapter. These cancers are not notifiable in most registries, and GLOBOCAN's implied 1.1 to 1.2 million is inconsistent with PDQ's 3 million United States diagnoses in 2012 alone. No reliable global figure exists. No SEER stage-specific survival table exists, so this entry cannot give the stage-by-stage figures that every other entry gives. The mortality figure inferred from PDQ's ratio, 10,000 to 15,000 globally, is four to six times below GBD 2023's 63,900, and the discrepancy is unexplained. PDQ gives no risk ratio for sun exposure despite rating the evidence solid. The transplant-recipient risk

multiples and the nicotinamide figure are not primary-source-verified. Why basal cell carcinoma does not metastasise despite an extreme mutation burden is unexplained. Sunscreen evidence is rated inadequate by PDQ while being universally recommended.

## 17. Brain and central nervous system tumours

**What it is.** Tumours arising in the brain, spinal cord and their coverings. The dominant malignant type in adults is glioma, and the commonest and worst of these is glioblastoma. Unlike almost every other cancer, brain tumours kill by local growth inside a closed bony box rather than by spreading to other organs. Benign meningiomas are far more common than malignant gliomas and behave quite differently.

**Measured.** GLOBOCAN 2022 gives 321,731 cases of brain and central nervous system tumours; GLOBOCAN 2024 gives 324,095 cases and 248,964 deaths, so deaths are 77 per cent of incidence. Five-year relative survival in the United States is 32.9 per cent overall. SEER publishes no stage-specific table for these tumours, because the localized-regional-distant system does not apply: they are staged by histology and grade rather than by anatomical spread. The relevant breakdown is by histology, and the figures are from the general neuro-oncology literature: glioblastoma, WHO grade 4 astrocytoma, five-year survival in the region of 5 to 7 per cent with median survival of roughly 15 months; anaplastic astrocytoma, grade 3, median survival roughly 3 to 5 years; IDH-mutant low-grade glioma, grade 2, median survival often over 10 years; 1p/19q-codeleted oligodendroglioma, median survival often exceeding 15 to 20 years; grade 1 meningioma, five-year survival in excess of 90 per cent and often cured by excision; pilocytic astrocytoma, mostly paediatric, five-year survival above 95 per cent and frequently cured by surgery alone. Median age 61, although brain tumours have a bimodal age distribution and are the commonest solid tumour of childhood and the second commonest cause of cancer death in children. United States incidence is falling about 1.4 per cent a year and the death rate about 0.3 per cent a year. **That mortality decline is the smallest of any cancer in this chapter**, which is the plainest statement of therapeutic failure in glioblastoma.

**Where it starts.** Ionising radiation to the head is the only established environmental cause. Therapeutic cranial irradiation — historically for tinea capitis, currently for childhood leukaemia and other childhood cancers — raises the risk of meningioma and glioma years to decades later, dose-dependently. Hereditary syndromes account for a small percentage: neurofibromatosis type 1 for optic pathway glioma, neurofibromatosis type 2 for meningioma and vestibular schwannoma, tuberous sclerosis for subependymal giant cell astrocytoma, Li-Fraumeni syndrome, Turcot and Lynch syndromes, Gorlin syndrome, and rhabdoid tumour predisposition from SMARCB1 mutation. On mobile telephones the weight of evidence has moved against an effect and both positions are printed. IARC classified radiofrequency electromagnetic fields as Group 2B, possibly carcinogenic, in 2011, on the INTERPHONE and Hardell case-control studies, which reported elevated odds ratios in the heaviest users. The counter-evidence is strong and now dominant: glioma incidence has not risen in any national registry during the period of near-universal mobile phone adoption, which is difficult to reconcile with a causal effect of the magnitude the case-control studies suggested, and recall bias in those studies is the leading explanation; a WHO-commissioned systematic review in 2024 found no association. The registry data are the stronger evidence. Allergy and atopy are inversely associated with glioma, consistently across studies, for reasons not established. Head injury, dietary nitrosamines, occupational exposures and power lines have been studied extensively with no established effect. Gliomas have a low to moderate point-mutation burden, around or below the adult reference of 1.8 per megabase. Glioblastoma is characterised by EGFR amplification, PTEN loss, CDKN2A deletion and TERT promoter mutation; IDH1 or IDH2 mutation defines the better-prognosis gliomas and is the single most important prognostic marker in neuro-oncology; 1p/19q codeletion defines oligodendroglioma; MGMT promoter methylation predicts temozolomide benefit. The 2021 WHO classification of central nervous system tumours reorganised the field around these molecular features rather than histology, which is why older survival statistics are hard to compare with current ones. Hypermutation in glioma is mostly iatrogenic, induced by temozolomide itself at recurrence. Not known: **the cause of the overwhelming majority of brain tumours, which is the largest aetiological void in this chapter.** Apart from radiation and rare syndromes, essentially nothing is established: there is no tobacco, no infection, no diet, no occupation,

no obesity link of any consequence. Also unknown: why the blood-brain barrier and the brain's immune environment defeat drug and immune therapies that work elsewhere; why glioblastoma invariably recurs; the significance of the inverse allergy association.

**Cure status.** Grade 1 meningioma: CURABLE by complete excision — five-year survival in excess of 90 per cent†; many small asymptomatic meningiomas need only observation and never grow enough to matter, and they are extremely common as incidental findings. Grade 1 pilocytic astrocytoma, mostly in children: CURABLE by resection alone — five-year survival above 95 per cent†. IDH-mutant grade 2 to 3 glioma: CONTROLLABLE over many years — median survival often exceeding 10 years, and 15 to 20 years in 1p/19q-codeleted oligodendroglioma† — and patients nonetheless almost all eventually die of the disease. Glioblastoma: RELIEF ONLY, and this should be stated without euphemism — median survival roughly 15 months and five-year survival 5 to 7 per cent with maximal safe resection, radiotherapy and temozolomide†. The treatment gain over the last twenty years has been measured in months, and glioblastoma belongs with pancreatic cancer and anaplastic thyroid carcinoma on the short list of cancers where current medicine achieves very little. Diffuse midline glioma, H3 K27M-altered, a childhood tumour: RELIEF ONLY — median survival roughly 9 to 12 months†; it is inoperable by location and no treatment has ever improved survival in a randomised trial. Brain metastases from other cancers, far more common than primary brain tumours: CONTROLLABLE — stereotactic radiosurgery, surgery for single accessible lesions and drugs that cross into the brain have substantially improved outcomes. Early detection would not help in malignant glioma, because grade is determined at onset rather than acquired by delay: that is a fundamental difference from the epithelial cancers in this chapter and the reason there is no screening rationale.

**Prevention.** Avoiding unnecessary therapeutic and diagnostic cranial irradiation, particularly in children — STRONG, and the only established prevention. Everything else: no diet, no supplement, no behaviour and no exposure avoidance has demonstrated efficacy. This is the shortest prevention section in this chapter and the honest answer is that brain tumours cannot currently be prevented. Mobile phone avoidance — CONTESTED, and on the registry evidence unnecessary: IARC Group 2B from 2011 rests on case-control data, national incidence trends show no rise, and the 2024 WHO-commissioned systematic review found no association. Both printed. There is no screening programme anywhere and no rationale for one: prevalence is too low, there is no pre-malignant stage to intercept, and for the lethal tumours early detection does not change grade or outcome. Incidental detection of meningiomas and low-grade gliomas on magnetic resonance imaging done for other reasons is nonetheless common and growing, and it creates a real overdiagnosis problem, because a substantial proportion of incidental meningiomas never grow and intervening on them carries neurosurgical risk. **No overdiagnosis percentage has been published for incidental meningioma**, and it is a genuine and unquantified harm of expanding imaging use.

**Treatment.** Maximal safe surgical resection is one of the few modifiable prognostic factors in glioma and requires neurosurgical capability, imaging, and often intraoperative adjuncts. Radiotherapy is the single most effective modality in malignant glioma and requires a linear accelerator with planning capability. **Temozolomide is a listed medicine, for other specified gliomas of the brain and three further indications**. It is off-patent, and generic temozolomide is comparatively inexpensive, against an originator price in the thousands of dollars a cycle. Added to radiotherapy it increased median survival from roughly 12.1 to 14.6 months and two-year survival from 10 to 27 per cent in the pivotal Stupp trial†, and the benefit is concentrated almost entirely in MGMT-methylated tumours. PCV chemotherapy for oligodendroglioma and anaplastic glioma uses procarbazine and vincristine, both listed and off-patent, with lomustine, which is not listed. Lomustine has been subject to extreme price rises in the United States after acquisition by a single manufacturer, a documented increase of roughly 1,400 per cent between 2013 and 2018†. That is one of the clearest examples of off-patent price exploitation in oncology. PCV in 1p/19q-codeleted oligodendroglioma produced one of the largest survival gains in neuro-oncology, with median survival roughly doubled in long-term follow-up. Bevacizumab for recurrent glioblastoma is not listed for this indication; biosimilars are available, and it improves radiological appearance and reduces steroid need and has never improved overall survival in a randomised trial, which is worth stating plainly. Tumour-treating fields is a device rather than a drug, showed a survival benefit in a randomised trial, and is expensive and not widely adopted. Dexamethasone is listed and off-

patent at an indicative 24 cents a 4 mg tablet in the UNICEF Supply Catalogue, October 2026, and it is the most important drug in symptomatic brain tumour care: it reduces peritumoural oedema and can reverse hemiparesis, aphasia, headache and drowsiness within hours, and for a patient with a large brain tumour it does more for daily function, faster and more cheaply, than any antineoplastic agent here. Levetiracetam, phenytoin, carbamazepine and valproate are listed, off-patent and cheap, and phenobarbital is listed for epilepsy and status epilepticus at an indicative 1.7 cents a 30 mg tablet, US$6.24 a patient-year at one tablet a day in the UNICEF Supply Catalogue, October 2026; seizures affect a large proportion of glioma patients. In defined subsets, BRAF with MEK inhibitors serve BRAF V600E-mutant gliomas; everolimus is listed and shrinks subependymal giant cell astrocytoma in tuberous sclerosis, avoiding surgery; vorasidenib, approved in 2024 for residual or recurrent IDH-mutant grade 2 glioma, is not listed and is on patent, with a large progression-free survival gain in the INDIGO trial — the first genuinely new drug class in glioma in two decades. Checkpoint inhibitors have failed in glioblastoma: multiple large randomised trials of PD-1 blockade showed no survival benefit†, one of the most consistent negative results in immuno-oncology, attributed to the low mutation burden, the immunosuppressive microenvironment and the absence of normal lymphatic drainage.

**Simple means.** Dexamethasone is the single most valuable simple intervention in this entry: listed, off-patent, pennies a dose, oral or injectable, no cold chain. It relieves raised intracranial pressure and focal deficit quickly, restores the ability to walk, speak and eat in many patients, and transforms the final months, and its routine availability matters more for brain tumour patients in low-resource settings than any other intervention. Anticonvulsants — phenytoin, carbamazepine, valproate, phenobarbital — are all listed, off-patent, oral and cheap, and seizure control is a major determinant of quality of life and of the capacity to remain at home. Oral morphine serves headache, with antiemetics. A burr-hole, a simple decompressive craniotomy, or a ventriculoperitoneal shunt for obstructive hydrocephalus can be done with basic neurosurgical instruments where a trained surgeon exists, and a shunt for obstructive hydrocephalus from a posterior fossa tumour is life-saving and does not require an operating microscope. Nursing care is the substance of what is needed as patients become dependent for feeding, continence and mobility, and it requires no technology: pressure-area care, bowel management and carer support. For malignant brain tumours nothing simple extends life, and that should be plain. Resection requires a neurosurgeon and imaging; radiotherapy requires a linear accelerator; temozolomide requires a reliable oral supply and blood-count monitoring. **No diagnosis is even possible without computed tomography or magnetic resonance imaging**, which makes brain tumours the clearest case in this chapter where the diagnostic step alone is beyond simple means. The entire simple-means contribution in neuro-oncology is symptom control, and dexamethasone with anticonvulsants, morphine and nursing is a genuinely large contribution on those terms, without altering the disease.

**Gaps.** SEER publishes no stage-specific survival table for brain and central nervous system tumours, so the histology-specific figures are literature-derived. The aetiology of the great majority of brain tumours is unknown, which is a gap in the field. On mobile phones, IARC's Group 2B classification of 2011 stands against flat registry incidence and a null WHO-commissioned review of 2024; both are printed and the disagreement persists in public discussion despite the registry evidence. The 2021 classification reorganised the field molecularly, which makes survival statistics published before and after it non-comparable, and most quoted figures mix the two. Overdiagnosis of incidental meningioma and low-grade glioma from expanding imaging use is real and entirely unquantified. Lomustine pricing is literature-derived.

---

# Leukaemias

Cancers of the blood-forming cells of the bone marrow. The four main types are treated separately below, because they share an organ and differ in almost everything else — age of onset, speed, treatment and curability. Chronic myeloid leukaemia is the single greatest therapeutic success in oncology and acute myeloid leukaemia in the elderly is among the

greatest failures, so one label across the group would be false in both directions and none is assigned here.

GLOBOCAN 2022 gives 487,294 cases of leukaemia of all types; GLOBOCAN 2024 gives 495,113 cases and 292,234 deaths. GLOBOCAN reports leukaemia as a single category and does not disaggregate the four types, which is a significant limitation, so the type-specific figures below are from SEER. Leukaemia is the commonest cancer of childhood, with acute lymphoblastic leukaemia accounting for roughly three-quarters of childhood leukaemia.

## 18. Acute myeloid leukaemia

**What it is.** A rapidly progressive cancer in which immature myeloid cells fill the bone marrow and crowd out normal blood production. Untreated it kills within weeks to a few months, from infection or bleeding. It is predominantly a disease of older people, and age is the dominant determinant of whether it can be cured.

**Measured.** United States incidence is 4.4 per 100,000 a year, with 22,720 projected new cases and 11,500 projected deaths for 2026, about 1.1 per cent of United States cancer cases and 1.8 per cent of cancer deaths. Five-year relative survival is 33.4 per cent overall. SEER does not stage acute myeloid leukaemia, so no localized-regional-distant breakdown exists; the meaningful stratification is by age and by cytogenetic and molecular risk, and those figures are from the general haematology literature: children and young adults roughly 65 to 70 per cent; adults under 60 with favourable cytogenetics roughly 55 to 65 per cent; adults over 60 roughly 5 to 15 per cent; adverse-risk cytogenetics, including complex karyotype, monosomy 7 and TP53 mutation, under 10 per cent regardless of age; and acute promyelocytic leukaemia above 90 per cent. Median age at diagnosis 70, which is the central clinical fact: it is a disease of people too old to tolerate the treatment that cures it. Prevalence in the United States in 2023 was 83,311 people. Incidence is stable and the death rate falling about 0.9 per cent a year.

**Where it starts.** Prior cytotoxic chemotherapy and radiotherapy give a well-defined entity. Alkylating agents — cyclophosphamide, melphalan, chlorambucil — cause it at a latency of five to seven years with adverse cytogenetics; topoisomerase II inhibitors — etoposide, anthracyclines — at a latency of one to three years with KMT2A rearrangements†. This is an iatrogenic cancer, caused by the treatment of other cancers. Benzene is IARC Group 1 for acute myeloid leukaemia, the classic occupational cause, established in rubber, shoemaking, painting and petroleum work. Ionising radiation is established from the atomic bomb survivor cohorts, dose-dependently and with a latency of several years. Smoking is an established cause at a relative risk generally reported in the region of 1.4 for current smokers, with an attributable fraction of roughly 20 per cent of adult cases†. Myelodysplastic syndrome, myeloproliferative neoplasms and aplastic anaemia transform to it, and clonal haematopoiesis of indeterminate potential, present in over 10 per cent of people over 70, carries a small annual risk of progression of roughly 0.5 to 1 per cent a year†. Germline predisposition comes from Down syndrome, with a large increase in childhood megakaryoblastic disease, Fanconi anaemia, Li-Fraumeni syndrome, and germline RUNX1, CEBPA, GATA2 and DDX41 mutations. Acute myeloid leukaemia has one of the lowest point-mutation burdens of any adult cancer, typically fewer than ten coding mutations per genome, far below the adult reference of 1.8 per megabase, with the TCGA study finding a mean of thirteen coding mutations. It is driven by a small number of recurrent events — FLT3, NPM1, DNMT3A, IDH1 and IDH2, TET2, RUNX1, TP53 and the fusion genes — rather than by a mutational storm, and that low burden explains its near-total resistance to checkpoint blockade. Not known: the cause of the large majority of de novo disease; why the same genetic lesions give such different outcomes at different ages; whether the age effect is tumour biology, host tolerance of treatment, or both, and in what proportion; which carriers of clonal haematopoiesis will progress.

**Cure status.** Acute promyelocytic leukaemia, t(15;17) with PML-RARA: CURABLE, and it is the most important exception here — once the most rapidly fatal form of leukaemia, it is now cured in over 90 per cent of patients†. The curative treatment is all-trans retinoic acid with arsenic trioxide, and in non-high-risk disease that combination cures without any conventional chemotherapy at all. Both are listed and both are off-patent. Children and fit adults under 60: CURABLE in roughly 55 to 70 per cent at five years, depending on cytogenetic risk†, with intensive induction, consolidation, and allogeneic stem cell transplantation for

higher-risk disease. Adults over 60 who tolerate hypomethylating therapy: CONTROLLABLE — five-year survival roughly 5 to 15 per cent†. Adults over 60 who do not: RELIEF ONLY. Adding venetoclax to azacitidine changed this materially, with median survival in unfit older patients roughly doubled from about 10 to 15 months and complete remission rates above 60 per cent†, and it is not curative. Adverse-risk and TP53-mutated disease: RELIEF ONLY — five-year survival under 10 per cent even with transplantation†. Relapsed disease after transplantation: RELIEF ONLY. Early detection does not apply: there is no detectable preclinical phase that screening could find, no stages, and no benefit from earlier diagnosis beyond avoiding presentation in crisis. Curability is determined by the biology of the clone and the age of the patient, not by timing.

**Prevention.** Benzene exposure control — STRONG, on an IARC Group 1 classification. Occupational limits have reduced it substantially in regulated economies and less so elsewhere. Smoking cessation — MODERATE, at a relative risk of about 1.4 and an attributable fraction of about 20 per cent†. Minimising cumulative alkylating-agent and topoisomerase-inhibitor dose in the treatment of curable cancers — STRONG as a principle, and the reason de-escalation trials in Hodgkin lymphoma, testicular cancer and childhood leukaemia matter so much. This is prevention of a cancer caused by cancer treatment, and it is one of the main justifications for de-escalation research. Radiation protection — STRONG. There is no screening and no rationale for one: there is no pre-malignant lesion to intercept at population level. Clonal haematopoiesis is detectable incidentally on sequencing, carries roughly a 0.5 to 1 per cent annual progression risk, and has no intervention proven to reduce that risk, so detecting it creates anxiety without an action. Monitoring of known myelodysplastic syndrome and of germline predisposition carriers is surveillance of established risk rather than screening, and has no randomised mortality evidence. Overdiagnosis is not a meaningful concept here.

**Treatment.** Relapse after transplantation is not curable in most patients, and the proportion rescued is not given. All-trans retinoic acid with arsenic trioxide for acute promyelocytic leukaemia comes first. Tretinoin and arsenic trioxide are both listed and both off-patent, at a cure rate over 90 per cent†. Generic all-trans retinoic acid costs in the order of tens to low hundreds of dollars a course and generic arsenic trioxide is similarly inexpensive, against a far higher originator price. **That is a striking cost-effectiveness fact: a formerly near-universally fatal leukaemia is cured in over 90 per cent of patients by two off-patent Essential Medicines, one a vitamin A derivative and the other a traditional arsenic preparation.** Intensive induction chemotherapy, cytarabine with daunorubicin, follows for fit patients; both are listed and off-patent, at tens of dollars a vial, and this regimen, essentially unchanged since the 1970s, remains the backbone of curative therapy. The drugs are cheap and the supportive care is not. Consolidation uses high-dose cytarabine, listed and off-patent. Allogeneic haematopoietic stem cell transplantation is the most effective anti-leukaemic treatment available and the only cure for many higher-risk patients, at a treatment-related mortality of 10 to 20 per cent†, and it requires a transplant unit, tissue typing, a donor and intensive supportive care: the least transferable intervention in this chapter. Venetoclax with azacitidine serves unfit or older patients. **Venetoclax is not on the Essential Medicines List in any form: a query of the electronic list returns zero recommendations, zero medicines and zero therapeutic equivalents**. It is on patent, at a United States list price in the region of US$10,000 to 15,000 a month†; azacitidine is off-patent with generics available cheaply and is likewise not listed. Complete remission rates above 60 per cent and roughly doubled median survival in unfit older patients in the VIALE-A trial make this the most important advance in acute myeloid leukaemia in decades, and the key drug is not on the list. Midostaurin, gilteritinib and quizartinib for FLT3-mutant disease are not listed and all on patent, and add a survival benefit to chemotherapy. Ivosidenib, enasidenib and olutasidenib are not listed, and nor is gemtuzumab ozogamicin. Hydroxyurea is listed, for chronic myeloid leukaemia and for haemoglobinopathies, off-patent, at cents a day, and reduces a dangerously high white cell count quickly; in a setting with no capacity for intensive chemotherapy, hydroxyurea with transfusion support is palliative management achievable almost anywhere. Checkpoint inhibitors are inactive, consistent with the very low mutation burden. Supportive care — red cell and platelet transfusion, broad-spectrum antibiotics, antifungals, and granulocyte colony-stimulating factor, with filgrastim and pegfilgrastim both listed and filgrastim off-patent with biosimilars — is not adjunctive. It is the reason intensive therapy is survivable at all.

**Simple means.** All-trans retinoic acid for acute promyelocytic leukaemia, started on clinical suspicion before confirmation, is the highest-value simple intervention in leukaemia care. Acute promyelocytic leukaemia kills by catastrophic haemorrhage in the first days, and the drug is an oral capsule, off-patent, listed, and reverses the coagulopathy within days. A clinician who suspects it from the blood film and the bleeding and starts the drug immediately, before cytogenetics are available, prevents deaths. It needs no cold chain, no infusion and no monitoring beyond clinical observation, and where confirmatory genetics are unavailable, starting on morphological suspicion is defensible and is practised. Arsenic trioxide requires intravenous administration and electrocardiographic monitoring for QT prolongation, which is a modest requirement. Hydroxyurea is oral, listed, off-patent and cents a day, and reduces hyperleucocytosis and relieves symptoms; in a setting with no chemotherapy capability it is the realistic option. Transfusion of red cells and platelets requires a blood bank, which is a real but attainable requirement. **The absence of a platelet supply is the binding constraint on treatment in most of the world: without platelets, intensive chemotherapy kills by haemorrhage, so the low drug cost is irrelevant.** Oral antibiotics and antifungals, handwashing, isolation where possible and prompt empirical antibiotics for fever carry much of what makes neutropenia survivable, and most of that is organisational rather than technological. Oral morphine, antiemetics, mouth care for mucositis and nutritional support follow. This entry requires an unusually sharp honest statement: the cytotoxic drugs that cure acute myeloid leukaemia are cheap, off-patent and listed, and they are useless without the supportive care chain. Cytarabine and daunorubicin cost tens of dollars; the four weeks of profound neutropenia and thrombocytopenia they cause require platelet transfusions, blood cultures, intravenous antifungals and an inpatient bed, and without those the treatment has a very high mortality. **Acute myeloid leukaemia is therefore the clearest case in this chapter where cheap off-patent drugs do not translate into simple means.** The promyelocytic exception is genuine and important precisely because it bypasses the marrow-ablating chemotherapy and therefore bypasses the supportive care requirement.

**Gaps.** GLOBOCAN does not disaggregate leukaemia by type, so all type-specific burden figures here are United States SEER. SEER publishes no risk-stratified survival table, so the age- and cytogenetic-risk figures are literature-derived. The smoking relative risk is not primary-source-verified. Venetoclax, the key advance for older patients, is confirmed absent from the Essential Medicines List and no rationale for its absence is retrievable. There is no established cause for most de novo disease. Clonal haematopoiesis progression risk is known and no intervention exists, so its detection has no actionable consequence.

## 19. Acute lymphoblastic leukaemia

**What it is.** A cancer of immature lymphoid cells, predominantly affecting children, in whom it is the commonest cancer of all. In children it is now curable in the large majority; in adults the same disease with the same name is far less curable. The difference between those two outcomes is one of the most instructive facts in oncology.

**Measured.** United States incidence is 1.9 per 100,000 a year, with 6,250 projected new cases and 1,600 projected deaths for 2026, about 0.3 per cent of United States cancer cases. Five-year relative survival is 73.2 per cent overall. SEER publishes no child-specific survival figure on its page and records that people under 20 account for 52.1 per cent of new cases. The age split is the whole story, and the figures are from the general haematology literature: children aged 1 to 14 approximately 90 to 94 per cent in contemporary cooperative-group protocols in high-income countries; adolescents and young adults roughly 70 to 75 per cent; adults 40 to 60 roughly 40 to 50 per cent; adults over 60 roughly 20 per cent or less; and infants under one year, usually with KMT2A rearrangement, roughly 40 to 50 per cent. Median age at diagnosis 18, the youngest of any entity in this chapter. Incidence has not significantly changed and the death rate is falling about 1.8 per cent a year. The geographical gap is not biological: WHO states that more than 80 per cent of children with cancer are cured in high-income countries against less than 30 per cent in most low- and middle-income countries. For childhood acute lymphoblastic leukaemia specifically the divergence is at its starkest, because the disease is highly curable with off-patent drugs and the cure depends on eighteen months to three years of uninterrupted protocol-adherent treatment with supportive care, which is exactly what fails when health systems are weak. Abandonment of treatment, not drug cost and not drug availability, is a leading cause of death from it in low-income settings.

**Where it starts.** The cause of childhood acute lymphoblastic leukaemia is not established, and it is one of the most studied unanswered questions in cancer epidemiology. The dominant hypothesis is a two-hit model. The first hit is an in-utero initiating translocation, detectable on neonatal blood spots in a proportion of children who later develop the disease, and present in far more children than ever develop it. The second is a genetic hit precipitated by an abnormal immune response to common infection, in a child whose immune system has had insufficient early microbial exposure. The epidemiological support is indirect — the association with higher socioeconomic status and with reduced early-life infection exposure, the protective associations of breastfeeding, day-care attendance and vaginal delivery, and the delayed infection pattern — and no single infectious agent has been identified. The hypothesis is widely regarded as the best available and it is not proven. Ionising radiation is established, including in-utero exposure, and is the clearest established environmental cause. Down syndrome gives a roughly twentyfold increase in childhood risk; ataxia-telangiectasia, Nijmegen breakage syndrome, Li-Fraumeni syndrome, Bloom syndrome, germline PAX5, ETV6 and IKZF1 variants and constitutional mismatch repair deficiency follow, and germline predisposition accounts for roughly 5 to 10 per cent of childhood cases†. Prior chemotherapy causes therapy-related disease, far less commonly than therapy-related acute myeloid leukaemia. Benzene and other occupational exposures are established for adult disease at much weaker effect sizes than for acute myeloid leukaemia. Childhood acute lymphoblastic leukaemia has among the very lowest mutation burdens ever measured in human cancer. Gröbner and colleagues, in *Nature* in 2018, analysed 961 tumours across 24 molecular cancer types and found an overall paediatric somatic mutation frequency of 0.13 mutations per megabase against the adult reference of 1.8 — about fourteen times lower — and this disease sits at or below the paediatric average. It is driven by structural events — ETV6-RUNX1, high hyperdiploidy, TCF3-PBX1, BCR-ABL1, KMT2A rearrangements and the Philadelphia-like signature — rather than by point mutations. That has a practical consequence: there is essentially no mutational burden for checkpoint inhibitors to exploit, and checkpoint blockade has no role here. The successful immunotherapies — blinatumomab and CD19-directed cell therapy — work by redirecting T cells against a lineage antigen that is present whether or not the tumour is mutated. Not known: the cause of the large majority of childhood cases; why the identical translocation is present in many more newborns than ever develop leukaemia; **why the same disease is 90 per cent curable at age 5 and 20 per cent curable at age 70** — the contributions of clonal biology, treatment tolerance and marrow reserve are not separable with current data.

**Cure status.** Childhood disease, ages 1 to 14: CURABLE, and the outstanding success of paediatric oncology — five-year survival approximately 90 to 94 per cent in high-income settings†, from essentially zero in 1960. The cure is achieved by two to three years of multi-agent chemotherapy with central nervous system prophylaxis, risk-stratified by minimal residual disease response. Adolescents and young adults: CURABLE, and a majority are cured, better with paediatric-intensity protocols than with adult protocols, a finding that changed practice. Adults 40 to 60: CURABLE, and roughly half are cured†. Adults over 60: CONTROLLABLE — roughly 20 per cent or less survive five years†. Philadelphia-positive disease, with the BCR-ABL1 fusion: CURABLE, including in the elderly — transformed from the worst-prognosis subtype to one of the better ones. Adding a tyrosine kinase inhibitor to chemotherapy raised long-term survival substantially, and chemotherapy-free regimens of dasatinib or ponatinib with blinatumomab have produced complete molecular response rates above 80 per cent in older adults who could not tolerate chemotherapy†. Relapsed childhood disease: CURABLE in roughly 40 to 50 per cent with reinduction and transplantation, or with CD19-directed therapy†. Infant KMT2A-rearranged disease: CURABLE in roughly 40 to 50 per cent†, the worst paediatric subgroup. Early detection does not apply: there is no pre-clinical detectable phase and no stages, and curability is determined by age, immunophenotype, cytogenetics and minimal residual disease response rather than by how soon it is found.

**Prevention.** Avoiding unnecessary diagnostic and therapeutic ionising radiation, especially in pregnancy and childhood — STRONG, and the only established prevention. Everything suggested by the delayed-infection hypothesis — breastfeeding, day-care attendance, early microbial exposure — is CONTESTED: the associations are consistent and biologically coherent and there is no interventional evidence. A defined microbial exposure in infancy has been proposed as preventive; that is a hypothesis with no trial behind it and should not be presented as established. There is no screening and no rationale for one. Neonatal blood

spots can detect the ETV6-RUNX1 fusion, and it is present in roughly 1 per cent of newborns while only about one in a hundred of those ever develops leukaemia, so a positive test would be wrong 99 times out of 100: a clear illustration of why a detectable pre-clinical marker does not make a screening test. Overdiagnosis is not a meaningful concept here. Childhood acute lymphoblastic leukaemia cannot currently be prevented. Its cure rate, not its prevention, is where the achievement lies, and the achievable gain now is in delivering existing treatment to the children who do not receive it.

**Treatment.** The proportion of Philadelphia-positive disease cured is not given. Adding a tyrosine kinase inhibitor to chemotherapy raised long-term survival substantially, including in the elderly. Multi-agent risk-stratified chemotherapy over two to three years, in phases — induction, consolidation, interim maintenance, delayed intensification and maintenance. The drugs are, almost without exception, listed and off-patent. Vincristine is listed, with leukaemias among its listed indications. Prednisolone, prednisone and dexamethasone are all listed, and dexamethasone's listed indications in the antineoplastic section include acute lymphoblastic leukaemia. Asparaginase and pegaspargase are listed. Methotrexate is listed, with leukaemias among its indications. Mercaptopurine, cytarabine, cyclophosphamide, daunorubicin, doxorubicin, tioguanine and calcium folinate are all listed and all off-patent. **The regimen that cures over 90 per cent of children with acute lymphoblastic leukaemia is built entirely from off-patent Essential Medicines, and the total drug cost of a full two- to three-year protocol is in the region of a few hundred to a low thousands of dollars**. The barrier to curing it worldwide is not drug cost and not patents. Intrathecal methotrexate, with or without cytarabine, gives central nervous system prophylaxis; both are listed, off-patent and pennies a dose. Without that prophylaxis the disease relapses in the central nervous system in a large proportion of children and is then usually fatal, so this cheap intrathecal injection is one of the most important single components of the cure, and it requires only a lumbar puncture needle and a skilled operator. Cranial irradiation, formerly used for the same purpose, has largely been abandoned because of its late effects — second cancers and cognitive impairment — which is itself an example of successful de-escalation. Imatinib for Philadelphia-positive disease is listed and off-patent, at United States generic cash prices, October 2026, of US$1.49 to 5.37 per 400 mg tablet and US$44.75 to 161.09 for thirty, which is US$540 to 1,960 a year at 400 mg daily. The originator price was in the region of US$90,000 to 145,000 a year at United States list by the time of generic entry in 2016†. Dasatinib is listed and off-patent in many markets; ponatinib is not listed and is on patent. **Blinatumomab is a listed medicine, for B-cell acute lymphoblastic leukaemia**, and is not off-patent. In relapsed or refractory paediatric and adult disease it produces complete remission in the region of 35 to 45 per cent as monotherapy†. Added to consolidation in first remission it improved survival substantially in randomised trials and is now moving into frontline use. The course cost at United States list is in the region of US$180,000 or more†. Its inclusion on the list at that price is notable, and section F returns to it. CD19-directed CAR T-cell therapy — tisagenlecleucel for paediatric and young adult relapsed or refractory B-cell disease, obecabtagene autoleucel and brexucabtagene autoleucel for adult disease — is on patent, and **no CAR-T product is on the Essential Medicines List**. In the pivotal paediatric trial complete remission was achieved in the large majority; NCI states that the treatment eliminated leukaemia in most children without giving a percentage, and the commonly cited figure is around 80 per cent complete remission with roughly half remaining in remission at longer follow-up. A precise per-treatment price could not be retrieved from the price guide, which states only that pricing varies; the United States list price of tisagenlecleucel for this indication has been reported at US$475,000 for a single infusion, with total episode costs higher once lymphodepletion, hospitalisation and toxicity management are included. Allogeneic stem cell transplantation serves high-risk and relapsed disease. Nelarabine for T-cell disease is not listed and is off-patent. Checkpoint inhibitors have no role. Supportive care — transfusion, antibiotics, antifungals, filgrastim, and rasburicase and allopurinol for tumour lysis syndrome, all listed and the last two off-patent — closes the regimen. Tumour lysis syndrome is a specific early killer: a high tumour burden dissolving rapidly releases potassium, phosphate and urate and causes renal failure and arrhythmia. Allopurinol is listed for tumour lysis syndrome and costs cents, hydration costs almost nothing, and together they prevent most of it.

**Simple means.** Oral prednisolone, oral mercaptopurine and oral methotrexate carry the maintenance phase, which occupies most of the two to three years and is almost entirely

oral, off-patent, listed and cheap. It requires a blood count every few weeks and a clinician to adjust the dose, so it is genuinely deliverable with modest infrastructure, and it is where much of the cure is consolidated. Vincristine and intrathecal methotrexate are injections given in an outpatient clinic, and the intrathecal route needs a lumbar puncture, a needle and training, with no imaging. Allopurinol and hydration prevent tumour lysis for cents, and are universally available. Oral antibiotics, infection control, oral rehydration and nutritional support follow. The honest statement here matters because the gap is organisational rather than technological: the drugs that cure childhood acute lymphoblastic leukaemia are cheap and listed, and the cure still fails in most of the world. What is missing is not the pharmacy but the system. It needs a reliable blood and platelet supply for the intensive phases, inpatient beds for febrile neutropenia, an uninterrupted drug supply for three years, and a laboratory that can do a blood count and a blast percentage. It also needs families who can afford to stay in treatment, and a service that follows up a child who misses an appointment. Abandonment of treatment is a leading cause of death in low-income settings, and it is a failure of social and financial support rather than of medicine. Where nothing simple exists: relapsed and refractory disease. Blinatumomab requires continuous intravenous infusion by pump for weeks; CAR-T requires apheresis, a cell-processing facility and intensive care for cytokine release syndrome; transplantation requires a transplant unit. None is achievable by simple means, and the reported CAR-T price of US$475,000 an infusion at United States list places it outside the reach of the large majority of the world's children who need it.

**Gaps.** GLOBOCAN does not disaggregate leukaemia by type. SEER's page gives no child-specific survival figure, only that under-20s are 52.1 per cent of cases, so the paediatric figure of 90 to 94 per cent is literature-derived. CAR-T pricing could not be retrieved from a primary source and NCI's own page gives no prices at all. NCI gives the paediatric response as "most children" without a percentage. The cause of childhood acute lymphoblastic leukaemia is unknown and the delayed-infection hypothesis has no interventional evidence. The reason for the age-curability gradient is not resolved. Blinatumomab is listed at a reported course price of US$180,000 at United States list, and no listing rationale was retrievable.

## 20. Chronic myeloid leukaemia

**What it is.** A cancer of the myeloid cells caused by a single specific genetic accident: a fusion of the BCR and ABL1 genes produced by a translocation between chromosomes 9 and 22. It produces one abnormal protein, and a tablet that blocks that protein converts the disease from fatal to compatible with a normal lifespan. It is the proof of principle for all targeted cancer therapy.

**Measured.** United States projections for 2026 are 9,650 new cases and 1,170 deaths, about 0.5 per cent of cancer cases and 0.2 per cent of cancer deaths. Five-year relative survival is 71.1 per cent, and that figure substantially understates current outcomes: it covers a cohort including older patients diagnosed across the period and those with advanced-phase disease. In contemporary series of patients diagnosed in chronic phase and treated with a tyrosine kinase inhibitor, ten-year survival is roughly 85 to 90 per cent and life expectancy approaches that of the general population. The long-term follow-up of the IRIS trial reports an estimated ten-year overall survival of 83.3 per cent†. Median age at diagnosis 67. United States incidence is rising about 1.0 per cent a year and the death rate falling about 0.7 per cent a year. Prevalence is rising steeply, because patients now live for decades on treatment rather than dying within three to five years, and that is a new kind of health-system problem: a growing population needing an indefinite daily tablet. Before imatinib, median survival in chronic-phase disease was roughly three to five years and allogeneic transplantation was the only cure.

**Where it starts.** Ionising radiation is the only established cause, demonstrated in the atomic bomb survivor cohorts and in patients given therapeutic radiation, dose-dependently. No other risk factor is established: smoking, benzene, occupation, diet, infection and family history have all been studied and none is established, and there is essentially no familial disease and no germline predisposition syndrome that produces it. Chronic myeloid leukaemia has the lowest mutation burden of any cancer in this chapter and is the closest thing in oncology to a single-mutation disease. Chronic-phase disease carries very few somatic mutations beyond the fusion itself, often almost none detectable by exome sequencing, against an adult reference of 1.8 per megabase. The fusion is present in essentially 100 per cent of cases†:

it is both necessary and, in chronic phase, very nearly sufficient. Progression to accelerated phase and blast crisis is accompanied by the acquisition of further lesions — TP53, RUNX1, ASXL1, IKZF1 and additional cytogenetic abnormalities — and that acquisition is what makes advanced-phase disease behave like acute leukaemia. Not known: what causes the translocation in the great majority of patients, who have had no radiation exposure; **why a small proportion of patients in deep molecular remission relapse after stopping treatment and most do not** — the biology of the residual leukaemic stem cell is the central unanswered question, and it determines whether a patient can ever stop treatment.

**Cure status.** Chronic phase on continuous therapy: CONTROLLABLE with near-normal life expectancy — roughly 85 to 90 per cent ten-year survival, with most deaths from unrelated causes†. That is the best outcome of any malignancy in this chapter achieved by a drug alone. Chronic phase in sustained deep molecular response who stop treatment: CURABLE in roughly 50 per cent — patients in sustained MR4.5 response for at least two years who stop remain in remission in roughly 50 per cent of cases at two to three years, and the remainder relapse and almost all regain response on restarting. For the half who remain off treatment, they have no detectable disease and take no drug, though residual leukaemic cells are usually still present and the field uses the term operational cure. Accelerated phase: CONTROLLABLE, with a worse prognosis. Blast crisis: RELIEF ONLY — it behaves as acute leukaemia with poor response and median survival in months; allogeneic transplantation after returning to chronic phase is the only curative option. Allogeneic stem cell transplantation: CURABLE — long-term disease-free survival above 60 to 70 per cent in young patients with matched donors, at a treatment-related mortality of 10 to 20 per cent†. It has been displaced to third or fourth line by the oral inhibitors, which achieve better survival with no mortality risk, and that displacement is one of the clearest cases in medicine of a curative but dangerous treatment being correctly abandoned in favour of a non-curative but safe one. Early detection partly applies: diagnosis in chronic phase rather than in blast crisis matters enormously, and the disease is often found incidentally on a routine blood count showing a high white cell count. This is close to the only cancer in this chapter where a full blood count — the cheapest laboratory test in medicine — functions as an effective early-detection test, even though no screening programme exists.

**Prevention.** Avoiding unnecessary ionising radiation — STRONG as the only established measure, and of negligible population impact, because radiation accounts for a tiny fraction of cases. No other prevention exists: there is nothing to avoid, nothing to take and no behaviour to change. There is no screening programme and no recommendation for one, because the prevalence is far too low. However, the disease is routinely detected incidentally by a full blood count done for another reason, and because it is silent in early chronic phase and highly treatable, incidental detection is unambiguously beneficial. **There is no overdiagnosis problem in chronic myeloid leukaemia**: every case detected is a real disease that would have progressed to blast crisis and death if untreated. It is one of very few entries in this chapter where more detection is simply good.

**Treatment.** Imatinib is listed and off-patent, with United States generic cash prices, October 2026, of US$1.49 to 5.37 per 400 mg tablet, US$44.75 to 161.09 for thirty tablets, and US$0.40 to 1.73 per 100 mg tablet, so US$540 to 1,960 a year at the standard chronic-phase dose of 400 mg daily. The originator was priced at roughly US$30,000 a year at launch in 2001 and had risen to roughly US$90,000 to 145,000 a year in the United States by the time of generic entry in 2016†, and the price guide lists the brand with no price. **The originator-to-generic ratio is therefore about 46- to 269-fold, and this is a large price fall in cancer medicine**: it converted the definitive treatment for a fatal leukaemia from one of the most expensive drugs in the world into one costing a few dollars a day. In generic-supplying markets it has been available at under US$400 a year, and reported as low as US$100 to 200 a year at the most competitive prices†. Complete cytogenetic response is achieved in roughly 80 to 85 per cent of chronic-phase patients, with an estimated ten-year overall survival of 83.3 per cent in long-term follow-up†. Dasatinib and nilotinib are both listed; dasatinib is off-patent in many markets, with generic prices a fraction of the originator price of US$150,000 to 200,000 a year at United States list†, and nilotinib's patent status is market-dependent. They achieve deeper and faster molecular responses and are preferred in higher-risk disease and in some resistance mutations, and they have not been shown to improve overall survival over imatinib, which is worth stating plainly, because it means the cheap off-patent drug is not inferior on the endpoint that matters most. Bosutinib, ponatinib and asciminib are not

listed and are on patent in most markets; ponatinib is the only inhibitor active against the T315I resistance mutation and carries substantial arterial thrombotic toxicity. Hydroxyurea is listed, with chronic myeloid leukaemia among its listed indications, off-patent, at cents a day, and reduces a very high white cell count at presentation while the diagnosis is confirmed and an inhibitor is obtained; in a setting with no access to any inhibitor it controls the count and the symptoms for a period and does not prevent progression to blast crisis. Interferon alfa was the pre-imatinib standard, produced long-term survival in a small minority, and is now used mainly in pregnancy, where the inhibitors are contraindicated; it is off-patent. Allogeneic transplantation is curative and now reserved for resistant disease and blast crisis. Molecular monitoring by quantitative polymerase chain reaction for the fusion transcript is integral to modern management: response milestones at three, six and twelve months determine whether to change drug, and achieving a deep molecular response determines eligibility for discontinuation. That is the binding infrastructure requirement.

**Simple means.** One oral tablet a day, off-patent, listed, at US$1.50 to 5 a day at United States generic cash prices, October 2026, and under a dollar a day at the most competitive international generic prices. No infusion, no cold chain, no inpatient bed, no transfusion support, no radiotherapy, no surgery. A patient takes a tablet and lives a normal lifespan. **In terms of benefit delivered per unit of infrastructure, imatinib for chronic myeloid leukaemia is the single best intervention in this chapter.** Diagnosis is possible by full blood count and blood film: a raised white cell count with the characteristic spectrum of myeloid maturation, with basophilia and splenomegaly on examination, is highly suggestive and can be recognised with a microscope and a trained eye. Confirmation requires cytogenetics or polymerase chain reaction, which is the one genuine technological requirement, and where that is unavailable the clinical and morphological diagnosis of chronic-phase disease is reliable enough that treating on it has been considered defensible, and some access programmes have operated that way. Hydroxyurea is oral at cents a day and controls the white count where no inhibitor is available. Splenectomy for massive symptomatic splenomegaly is rarely needed now and is a conventional operation. Allopurinol and hydration prevent tumour lysis at presentation for cents. The real constraint is that the drug is cheap and simple and the monitoring is not. Quantitative polymerase chain reaction at an international-standard reference laboratory is required to know whether a patient is responding adequately, to decide whether to switch drug, and above all to know whether a patient can safely stop treatment. Without molecular monitoring, patients can be treated and most will do well on imatinib, and they cannot be optimised, and treatment-free remission cannot be attempted at all, because stopping without molecular surveillance is unsafe. **This is the clearest example in the chapter of a disease where the therapeutic problem has been solved by simple means and the remaining gap is diagnostic infrastructure.** The second constraint is continuity: treatment is indefinite, and an interruption of supply allows the disease to progress.

**Gaps.** GLOBOCAN does not disaggregate leukaemia by type. SEER's 71.1 per cent five-year relative survival materially understates contemporary chronic-phase outcomes, and SEER publishes no phase-stratified or inhibitor-era-restricted figure. The ten-year IRIS figure, originator pricing, international generic prices and the treatment-free remission rate are all literature-derived. Why some patients relapse after discontinuation and most do not is unknown, and it is the central open question. The cause of the translocation in non-irradiated patients is unknown.

## 21. Chronic lymphocytic leukaemia

**What it is.** A slowly accumulating cancer of mature B lymphocytes, the commonest leukaemia of older adults in Western countries. Many patients never need treatment at all and die of something else; others progress and require years of therapy. It is the cancer in which watch and wait is a proven standard of care rather than a failure to act.

**Measured.** United States projections for 2026 are 22,760 new cases and 4,350 deaths, about 1.1 per cent of cancer cases and 0.7 per cent of cancer deaths. Five-year relative survival is 90.2 per cent. SEER does not stage it in the localized-regional-distant scheme; the clinical staging systems are Rai and Binet, and the key prognostic markers are immunoglobulin heavy-chain variable-region mutational status, deletion of 17p or TP53 mutation, and deletion of 11q. The prognostic strata, from the general haematology literature: mutated variable region with no TP53 abnormality, median survival often exceeding 20 to 25 years,

with many such patients never requiring treatment; unmutated variable region, shorter time to treatment and shorter survival; deletion of 17p or TP53 mutation, historically the worst subgroup with survival of a few years, substantially improved by the BTK and BCL2 inhibitors. Median age at diagnosis 71. United States incidence is falling about 0.7 per cent a year and the death rate about 1.9 per cent a year, with the mortality decline accelerating after the introduction of the BTK and BCL2 inhibitors from 2014. The geography is unusual and informative: the disease is roughly five to ten times less common in East Asian populations than in European-ancestry populations, and the difference persists in migrants and their descendants, which indicates a genetic rather than an environmental basis. It also has the strongest familial clustering of any leukaemia, at a roughly seven- to eightfold increased risk in first-degree relatives. Monoclonal B-cell lymphocytosis, the pre-malignant precursor, is present in roughly 3 to 5 per cent of adults over 40 and over 10 per cent of those over 80 on sensitive flow cytometry†. It progresses to disease requiring treatment at roughly 1 to 2 per cent a year†, which bears directly on the screening question.

**Where it starts.** Family history is the strongest established risk factor of any leukaemia, at a roughly seven- to eightfold increased risk in first-degree relatives; no single high-penetrance gene accounts for it, and genome-wide association studies have identified dozens of common low-penetrance variants. Ancestry gives a substantially lower incidence in East Asian populations, persisting after migration. Agricultural work and pesticide exposure show a consistent association in cohort studies of farmers, with the specific agents not established. Hepatitis C virus is associated with some B-cell lymphoproliferative disorders, more clearly with marginal zone lymphoma than with this disease. Notably, this is the one leukaemia not clearly caused by ionising radiation: the atomic bomb survivor cohorts show increases in acute myeloid, acute lymphoblastic and chronic myeloid leukaemia and not in this one, a long-standing and unexplained exception, and benzene is likewise not clearly associated with it. Chronic lymphocytic leukaemia has a low point-mutation burden, below the adult reference of 1.8 per megabase. Recurrent drivers include TP53, NOTCH1, SF3B1, ATM, BIRC3 and MYD88, and the key cytogenetic lesions are deletion of 13q, favourable, trisomy 12, and deletions of 11q and 17p, adverse. Richter transformation — the development of aggressive diffuse large B-cell lymphoma from it in roughly 2 to 10 per cent of patients — is accompanied by acquisition of further lesions and carries a poor prognosis. Not known: what causes it in the great majority; why familial clustering is so strong without a high-penetrance gene; why ionising radiation and benzene, which cause every other leukaemia, do not appear to cause this one; why incidence differs so markedly by ancestry; which carriers of monoclonal B-cell lymphocytosis will progress.

**Cure status.** Early-stage asymptomatic disease, Rai 0 or Binet A: CONTROLLABLE by watchful waiting — intervention adds nothing and demonstrably harms. Randomised trials of early chemotherapy in asymptomatic early-stage disease showed no survival benefit, and the French Cooperative Group trials of early chlorambucil showed a possible survival disadvantage. Watch and wait is the evidence-based standard, and a substantial minority of patients never require any treatment and die of unrelated causes with their disease untreated. Progressive or symptomatic disease: CONTROLLABLE — five-year relative survival 90.2 per cent overall. Modern targeted therapy produces very long progression-free intervals, with the majority of patients remaining progression-free at five to seven years in the first-line BTK inhibitor trials, and the disease is not eradicated and treatment is often continuous or repeated. Fixed-duration venetoclax with obinutuzumab produces undetectable minimal residual disease in a majority and allows treatment-free intervals of years, which is the closest this disease comes to functional cure, and most patients eventually relapse. Allogeneic stem cell transplantation: CURABLE — and it carries 10 to 20 per cent treatment-related mortality† and has been almost entirely displaced by the targeted agents in a disease of elderly patients. Richter transformation: RELIEF ONLY — median survival under a year in most series, with no established effective treatment. Early detection confers no benefit, and this is the clearest case in the chapter where earlier detection is demonstrably useless: the pre-malignant state is extremely common, early-stage disease should not be treated, and randomised trials of early intervention showed no gain. It is the counterexample to the general principle that earlier is better.

**Prevention.** There is no established means of preventing it. No modifiable exposure of consequence has been identified, and the dominant risk factors — family history and ancestry — are not modifiable. Reducing occupational pesticide exposure — CONTESTED: consistent

associations in agricultural cohorts, no identified agent, no interventional evidence. Notably the measures that prevent other leukaemias, radiation protection and benzene control, do not appear to prevent this one, since neither exposure is clearly causal for it. There is no screening, and screening would be actively harmful. The reasoning is unusually clear and this is the textbook case. The precursor is present in 3 to 5 per cent of adults over 40 and over 10 per cent over 80, and progresses at only 1 to 2 per cent a year†. Sensitive flow cytometry applied to a population would therefore label a large fraction of older adults with a pre-malignant haematological condition, and the great majority of them would never develop clinically significant disease. Early-stage disease should not be treated, on clear randomised evidence. A screening programme would therefore generate enormous numbers of diagnoses, offer no treatment for them, and deliver only anxiety, insurance consequences and follow-up appointments, and **the overdiagnosis fraction would approach the full population prevalence of the precursor, which has never been quantified as an overdiagnosis percentage.** Incidental detection on a routine blood count nonetheless happens constantly and accounts for a large proportion of diagnoses, with an estimated majority of patients now diagnosed while asymptomatic: unintentional screening at scale, and the reason the measured survival figures have improved partly without any treatment change.

**Treatment.** Observation for asymptomatic early-stage disease is free, evidence-based and the correct first-line management for a large fraction of patients; it is listed first here because it is the treatment of choice rather than the absence of one. Ibrutinib and zanubrutinib are both listed, which is notable for modern targeted agents, and neither is off-patent; acalabrutinib is not listed. United States list prices for BTK inhibitors are in the region of US$150,000 to 180,000 a year, with ibrutinib reported at US$17,000 a month†. In first-line treatment they give objective response rates above 90 per cent with progression-free survival at five to seven years in the majority, the largest and most durable benefit ever achieved in this disease, and ibrutinib is given continuously and indefinitely, which is what drives the cumulative cost. **Venetoclax is not on the Essential Medicines List in any form** and is on patent, at a United States list price in the region of US$10,000 to 15,000 a month†; combined with obinutuzumab as a fixed twelve-month first-line course it gives undetectable minimal residual disease in roughly 75 per cent and progression-free survival at four to five years in the large majority, with treatment then stopped, which makes the total cost finite rather than indefinite. Rituximab is a listed medicine, with chronic lymphocytic leukaemia among its listed indications; the originator is off-patent and biosimilars are widely available, having reduced the price by roughly 50 to 70 per cent in many markets†. **Rituximab's availability as an off-patent biosimilar is the single most important affordability fact in B-cell malignancy treatment**, and it applies here, to non-Hodgkin lymphoma and to several non-malignant diseases. Obinutuzumab is not listed and is on patent. Chemoimmunotherapy is now largely superseded and it is the off-patent option: fludarabine, cyclophosphamide, bendamustine and chlorambucil are all listed and all off-patent and inexpensive. Fludarabine with cyclophosphamide and rituximab produced long remissions and possible functional cure in the mutated-variable-region subgroup without TP53 abnormality†, which is genuinely important, because it means that for a defined subset there exists an entirely off-patent regimen producing outcomes comparable to the targeted agents. Chlorambucil as a single oral agent, the standard from the 1950s, remains the simplest option of all, and bendamustine with biosimilar rituximab is an off-patent regimen with high response rates. Allogeneic transplantation serves younger patients with high-risk or doubly refractory disease. Lisocabtagene maraleucel is approved for this disease, is not listed and is on patent, with a price not retrievable from the price guide and reported in the general literature in the region of US$400,000 to 500,000 an infusion at United States list†. Checkpoint inhibitors are inactive, consistent with the low mutation burden. Supportive care matters disproportionately: immunoglobulin replacement for recurrent infection, because the disease causes profound secondary antibody deficiency and infection is the commonest cause of death; vaccination against pneumococcus and influenza; and aciclovir and co-trimoxazole prophylaxis during fludarabine or BTK-inhibitor therapy, both listed, off-patent and costing cents. **Infection prevention delivers more survival benefit per dollar here than anything except the decision not to treat early disease.**

**Simple means.** Observation comes first, deliberately. For a substantial proportion of patients the correct management requires nothing at all beyond a periodic blood count and clinical review, and the evidence for it is randomised. That is the cheapest correct cancer

management in this chapter. Oral chlorambucil is listed, off-patent, a tablet at cents a day, with no cold chain, no infusion and no monitoring beyond a blood count. It controls disease, shrinks nodes and relieves symptoms, and it is inferior to modern therapy on progression-free survival; in a setting with no access to rituximab or a BTK inhibitor it is real and effective palliation that can be given in any clinic, and it was the standard of care for half a century. Diagnosis is possible by full blood count and blood film: a sustained lymphocytosis of mature-looking small lymphocytes, with smudge cells, in an older adult is recognisable with a microscope. Confirmation requires flow cytometry for the immunophenotype, which is the genuine technological requirement, and as with chronic myeloid leukaemia the morphological diagnosis in a typical case is reliable enough that treatment decisions have been made on it where flow cytometry is unavailable. Co-trimoxazole, aciclovir and vaccination cost cents and are listed, and infection is the commonest cause of death here, so these prevent a large share of it. Blood transfusion treats the anaemia of marrow infiltration or autoimmune haemolysis, and prednisolone, listed, off-patent and cents, treats the autoimmune haemolytic anaemia and immune thrombocytopenia that complicate the disease and respond well. Splenectomy serves massive symptomatic splenomegaly or refractory cytopenias and is a conventional operation. The modern agents that transformed the disease have no simple-means equivalent, require indefinite or twelve-month supply chains and cost hundreds of thousands of US dollars a year at list, and the two on the list are still on patent. The gap this creates is narrower here than in most entries, for two reasons: a large fraction of patients need no treatment at all, and the off-patent chemoimmunotherapy option delivers a substantial share of the achievable benefit. Chronic lymphocytic leukaemia is a disease where the simple means — observation, a cheap oral alkylator, infection prophylaxis and transfusion — go a surprisingly long way.

**Gaps.** GLOBOCAN does not disaggregate leukaemia by type. SEER publishes no prognostic-marker-stratified survival, so the variable-region and TP53 strata are literature-derived. Precursor prevalence and progression rates are literature-derived. Why ionising radiation and benzene do not cause this leukaemia when they cause every other one is unexplained. The strong familial clustering has no identified high-penetrance gene, and the ancestry difference in incidence is unexplained. BTK inhibitor, venetoclax and CAR-T prices are literature-derived; the price guide did not yield figures. Richter transformation has no established effective treatment and it is the principal unmet need.

## 22. Hodgkin lymphoma

**What it is.** A cancer of B lymphocytes in which a small number of large abnormal cells sit in a mass of reactive immune cells in the lymph nodes. It mostly affects young adults. It was the first disseminated cancer ever cured by drugs, and it remains one of the most curable cancers that exists, which has shifted the central problem from achieving cure to avoiding the long-term damage done by curing it.

**Measured.** GLOBOCAN 2022 gives 82,469 cases; GLOBOCAN 2024 gives 84,495 cases and 19,515 deaths. Five-year relative survival in the United States is 89.3 per cent overall, and this is one of the few entries where SEER publishes survival by Ann Arbor stage: stage I, 13 per cent of cases, 92.7 per cent; stage II, 38 per cent of cases, 95.4 per cent; stage III, 19 per cent, 87.7 per cent; stage IV, 25 per cent, 82.8 per cent; unknown, 5 per cent, 82.1 per cent. **The flatness of that gradient is the most important number in this entry.** Stage IV Hodgkin lymphoma has 82.8 per cent five-year survival, higher than stage I survival in most of the cancers in this chapter. It is essentially stage-independent in its curability, which is almost unique among malignancies and is the reason there is no screening rationale. Median age at diagnosis 38, on a bimodal age distribution with a peak in the twenties and a second after sixty. United States incidence is falling about 1.3 per cent a year and the death rate about 3.1 per cent a year, one of the steeper mortality declines in this chapter. Incidence is higher in high-income countries; the childhood-onset, Epstein-Barr-virus-positive, mixed-cellularity form predominates in low-income settings and in HIV-positive populations, while the young-adult nodular sclerosing form predominates in high-income countries.

**Where it starts.** Epstein-Barr virus genome is present in the Reed-Sternberg cells in roughly 20 to 50 per cent of classical cases in high-income countries†. The proportion is substantially higher, often above 80 to 90 per cent, in children in low-income countries, in older adults, in the mixed-cellularity subtype and in HIV-positive patients. de Martel and colleagues, 2020, gave case counts for *H. pylori*, human papillomavirus and hepatitis B and C only, so no pub-

lished Epstein-Barr-attributable case number for Hodgkin lymphoma is quoted here. The commonly cited global estimate is that the virus accounts for roughly a third of cases, which on GLOBOCAN 2024 incidence would be in the region of 25,000 to 30,000 cases annually; that is an inference and is marked as one. Prior infectious mononucleosis carries a relative risk of roughly 2.5 to 4 for virus-positive disease specifically†. HIV infection raises incidence roughly five- to fifteenfold, and unlike most AIDS-associated malignancies its incidence did not fall with antiretroviral therapy and may have risen — a genuine anomaly attributed to the partially restored but abnormal CD4 compartment that Reed-Sternberg cells appear to require. Immunosuppression after organ transplantation raises risk. Family history gives a roughly three- to ninefold increased risk in siblings, with very high concordance in monozygotic twins, indicating a substantial inherited component without an identified high-penetrance gene. Higher socioeconomic status and small family size are associated with the young-adult form, paralleling the delayed-infection pattern described for childhood acute lymphoblastic leukaemia. The Reed-Sternberg cells are a small minority of the tumour mass, which has made sequencing technically difficult, and the measured coding mutation burden is low to moderate against the adult reference of 1.8 per megabase. The defining molecular features are amplification at 9p24.1 causing PD-L1 and PD-L2 overexpression, and loss of major histocompatibility class I and II expression. **That amplification is the key fact for treatment: Hodgkin lymphoma overexpresses the PD-1 ligand constitutively, which is why checkpoint inhibitors produce response rates in relapsed disease of roughly 65 to 85 per cent**† — the highest of any cancer for this drug class, achieved despite a low mutation burden. This directly contradicts the general rule that mutation burden predicts checkpoint response, and it is the cleanest counterexample available. Not known: why a virus carried by more than 90 per cent of adults† causes lymphoma in a vanishingly small fraction; why the age distribution is bimodal; why incidence did not fall with antiretroviral therapy when other AIDS-defining cancers did.

**Cure status.** Early-stage favourable, stages I to II: CURABLE — five-year relative survival 92.7 per cent for stage I and 95.4 per cent for stage II, with short combined chemotherapy with or without involved-site radiotherapy. Long-term cure rates in trial populations exceed 90 per cent† and most relapses occur within five years, so five-year figures approximate cure here better than in most cancers. Advanced-stage, III to IV: CURABLE in 87.7 per cent at stage III and 82.8 per cent at stage IV (five-year relative survival). **That is a striking curability figure: a widely disseminated malignancy cured in over 80 per cent of patients.** Relapsed after first-line therapy: CURABLE, and roughly half are cured with salvage chemotherapy and autologous stem cell transplantation. Relapsed after transplantation: CONTROLLABLE — brentuximab vedotin and checkpoint inhibitors produce high response rates, 65 to 85 per cent for PD-1 blockade†. Some patients achieve durable remission and allogeneic transplantation can cure; the proportion cured is not given. Essentially no stage of Hodgkin lymphoma is incurable, which is close to unique in this chapter. Early detection barely applies, because it is also reliably curable when caught late: the flat stage gradient, 92.7 to 82.8 per cent, is why there is no screening programme and no rationale for one. Earlier detection would move patients from an 83 per cent cure rate to a 93 per cent cure rate at best, while exposing a young population to the harms of screening. The dominant clinical problem is not cure but the cost of cure. Survivors treated with the regimens of the 1970s to 1990s carry a substantial excess of second cancers. Breast cancer after chest irradiation in young women runs at relative risks reported in the region of 4 to 7, with a cumulative incidence at thirty years of 20 to 30 per cent in women irradiated before age 30†. Lung cancer, sarcoma, and therapy-related acute myeloid leukaemia and myelodysplasia from alkylators and etoposide follow. So do cardiac disease from mediastinal radiation and anthracyclines, thyroid dysfunction and infertility. The excess mortality from these late effects in long-term survivors has in several cohorts exceeded mortality from the lymphoma itself. That is why the whole field has moved towards de-escalation: smaller radiation fields, lower doses, fewer alkylators, response-adapted therapy, and substitution of brentuximab vedotin or nivolumab for bleomycin and procarbazine. Hodgkin lymphoma is the clearest case in oncology where the research agenda is driven by iatrogenic harm rather than by failure to cure.

**Prevention.** There is no established means of preventing Hodgkin lymphoma. There is no vaccine against Epstein-Barr virus, candidates being in early trials, no behaviour to change, and the dominant risk factors — virus seropositivity, genetic background, socioeconomic pattern — are not modifiable. Antiretroviral therapy in HIV — CONTESTED for this cancer

specifically: it reduces most AIDS-associated malignancies dramatically, and Hodgkin lymphoma incidence did not fall and may have risen. That should be stated plainly rather than assimilated to the general HIV-cancer picture. An Epstein-Barr vaccine, if developed, would be the only plausible primary prevention, and it would also address nasopharyngeal carcinoma, Burkitt lymphoma and a share of gastric cancer; it is a hypothetical rather than an available intervention. There is no screening and no rationale for one. The prevention that does exist and is real is prevention of the late effects of treatment, achieved by giving less treatment. Omitting or reducing radiotherapy where response permits — STRONG: randomised response-adapted trials showed that radiotherapy can be omitted in response-negative early-stage patients with a small loss of progression-free survival and no loss of overall survival, while removing the breast and lung cancer risk entirely. Replacing bleomycin, for pulmonary toxicity, and procarbazine, for leukaemogenesis and infertility, with brentuximab vedotin or nivolumab — MODERATE on the toxicity endpoint. Reducing radiation field size and dose — STRONG. Breast cancer surveillance in women irradiated to the chest before age 30 is recommended from eight years after treatment or age 25, using magnetic resonance imaging with mammography. **This is the one place in this chapter where intensive breast screening of young women is clearly justified**, because the absolute risk is high enough to change the balance that makes population screening of young women inappropriate, and no randomised mortality evidence exists for it: it is recommended on risk grounds. Smoking cessation in survivors — STRONG, because the lung cancer risk from chest radiation and smoking is multiplicative rather than additive.

**Treatment.** The proportion cured after relapse following transplantation is not given. ABVD chemotherapy — doxorubicin, bleomycin, vinblastine and dacarbazine — has been the standard for decades and is still widely used. **All four drugs are listed and all four are off-patent**, inexpensive generics, and the drug cost of six cycles is in the region of a few hundred to a low thousands of dollars. ABVD cures over 80 per cent of advanced Hodgkin lymphoma using four off-patent Essential Medicines, and with acute promyelocytic leukaemia and childhood acute lymphoblastic leukaemia that is one of the three clearest demonstrations in this chapter that high cure rates do not require expensive drugs. Escalated BEACOPP — bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine and prednisone — gives a higher cure rate than ABVD in advanced disease at the cost of more toxicity, infertility and secondary leukaemia, and every single drug in it is listed and off-patent. Involved-site radiotherapy makes a curative contribution in early-stage disease, requires a linear accelerator, and is being de-escalated. Brentuximab vedotin is not listed and is on patent, at a United States list price in the region of US$15,000 to 20,000 a cycle and a course cost well above US$100,000†; in relapsed or refractory disease it gives objective response of roughly 75 per cent with complete response of roughly 34 per cent as monotherapy, and added to AVD in frontline advanced disease it improved overall survival in the ECHELON-1 trial. Pembrolizumab is a selected medicine on the list and nivolumab is listed as a therapeutic equivalent to it, for melanoma and for malignant neoplasms of the bronchus and lung; neither is off-patent, and pembrolizumab costs US$1,530.35 per 4 mL (100 mg) unit and US$6,121.41 per four-unit pack at the United States cash price, October 2026, which is about US$53,000 a year at 200 mg every three weeks, against US$150,000 to 200,000 a year at United States list price. Objective response in relapsed or refractory Hodgkin lymphoma is roughly 65 to 85 per cent, the highest for this drug class in any malignancy; pembrolizumab was superior to brentuximab vedotin in relapsed disease in KEYNOTE-204, and nivolumab with AVD was superior to brentuximab vedotin with AVD in frontline advanced disease in SWOG S1826†. The mechanism is the 9p24.1 amplification, not a high mutation burden. Autologous stem cell transplantation after salvage chemotherapy for first relapse is curative in roughly half, and allogeneic transplantation serves multiply relapsed disease. The salvage regimens are built from ifosfamide, carboplatin, etoposide, cisplatin, cytarabine, dexamethasone and gemcitabine, all listed and all off-patent. Supportive care uses filgrastim, listed and off-patent with biosimilars, antiemetics, mesna with ifosfamide, listed and off-patent, and allopurinol, listed. Fertility preservation — sperm banking, or oocyte or ovarian tissue cryopreservation — should be offered before alkylating or BEACOPP therapy in a disease whose median age is 38 and whose cure rate is over 80 per cent, and the failure to offer it is a recognised and avoidable harm.

**Simple means.** ABVD is the outstanding fact in this section. Four off-patent Essential Medicines, given intravenously every two weeks for six months, cure over 80 per cent of

advanced Hodgkin lymphoma, and the drugs cost a few hundred to a low thousands of dollars in total. No targeted agent, no antibody, no transplant and no radiotherapy is required for the majority of patients. The requirements are intravenous access, a reliable drug supply, an antiemetic, a blood count before each cycle, and a clinician who follows the protocol. In terms of lives saved per dollar of drug, ABVD for Hodgkin lymphoma is among the best interventions in this chapter. Diagnosis requires a lymph node biopsy and histopathology. A node can be excised under local anaesthetic with basic instruments, and the binding constraint is the histopathologist: the Reed-Sternberg cells are morphologically distinctive and a competent pathologist with a microscope and basic immunohistochemistry for CD30 and CD15 can make the diagnosis. **Where there is no pathology service the diagnosis cannot be made, and that is the single most common reason Hodgkin lymphoma goes untreated in low-income settings — not the cost of the drugs.** Prednisone or prednisolone alone, listed, off-patent and cents a day, produces rapid symptomatic improvement and nodal shrinkage, and is useful palliation and a bridge while a diagnosis is established or drugs obtained; it does not cure. Oral morphine serves pain and drainage of a pleural effusion with a needle and a set serves breathlessness. Sperm banking requires only a container and a freezer. Where nothing simple exists: relapsed disease requires autologous transplantation, or brentuximab vedotin, or a checkpoint inhibitor, all expensive and infrastructure-dependent. Because first-line ABVD cures over 80 per cent of all patients regardless of stage using only off-patent listed drugs, the proportion of total achievable benefit reachable by simple means is higher in Hodgkin lymphoma than in almost any other malignancy here. The gap is diagnostic and organisational, not pharmaceutical.

**Gaps.** A published Epstein-Barr-attributable case count for Hodgkin lymphoma was not retrievable; de Martel and colleagues gave figures for four agents only, and the one-third figure used above is an inference. Virus-positive proportions, the mononucleosis relative risk, the HIV relative risk and the familial relative risk are all literature-derived. Second-cancer and cardiac late-effect figures are literature-derived, and they are central to the management of this disease, so their absence from the retrievable primary sources is a real limitation. Brentuximab vedotin pricing is literature-derived. Why incidence did not fall with antiretroviral therapy is unexplained. Why a low-burden tumour responds to checkpoint blockade better than any high-burden tumour is mechanistically understood and it undermines mutation burden as a general predictive biomarker, and that tension is unresolved.

## 23. Non-Hodgkin lymphoma

**What it is.** Not one disease but a large family of cancers of lymphocytes, ranging from indolent types that may need no treatment for years to aggressive types that kill within months if untreated. The two commonest are diffuse large B-cell lymphoma, aggressive and curable, and follicular lymphoma, indolent and not curable. Grouping them under one heading, as the cancer registries do, conceals more than it reveals.

**Measured.** GLOBOCAN 2022 gives 553,389 cases; GLOBOCAN 2024 gives 562,793 cases and 234,903 deaths. Five-year relative survival in the United States is 74.3 per cent overall, and SEER publishes Ann Arbor stage-specific survival: stage I, 21 per cent of cases, 87.6 per cent; stage II, 15 per cent, 79.7 per cent; stage III, 17 per cent, 74.0 per cent; stage IV, 37 per cent, 63.6 per cent; unknown, 10 per cent, 71.9 per cent. As with Hodgkin lymphoma the stage gradient is shallow compared with the epithelial cancers in this chapter, and the aggregate averages across subtypes with completely different natural histories, so it is of limited use. The subtype figures are the ones that matter, and they come from the general haematology literature: diffuse large B-cell lymphoma, roughly 30 to 35 per cent of cases, cured in roughly 60 to 65 per cent with R-CHOP and fatal within months if untreated; follicular lymphoma, roughly 20 per cent, median overall survival now exceeding 15 to 20 years and not cured, with many patients never needing treatment initially; marginal zone lymphoma, indolent with long survival, and gastric mucosa-associated lymphoid tissue lymphoma curable by *H. pylori* eradication alone; mantle cell lymphoma, historically poor, median survival now 8 to 10 years and not curable by chemotherapy; Burkitt lymphoma, extremely aggressive with a doubling time of about 24 hours, cured in over 85 to 90 per cent of children and roughly 70 to 80 per cent of adults with intensive short-course chemotherapy; peripheral T-cell lymphomas, roughly 10 per cent, markedly worse than the B-cell lymphomas at five-year survival of roughly 30 to 40 per cent; adult T-cell leukaemia-lymphoma, acute type, me-

dian survival under a year; and primary central nervous system lymphoma, five-year survival roughly 30 per cent. Median age at diagnosis 68, with Burkitt and lymphoblastic lymphomas childhood diseases and most other subtypes rising with age. United States incidence is 18.7 per 100,000 and the death rate 4.8 per 100,000, with a lifetime risk of about 2.0 per cent and 872,940 people living with the disease in 2023. Incidence is falling about 0.6 per cent a year and the death rate about 2.4 per cent a year, the decline following the introduction of rituximab from 1997. Burkitt lymphoma is endemic in the malaria belt of equatorial Africa, where it is the commonest childhood cancer in several countries; adult T-cell leukaemia-lymphoma clusters where HTLV-1 is endemic, in southern Japan, the Caribbean, parts of West Africa, Iran and Romania; and gastric mucosa-associated lymphoid tissue lymphoma follows *H. pylori* prevalence.

**Where it starts.** Non-Hodgkin lymphoma has more established infectious causes than any other cancer group in this chapter. *Helicobacter pylori* is classified as a Group 1 carcinogen for gastric mucosa-associated lymphoid tissue lymphoma as well as for gastric carcinoma. The attributable fraction for that lymphoma approaches 90 per cent, and — uniquely in oncology — eradicating the bacterium cures the lymphoma in roughly 60 to 80 per cent of early-stage cases†. Epstein-Barr virus causes Burkitt lymphoma, with the genome present in essentially 100 per cent of endemic African cases and roughly 20 to 30 per cent of sporadic cases†. It also causes post-transplant lymphoproliferative disorder, extranodal natural-killer T-cell lymphoma, a subset of diffuse large B-cell lymphoma in the elderly, and primary central nervous system lymphoma in immunosuppression. *Plasmodium falciparum* malaria is a co-factor for endemic Burkitt lymphoma, acting through chronic B-cell stimulation and immune dysregulation, and IARC classifies holoendemic malaria as a cause of Burkitt lymphoma in conjunction with the virus: the only parasitic co-carcinogen in this chapter apart from schistosomiasis in bladder cancer. WHO records 282 million malaria cases and 610,000 deaths in 2024, with 95 per cent of both in the African Region. HIV raises risk roughly sixty- to a hundredfold for aggressive B-cell lymphomas, and incidence fell substantially with antiretroviral therapy, unlike Hodgkin lymphoma. Hepatitis C virus causes splenic marginal zone lymphoma and a share of diffuse large B-cell lymphoma, and antiviral cure can induce lymphoma regression, which is a second instance of curing a lymphoma by treating its infectious cause; WHO records about 47 million people with chronic hepatitis C infection in its key facts, against regional figures in the body of the same page that sum to 50 million, and both are printed. HTLV-1 causes adult T-cell leukaemia-lymphoma, with a lifetime risk of roughly 2 to 5 per cent in those infected, usually acquired in infancy through breast milk; transmission is interruptible by avoiding prolonged breastfeeding in seropositive mothers, which has reduced incidence in Japan. Human herpesvirus 8 causes primary effusion lymphoma and multicentric Castleman disease. de Martel and colleagues, 2020, gave case counts for four agents, of which *H. pylori* at about 810,000 cases and hepatitis C at about 160,000 both contribute to the non-Hodgkin lymphoma total, and no published infection-attributable case count for non-Hodgkin lymphoma specifically was retrievable. Among the non-infectious causes, immunosuppression — organ transplantation, congenital immunodeficiency, iatrogenic immunosuppression — is one of the strongest risk amplifiers in oncology. Autoimmune disease follows a consistent and mechanistically coherent pattern: chronic antigenic stimulation at a site, then lymphoma at that site. Sjögren syndrome gives a very large increase in parotid mucosa-associated lymphoid tissue lymphoma, at relative risks reported in the region of 15 to 20†; coeliac disease gives enteropathy-associated T-cell lymphoma; Hashimoto thyroiditis gives thyroid mucosa-associated lymphoid tissue lymphoma; and rheumatoid arthritis and systemic lupus follow. On pesticides the regulators disagree directly and both positions are printed: IARC classified glyphosate as Group 2A, probably carcinogenic to humans, in 2015 with non-Hodgkin lymphoma as the principal endpoint, and the European Food Safety Authority and the United States Environmental Protection Agency concluded it is unlikely to pose a carcinogenic hazard. The broader association of agricultural work with non-Hodgkin lymphoma is consistent and the agents are not identified. Prior chemotherapy and radiotherapy are established. Mutation burden varies enormously across subtypes. Diffuse large B-cell lymphoma carries a moderate burden with recurrent lesions in MYD88, CD79B, EZH2, BCL2, BCL6 and MYC, and the cell-of-origin classification and the double-hit MYC-BCL2 rearrangement are the key prognostic molecular features. Burkitt lymphoma is driven by a single defining event — MYC translocation to an immunoglobulin locus, present in essentially 100 per cent of cases — on a low mutational background. Follicular lymphoma is defined by the

BCL2 translocation t(14;18), present in roughly 85 to 90 per cent, and notably that translocation is detectable in the blood of a substantial proportion of healthy adults who never develop lymphoma: a direct parallel to the ETV6-RUNX1 situation in childhood acute lymphoblastic leukaemia, and the same lesson about why a detectable marker is not a screening test. Not known: why chronic antigenic stimulation progresses to lymphoma in a small minority; why most carriers of t(14;18) never develop follicular lymphoma; the cause of the majority of diffuse large B-cell lymphoma; why T-cell lymphomas are so much less treatable than B-cell lymphomas.

**Cure status.** The answer differs more between subtypes here than anywhere else in this chapter, and a single label would be false. Gastric mucosa-associated lymphoid tissue lymphoma, early stage: **CURABLE by antibiotics alone** — eradication of *H. pylori* with a one- to two-week course of generic amoxicillin, clarithromycin or metronidazole and a proton-pump inhibitor produces complete histological remission in roughly 60 to 80 per cent of early-stage cases, with durable long-term remission†. That is the only malignancy in this entire chapter cured by a few dollars' worth of oral antibiotics, and it is stated first for that reason. Cases with the t(11;18) translocation or deeper invasion respond less well and need radiotherapy or rituximab. Diffuse large B-cell lymphoma: CURABLE — six cycles of R-CHOP cure roughly 60 to 65 per cent of all patients, including advanced-stage disease†, and localized disease is cured in over 90 per cent with abbreviated therapy†; the SEER stage-specific figures run from 87.6 per cent at stage I to 63.6 per cent at stage IV. Untreated it is fatal within months, so the gap between treating and not treating is as wide as in any cancer here. Burkitt lymphoma: CURABLE in over 85 to 90 per cent of children and 70 to 80 per cent of adults with intensive short-course multi-agent chemotherapy; untreated it kills within weeks. In endemic African settings cure rates with lower-intensity regimens have been reported at roughly 50 to 60 per cent†, far below the achievable figure and far above zero, and achieved with off-patent drugs. Follicular lymphoma: CONTROLLABLE — median overall survival now exceeds 15 to 20 years†. Early-stage asymptomatic follicular lymphoma should often not be treated at all; watch and wait is standard, and randomised evidence shows no survival benefit from early treatment. Localized stage I disease is curable in a minority by radiotherapy alone. Marginal zone and other indolent lymphomas: CONTROLLABLE, with the mucosa-associated exception above. Mantle cell lymphoma: CONTROLLABLE — median survival 8 to 10 years†, extended further by BTK inhibitors and cell therapy, and not curable by chemotherapy. Peripheral T-cell lymphomas: CURABLE in roughly 30 to 40 per cent (five-year survival), with most relapsing†; ALK-positive anaplastic large cell lymphoma is the exception, at cure rates above 70 to 80 per cent†. Adult T-cell leukaemia-lymphoma, acute type: RELIEF ONLY — median survival under a year. Primary central nervous system lymphoma: CURABLE in roughly 30 per cent (five-year survival) with high-dose methotrexate-based therapy. Relapsed aggressive B-cell lymphoma: CURABLE in roughly 30 to 40 per cent with salvage chemotherapy and autologous transplantation†. CD19-directed cell therapy cures a further substantial fraction of those who fail transplantation: NCI states that in large B-cell lymphoma trials more than 30 per cent of participants were alive without evidence of cancer five years after treatment, which in a population with otherwise near-universal mortality is a genuine cure fraction. Early detection cuts both ways here: for the aggressive B-cell lymphomas it matters, and for the indolent ones it confers no benefit and early treatment has no survival advantage. Non-Hodgkin lymphoma therefore contains both patterns simultaneously, which is why there is no screening programme and no coherent rationale for one.

**Prevention.** *H. pylori* eradication — STRONG, and it prevents gastric mucosa-associated lymphoid tissue lymphoma as well as gastric carcinoma. Effect sizes are as in entry 3: incidence rate ratio 0.53, interval 0.44 to 0.64, for gastric cancer, with a number needed to treat of 124. HIV prevention and antiretroviral therapy — STRONG: incidence in people with HIV fell substantially with effective therapy, unlike Hodgkin lymphoma. WHO records 41.0 million people living with HIV at the end of 2025, with 570,000 HIV-related deaths and 1.2 million new infections in 2025. In the care cascade, 88 per cent knew their status, 89 per cent of those diagnosed were on treatment, and 95 per cent of those on treatment were virally suppressed. Hepatitis C treatment — STRONG: direct-acting antivirals cure more than 95 per cent, and associated marginal zone lymphoma regresses with viral clearance. HTLV-1 transmission interruption — STRONG and simple: avoiding prolonged breastfeeding by seropositive mothers reduces mother-to-child transmission substantially, and Japan's programme of antenatal screening and feeding advice has reduced carrier prevalence in younger

cohorts. The trade-off against the benefits of breastfeeding must be weighed, and in settings where formula feeding is unsafe the calculation differs. Malaria control — MODERATE for endemic Burkitt lymphoma: reducing holoendemic transmission should reduce it, and the evidence is ecological rather than interventional, and insecticide-treated nets and antimalarials are simple, cheap and justified on other grounds anyway. Hepatitis B vaccination — MODERATE for the share associated with that virus. Reducing occupational pesticide exposure — CONTESTED, with the IARC and regulatory positions above, unresolved and politically charged. Minimising iatrogenic immunosuppression where possible — MODERATE. There is no screening and no rationale. The t(14;18) translocation is detectable in the blood of a substantial proportion of healthy adults who never develop lymphoma, the same problem as ETV6-RUNX1 in childhood acute lymphoblastic leukaemia: a detectable marker with a very low progression rate makes a useless screening test. **Overdiagnosis is not a quantified concept for non-Hodgkin lymphoma**, and the indolent lymphomas raise a closely related problem: incidental detection of asymptomatic follicular lymphoma on imaging leads to diagnoses in patients who should not be treated, and the benefit of knowing is unclear.

**Treatment.** *H. pylori* eradication for gastric mucosa-associated lymphoid tissue lymphoma comes first. Amoxicillin, clarithromycin, metronidazole, omeprazole, bismuth and tetracycline are all listed, all off-patent, and a complete course costs a few dollars, at a cure rate of 60 to 80 per cent in early-stage disease†: the cheapest cure for any cancer in this chapter. R-CHOP for diffuse large B-cell lymphoma — rituximab, cyclophosphamide, doxorubicin, vincristine and prednisone — follows. Every component is listed, and rituximab's listed indications include diffuse large B-cell lymphoma, Burkitt lymphoma, chronic lymphocytic leukaemia and follicular lymphoma. Cyclophosphamide, doxorubicin, vincristine and prednisone are all off-patent and inexpensive, and rituximab's originator is off-patent with widely available biosimilars that have reduced its price by roughly 50 to 70 per cent in many markets†. Adding rituximab to CHOP increased cure rates by roughly 10 to 15 percentage points absolute†, one of the largest single advances in lymphoma treatment. A full six-cycle course is achievable at a drug cost in the region of a low thousands of dollars with biosimilar rituximab, and a few hundred dollars for the CHOP component alone. Polatuzumab vedotin with R-CHP superseded R-CHOP on progression-free survival in the POLARIX trial for higher-risk disease; it is not listed and is on patent. The Burkitt lymphoma regimens are built from cyclophosphamide, vincristine, doxorubicin, methotrexate, ifosfamide, etoposide, cytarabine and rituximab, all listed, and all except rituximab fully off-patent. Tumour lysis prophylaxis with hydration, allopurinol, listed and off-patent, and rasburicase, listed, is essential, because Burkitt lymphoma has the highest tumour lysis risk of any cancer. Bendamustine with rituximab, or chlorambucil, serves indolent lymphoma; bendamustine, chlorambucil and rituximab are all listed, the first two off-patent and the third available as a biosimilar. Watch and wait for asymptomatic indolent lymphoma is free and evidence-based. Radiotherapy is curative for localized indolent lymphoma and for localized gastric disease unresponsive to antibiotics. Ibrutinib and zanubrutinib are both listed for mantle cell lymphoma and other B-cell lymphomas and neither is off-patent, at United States list prices in the region of US$150,000 to 180,000 a year†. Lenalidomide is listed and off-patent in many markets since about 2022, with generic prices a fraction of the originator price, which was in the region of US$200,000 a year and above at United States list†. CD19 CAR T-cell therapy — axicabtagene ciloleucel, tisagenlecleucel, lisocabtagene maraleucel and brexucabtagene autoleucel across large B-cell, follicular, mantle cell and chronic lymphocytic disease — is not listed in any product and all are on patent. NCI reports that in follicular lymphoma, axicabtagene ciloleucel eliminated the cancer in nearly 80 per cent of participants in one trial of advanced disease, with many of those patients having no return of disease three years later. In large cell lymphoma, NCI reports that more than 30 per cent of participants were alive without evidence of cancer five years after treatment. A per-treatment price could not be retrieved from the price guide, which states only that pricing varies; United States list prices have been reported in the region of US$400,000 to 500,000 per single infusion, with total episode costs substantially higher once apheresis, lymphodepletion, hospitalisation and management of cytokine release syndrome and neurotoxicity are included. Glofitamab, epcoritamab and mosunetuzumab are not listed and are on patent; they are off-the-shelf rather than patient-specific, which makes them logistically simpler than cell therapy, at response rates in the region of 50 to 60 per cent in relapsed large B-cell lymphoma†. High-dose methotrexate-based therapy serves primary central nervous system lymphoma; methotrexate and calcium folinate are both listed and

off-patent, and the requirement is the capacity to give high-dose methotrexate safely with rescue, hydration, alkalinisation and level monitoring. Autologous and allogeneic transplantation follow. Checkpoint inhibitors are largely inactive in most subtypes, in sharp contrast to Hodgkin lymphoma; the exceptions are primary mediastinal B-cell lymphoma and primary central nervous system lymphoma, which share the 9p24.1 amplification.

**Simple means.** *H. pylori* eradication for gastric mucosa-associated lymphoid tissue lymphoma is the single most remarkable simple-means fact in this chapter: a one-week course of generic oral antibiotics, costing a few dollars, cures 60 to 80 per cent of early-stage cases†. **It is a cancer cured by antibiotics.** It requires only the diagnosis, by endoscopic biopsy, and the drugs. CHOP chemotherapy without rituximab comes second: cyclophosphamide, doxorubicin, vincristine and prednisone are all off-patent listed drugs costing a few hundred dollars for a full six-cycle course, and CHOP alone cures roughly 45 to 50 per cent of diffuse large B-cell lymphoma, with biosimilar rituximab raising that to 60 to 65 per cent at a few thousand dollars†. In a setting where rituximab is unobtainable, CHOP alone is not a token gesture: it cures nearly half of patients with an otherwise rapidly fatal cancer, using four cheap generic drugs. Prednisone or prednisolone alone, listed, off-patent and cents a day, produces rapid nodal shrinkage and symptomatic relief and serves as a bridge or as palliation. Lymph node biopsy under local anaesthetic with basic instruments gives the diagnosis, and the binding constraint is histopathology with basic immunohistochemistry: a competent pathologist can distinguish aggressive from indolent lymphoma and B-cell from T-cell lineage with CD20, CD3 and Ki-67. Without that distinction treatment cannot be rationally chosen, and that is the commonest reason lymphoma is mistreated or untreated in low-resource settings. The drugs are not the problem. Allopurinol with intravenous or oral hydration prevents tumour lysis for cents and is essential in Burkitt lymphoma and bulky aggressive lymphoma, where tumour lysis is a major early cause of death: a very high-yield, very cheap intervention. Insecticide-treated nets and malaria treatment are simple, cheap, justified on other grounds and plausibly reduce endemic Burkitt lymphoma. Avoiding prolonged breastfeeding in HTLV-1-seropositive mothers requires a test and advice and prevents a lymphoma with a median survival under a year. Oral morphine, pleural and ascitic drainage with a needle and a set, and radiotherapy for localized disease where a machine exists complete the list. Where nothing simple exists: relapsed aggressive lymphoma, T-cell lymphomas, mantle cell lymphoma and primary central nervous system lymphoma. Cell therapy at a reported US$400,000 to 500,000 an infusion at United States list, bispecific antibodies requiring continuous monitoring for cytokine release, and autologous transplantation requiring apheresis and a transplant unit are none of them achievable by simple means, and they are where most of the recent progress has occurred. Gastric mucosa-associated lymphoid tissue lymphoma is cured by antibiotics, and CHOP cures nearly half and R-CHOP nearly two-thirds of diffuse large B-cell lymphoma using listed drugs that are off-patent or available as biosimilars. So non-Hodgkin lymphoma, like Hodgkin lymphoma and childhood acute lymphoblastic leukaemia, is a disease where a large fraction of the achievable cure is reachable cheaply. The constraint is diagnostic infrastructure and supportive care, not the price of the cytotoxics.

**Gaps.** GLOBOCAN and SEER report non-Hodgkin lymphoma as a single category, and the aggregate figures average across subtypes with completely different natural histories, curability and treatment. Every subtype-specific survival figure above is literature-derived, and that is the largest limitation of this entry, and a limitation of the source data rather than of this chapter alone. A published infection-attributable case count for non-Hodgkin lymphoma specifically was not retrievable. IARC and the European and United States regulators disagree directly on glyphosate and non-Hodgkin lymphoma; both are printed and it is unresolved. The HIV, Sjögren and *H. pylori* attributable figures and the mucosa-associated eradication cure rate are literature-derived. Cell therapy pricing could not be retrieved from a primary source and NCI's page gives no prices. Why most carriers of t(14;18) never develop follicular lymphoma is unknown, the same unanswered question as for ETV6-RUNX1. T-cell lymphomas are under-researched relative to their lethality.

## 24. Multiple myeloma

**What it is.** A cancer of plasma cells, the antibody-producing cells of the bone marrow. It causes bone destruction, anaemia, kidney failure and high calcium. It is preceded in essen-

tially every case by a symptomless precursor state that is common in older people. Survival has roughly tripled in twenty-five years and it is still not curable.

**Measured.** GLOBOCAN 2022 gives 187,952 cases; GLOBOCAN 2024 gives 196,157 cases and 119,029 deaths. Five-year relative survival in the United States is 63.7 per cent. SEER publishes no stage-specific table in the localized-regional-distant scheme; the staging systems are the Revised International Staging System and its successor, based on beta-2 microglobulin, albumin, lactate dehydrogenase and cytogenetics. The stage figures are from the myeloma literature: stage I, median overall survival not reached at five years in the defining analysis, so roughly 80 per cent or above five-year survival; stage III, with high lactate dehydrogenase and high-risk cytogenetics such as deletion of 17p or the t(4;14) or t(14;16) translocations, median overall survival roughly three to four years. Median age at diagnosis 69, and it is rare under 40. United States incidence is stable and the death rate falling about 3.0 per cent a year, one of the steepest mortality declines of any cancer in this chapter; modelled five-year relative survival was roughly 25 per cent in the mid-1970s and is 63.7 per cent now. Incidence is roughly two to three times higher in people of African ancestry than in people of European ancestry, one of the largest and most consistent ancestry differences in oncology, with the precursor state correspondingly commoner, and the difference is not explained by access or detection and appears to be constitutional. Monoclonal gammopathy of undetermined significance, the obligate precursor, is present in roughly 3 per cent of people over 50 and over 5 per cent of those over 70 in population screening studies, rising with age and roughly two to three times commoner in people of African ancestry. It progresses to myeloma or a related malignancy at roughly 1 per cent a year, and the risk does not diminish over time†. Smouldering myeloma, the intermediate state, progresses at roughly 10 per cent a year for the first five years†. Those figures bear directly on the screening question.

**Where it starts.** The precursor state precedes essentially every case. Stored-serum studies have shown a detectable monoclonal protein years to decades before diagnosis in virtually all patients. **Myeloma is therefore, uniquely among the cancers in this chapter, a malignancy with a known, universal, detectable and extremely common precursor state.** Age dominates, with incidence rising steeply after 60. African ancestry gives roughly two- to threefold increased incidence and precursor prevalence, persisting across settings. Male sex gives roughly 1.5-fold†. Family history gives roughly two- to fourfold increased risk in first-degree relatives, with no high-penetrance gene identified. Obesity shows a consistent association at relative risks in the region of 1.2 to 1.5 for a body mass index of 30 or more†, and it is one of the few modifiable risk factors identified. Ionising radiation is established at high doses from the atomic bomb survivor cohorts, with a weaker and debated relationship at occupational doses. Pesticides, benzene and firefighting have all been associated, and IARC classified occupational exposure as a firefighter as Group 1 in 2022, with mesothelioma and bladder cancer as the strongest endpoints and myeloma among those evaluated; the agents are not identified. Chronic inflammation and chronic infection have been proposed as drivers of the antigenic stimulation that precedes clonal plasma cell expansion, on associative evidence. Myeloma has a moderate point-mutation burden, around or somewhat above the adult reference of 1.8 per megabase. It is characterised by primary immunoglobulin heavy chain translocations — t(11;14), t(4;14), t(14;16) — or hyperdiploidy, with secondary events in KRAS, NRAS, BRAF, TP53 and TRAF3, and MYC rearrangements. It is strikingly subclonal and genomically unstable: multiple competing clones coexist at diagnosis and the dominant clone changes under treatment, which is the accepted explanation for why the disease is so reliably controllable and so reliably incurable — there is always another clone. Deletion of 17p and the t(4;14) translocation define high-risk disease. Not known: **why the precursor progresses in roughly 1 per cent of carriers a year and not in the other 99 per cent** — the single most consequential unanswered question in this disease; why myeloma is so much commoner in people of African ancestry; whether the precursor is preventable from progressing; what causes the initiating translocation.

**Cure status.** Monoclonal gammopathy of undetermined significance: no treatment is indicated and treating it is harmful. Observation only. It is a risk state rather than a disease: roughly 1 per cent of carriers a year progress to myeloma or a related malignancy, so none of the four labels applies to it and none is assigned. Smouldering myeloma: observation is standard for most, and high-risk smouldering myeloma is now treated — randomised trials of lenalidomide, and of daratumumab, in high-risk smouldering disease showed delayed progression and, in one trial, a survival benefit. That is a genuine and recent change: for the

first time a precursor state in myeloma is being treated, and whether this prevents myeloma or merely treats it early is not settled. Symptomatic multiple myeloma: CONTROLLABLE — five-year relative survival 63.7 per cent, with median overall survival in contemporary series exceeding seven to ten years for standard-risk patients and continuing to improve. A small fraction of patients achieving sustained absence of minimal residual disease for many years may be functionally cured, and no plateau has been convincingly demonstrated in the survival curves, and the consensus is that myeloma is not curable. High-risk myeloma, stage III or deletion of 17p: CONTROLLABLE — median survival roughly three to four years†. Plasma cell leukaemia and extramedullary relapse: RELIEF ONLY — median survival under a year. Penta-refractory myeloma, refractory to a proteasome inhibitor, an immunomodulator and an anti-CD38 antibody, in the substantial minority who respond to a cell or bispecific agent: CONTROLLABLE. Penta-refractory myeloma otherwise: RELIEF ONLY, which was the answer for the whole stratum until those agents arrived. Ciltacabtagene autoleucel produced objective responses above 95 per cent with complete response in roughly 80 per cent in heavily pre-treated myeloma†, among the highest response rates for any agent in any cancer in this chapter, and a proportion remain progression-free for years, and it is still not considered curative. Solitary plasmacytoma: CONTROLLABLE. Radiotherapy cures some, though a majority eventually progress to myeloma. Early detection does not deliver cure, and that is important and counterintuitive: myeloma has a universal, common, cheaply detectable precursor, and detecting it does not produce cure, because the disease is incurable at every stage, so moving diagnosis earlier moves treatment earlier without curing anyone. **Myeloma is the clearest demonstration in this chapter that a detectable precursor plus a sensitive test does not equal a useful screening programme.**

**Prevention.** There is no established means of preventing multiple myeloma. Age, sex, ancestry and family history are not modifiable. Weight control — WEAK, on a consistent association and no interventional evidence. Occupational exposure control — CONTESTED, the agents not being identified. Treating high-risk smouldering myeloma — MODERATE and genuinely new: lenalidomide, listed and off-patent in many markets, delayed progression to symptomatic disease and improved survival in one randomised trial. Whether that is prevention or early treatment is unresolved, and the distinction matters, because the drug carries toxicity, cost and second-cancer risk and the patients are asymptomatic. Screening is not recommended, and myeloma is one of the most instructive cases in this chapter for why. The precursor is detectable with a cheap serum protein electrophoresis and is present in roughly 3 per cent of people over 50 and over 5 per cent over 70, progressing at only about 1 per cent a year; there is no treatment for it and no evidence that treating it helps; and the Iceland iStopMM study screened over 75,000 people prospectively, whose principal finding so far is a very large prevalence of previously unknown precursor states with no established actionable consequence for the great majority. A population programme would therefore label millions of older adults with a pre-malignant haematological condition, offer them nothing, and generate lifelong surveillance. **The overdiagnosis fraction would approach the full precursor prevalence, and it has never been quantified as a percentage.** That is structurally identical to the monoclonal B-cell lymphocytosis situation in entry 21, and both are the clearest counterexamples in this chapter to the assumption that finding cancer precursors earlier is beneficial.

**Treatment.** Radiotherapy cures some solitary plasmacytomas, and the proportion is not given. Bortezomib is listed and off-patent, with generics available at a small fraction of the originator price, which was in the region of US$5,000 to 8,000 a cycle at United States list†. Carfilzomib and ixazomib are not listed and are on patent. Thalidomide is listed, off-patent and extremely cheap, and its history is worth recording: withdrawn worldwide in 1961 after causing severe birth defects, found in 1999 to be active in refractory myeloma, and now an inexpensive off-patent Essential Medicine that transformed the disease. In settings without access to lenalidomide or bortezomib, thalidomide with dexamethasone and melphalan or cyclophosphamide is an effective, entirely off-patent regimen. Lenalidomide is listed and off-patent in many markets since about 2022, against an originator price in the region of US$200,000 a year and above at United States list†; pomalidomide is on patent and not listed. Melphalan, cyclophosphamide, dexamethasone and prednisolone are all listed and all off-patent and inexpensive, and dexamethasone’s listed antineoplastic indications include multiple myeloma. Melphalan with prednisone was the standard of care from 1962 to the 2000s and produced median survival of roughly two to three years†, and it remains a legitimate op-

tion where nothing else is available. **Daratumumab is a listed medicine, for plasma cell myeloma**, and it too is frequently reported as absent. It is on patent, and isatuximab is not listed. Daratumumab added to standard regimens improved survival in every setting tested and is now part of first-line therapy in high-income countries, at a United States list cost in the region of US$120,000 to 150,000 a year†. Autologous stem cell transplantation after induction improves progression-free survival in fit patients and requires apheresis, high-dose melphalan — listed and off-patent — and an inpatient unit: the conditioning drug is a cheap off-patent listed medicine and the cost is entirely in the infrastructure. **Zoledronic acid is listed, in the supportive medicines section, for malignant neoplasm metastasis in bone or bone marrow and for osteogenesis imperfecta**; it is off-patent and costs a few dollars a generic infusion. It reduces skeletal events substantially and, in the MRC Myeloma IX trial, improved overall survival by a median of roughly five to six months compared with clodronate — a survival benefit from a cheap off-patent bone drug. Denosumab is not listed and is on patent. Idecabtagene vicleucel and ciltacabtagene autoleucel are both approved for myeloma, neither is listed and both are on patent; ciltacabtagene autoleucel produced objective response above 95 per cent with complete response around 80 per cent in heavily pretreated myeloma and idecabtagene vicleucel roughly 70 to 75 per cent†, at reported United States list prices of US$465,000 to 525,000 per single infusion. Teclistamab, elranatamab and talquetamab are not listed and are on patent, off-the-shelf, at response rates roughly 60 to 75 per cent†. Selinexor, belantamab mafodotin and venetoclax — the last for t(11;14) disease — are none of them listed, and venetoclax is confirmed absent from the list in any form. Radiotherapy for painful bone lesions and for cord compression is highly effective and often needs only a single fraction. Supportive care covers erythropoiesis-stimulating agents for anaemia, which are listed with epoetin forms as therapeutic equivalents rather than as selected medicines, plasmapheresis for hyperviscosity, dialysis for renal failure, and prompt treatment of hypercalcaemia with hydration and of infection. Infection is the commonest cause of death, because of the profound secondary antibody deficiency, and prophylactic co-trimoxazole, aciclovir and vaccination are cheap and effective.

**Simple means.** Thalidomide with dexamethasone, with or without melphalan or cyclophosphamide, is all listed, all off-patent, all oral or simple, at a total drug cost in the region of tens of dollars a month. That is an effective myeloma regimen deliverable in a clinic with no infusion suite and no cold chain. It is not equivalent to daratumumab-based therapy, and it produces real responses, relieves bone pain and anaemia, and extends life by years in responders. Thalidomide requires strict pregnancy prevention, which is a real and non-negotiable requirement, and it is organisational rather than technological. Dexamethasone alone is listed, off-patent and cents a dose, at an indicative 24 cents a 4 mg tablet in the UNICEF Supply Catalogue, October 2026. High-dose dexamethasone produces rapid response in a substantial proportion of patients, relieves bone pain, reverses hypercalcaemia and can reverse spinal cord compression within hours while awaiting radiotherapy: in an emergency it is the most valuable single drug in this entry. Zoledronic acid is listed and off-patent at a few dollars an infusion every few weeks, reduces fractures and vertebral collapse, and improved overall survival by roughly five to six months in a randomised trial: a cheap generic bone drug with a measured survival benefit is an unusual and valuable thing. Hydration, oral or intravenous, treats hypercalcaemia and the cast nephropathy that causes myeloma kidney failure; early aggressive hydration prevents renal failure, and renal failure at presentation is a major determinant of survival. It costs almost nothing and it is frequently done too late. Allopurinol for urate, and co-trimoxazole and aciclovir for infection prophylaxis, are all listed and cost cents, with vaccination. Oral morphine is essential, and myeloma bone pain is among the most severe in oncology; single-fraction palliative radiotherapy serves a painful lesion where a machine exists. A spinal brace and crutches prevent falls and vertebral collapse and require no technology, and surgical fixation of a long bone at risk of pathological fracture is a conventional orthopaedic operation. Diagnosis is possible by serum protein electrophoresis, a blood count, calcium, creatinine and a plain skeletal survey — cheap, widely available tests. Myeloma is one of the more diagnosable cancers by simple laboratory means, because the combination of anaemia, renal impairment, hypercalcaemia, bone pain and a monoclonal band is distinctive, and a bone marrow aspirate confirms it and requires a needle. The drugs that have produced most of the recent survival gain — daratumumab, carfilzomib, pomalidomide, the cell and bispecific products — are all on patent, mostly absent from the list, and cost from hundreds of thousands of US dollars a year to hundreds of thousands of US dollars

an infusion, so there is a real and widening gap. Myeloma is nonetheless better served by simple means than that comparison suggests: thalidomide, melphalan, cyclophosphamide, dexamethasone, bortezomib, lenalidomide and zoledronic acid are all off-patent Essential Medicines, and a regimen built from them delivers a substantial fraction of the achievable benefit at a cost of tens of dollars a month. What cannot be replicated simply is the incremental gain of the last decade.

**Gaps.** SEER publishes no staging-system-stratified survival for myeloma, so the stage-specific figures are literature-derived. Precursor prevalence and progression rates are literature-derived and central to the screening argument. Why the precursor progresses in 1 per cent a year and not the rest is unknown, and it is the key question. The two- to threefold higher incidence in people of African ancestry is unexplained. The obesity relative risk is not primary-source-verified. Cell therapy pricing is literature-derived. Whether treating high-risk smouldering myeloma is prevention or early treatment is unresolved, and it determines whether the toxicity and cost are justified in asymptomatic people.

## 25. Head and neck cancer

**What it is.** Cancers of the mouth, throat and voice box — lip, oral cavity, oropharynx, hypopharynx, larynx and salivary gland — almost all squamous cell carcinomas. They have two quite different causes: tobacco and alcohol, which cause the traditional disease in older people, and human papillomavirus, which causes a rising epidemic of oropharyngeal cancer in younger people with a far better prognosis. They are disfiguring and they damage speaking, swallowing and breathing.

**Measured.** GLOBOCAN 2022, with GLOBOCAN 2024 in brackets: lip and oral cavity 389,846 cases [452,205 cases and 194,108 deaths]; larynx 189,191 [193,937 and 96,619]; oropharynx 106,400 [107,887 and 51,823]; hypopharynx 86,257 [91,464 and 49,748]; salivary glands 55,083 [55,229 and 20,707]. Nasopharynx is reported separately and has its own entry. Combined excluding nasopharynx, that is roughly 826,800 cases in 2022 and roughly 900,700 in 2024, with roughly 413,000 deaths in 2024, which makes head and neck cancer collectively the sixth or seventh commonest cancer group in the world, larger than cervical cancer. WHO's oral health fact sheet gives 389,846 new lip and oral cavity cases and 188,438 deaths for 2022, and records lip, oral cavity and oropharynx combined as the thirteenth most common cancer worldwide, with most cases in men. Five-year relative survival for oral cavity and pharynx combined in the United States is 69.9 per cent overall: localized 88.7, regional 69.7, distant 36.0, unknown 62.3 per cent. Stage at diagnosis: localized 26, regional 55, distant 12, unknown 6 per cent, and the very high regional proportion reflects early nodal spread, which is characteristic. Median age 65, with virus-associated oropharyngeal cancer presenting roughly a decade younger. United States incidence is rising about 1.0 per cent a year and the death rate about 0.8 per cent a year: one of very few cancers in this chapter with both rising, and the explanation is the virus-associated oropharyngeal epidemic outpacing the decline in tobacco-related disease. The Indian subcontinent carries the world's largest burden of oral cavity cancer, where it is among the commonest cancers in men, driven by betel quid and smokeless tobacco; laryngeal and hypopharyngeal rates are highest in Eastern Europe and parts of South America, tracking tobacco and alcohol.

**Where it starts.** Current smokers against never-smokers carry about four to five times the risk for oral cavity, oropharyngeal and hypopharyngeal cancers and about ten times for laryngeal cancer, dose-relatedly. Two or more drinks a day against non-drinkers gives about two to six times the risk, dose-relatedly. The interaction is supra-multiplicative, about two to three times greater than the simple multiplicative effect, so heavy smoking with heavy drinking gives roughly five to fourteen times the risk of never-smoking, never-drinking; a pooled analysis of seventeen case-control studies comparing more than a pack a day with three or more drinks a day against neither reported fifteenfold for oral cavity, fourteenfold for oropharyngeal and **thirty-sixfold for laryngeal cancer**, among the largest relative risks for any exposure-cancer pair in this chapter. WHO records about 1.2 billion tobacco users worldwide, with around 80 per cent in low- and middle-income countries, more than 7 million deaths a year from tobacco and over 1.6 million from second-hand smoke, and tobacco as a cause of over twenty types or subtypes of cancer. On alcohol, WHO attributes 4.4 per cent of cancers diagnosed and 401,000 cancer deaths in 2019 to alcohol, within 2.6 million alcohol-attributable deaths overall. Oral infection with human papillomavirus type 16

is associated with about a fifteenfold increase in oropharyngeal cancer risk, with a meta-analysis giving odds ratios of 15.1 for tonsil cancer and 4.3 for other oropharyngeal sites. PDQ gives no population attributable fraction, and that fraction is the key number and is site- and country-specific: the virus accounts for roughly 70 per cent of oropharyngeal cancers in the United States and Northern Europe and a much lower proportion in India and Southern Europe, where tobacco dominates. For the global total, de Martel and colleagues, 2020, attributed about 690,000 cancer cases worldwide in 2018 to human papillomavirus, of which the great majority are cervical and the remainder oropharyngeal, anal, vulvar, vaginal and penile. Betel quid with tobacco gives about eightfold risk for oral cavity cancer on the Indian subcontinent and betel quid alone about twofold; for oropharynx, about fourfold with tobacco and about twofold alone; oral cavity risk in China or Taiwan is about tenfold. PDQ states that smokeless tobacco increases risk and gives no separate relative risk. Tobacco cessation gives about 50 per cent risk reduction for oral, oropharyngeal and hypopharyngeal cancers within five to nine years and about 40 per cent for laryngeal cancer, with risk returning to near never-smoker levels by twenty years. Alcohol cessation carries inadequate evidence: risk reduction for oral cavity and laryngeal cancer twenty years or more after cessation gives odds ratios of 0.45 and 0.69 respectively, with no support for an oropharyngeal or hypopharyngeal reduction. That asymmetry — strong evidence that alcohol causes the cancer, inadequate evidence that stopping reduces the risk — is stated as PDQ states it. Poor oral hygiene and chronic dental trauma, immunosuppression, Fanconi anaemia, occupational wood dust and formaldehyde, prior radiotherapy and Plummer-Vinson syndrome are the other established factors. Tobacco- and alcohol-associated disease carries a high mutation burden with a tobacco signature, near-universal TP53 mutation and frequent CDKN2A loss and FAT1, NOTCH1 and PIK3CA alterations. Virus-associated oropharyngeal carcinoma has a markedly lower burden, wild-type TP53 — because the viral E6 protein degrades the p53 protein instead of the gene being mutated — and a far better prognosis. The two diseases share a name and a site and almost nothing else, against an adult reference of 1.8 mutations per megabase. Not known: why only a small minority of people with oral infection develop cancer; why virus-positive disease responds so much better to treatment, where immune recognition, wild-type p53 and absence of field change are all proposed and none is established as the principal mechanism; the cause of the rising virus-positive incidence in cohorts born after about 1950.

**Cure status.** Pre-malignant lesions — leukoplakia, erythroplakia, oral submucous fibrosis: CURABLE by excision, though field change means new lesions frequently arise. Erythroplakia and non-homogeneous leukoplakia carry substantial malignant transformation risk and homogeneous leukoplakia much less. Localized, stage I to II: CURABLE — five-year relative survival 88.7 per cent, by surgery or radiotherapy alone, either curative, with the choice driven by functional outcome. Regional, stage III to IVB, the majority at 55 per cent of cases: CURABLE in 69.7 per cent (five-year relative survival), by surgery with adjuvant chemoradiotherapy or by definitive chemoradiotherapy with cisplatin. Virus-positive oropharyngeal carcinoma: CURABLE in roughly 80 to 90 per cent of non-smokers (five-year survival), markedly better than virus-negative disease at the same stage, at roughly 45 to 55 per cent†. The staging system was rewritten in 2017 to give virus-positive oropharyngeal cancer its own staging, because the old system misclassified these patients as having advanced disease when their outcome was excellent. De-escalation trials are active, and several attempts to replace cisplatin with cetuximab failed and reduced survival, which is an important negative result. Distant, stage IVC: RELIEF ONLY — 36.0 per cent. Distant with a durable checkpoint-inhibitor response, a minority: CONTROLLABLE. Recurrent disease after chemoradiotherapy: CONTROLLABLE. Salvage surgery cures some, and is technically difficult in irradiated tissue. Early detection is most achievable by simple means here of anywhere in the chapter, because the mouth can be looked at, so the 26 per cent localized rate is a failure of examination and presentation rather than of technology. One honest note on the meaning of cure here is necessary: cure in head and neck cancer frequently costs the ability to speak, swallow or eat normally. Total laryngectomy cures laryngeal cancer and removes the voice. Chemoradiotherapy preserves the organ and frequently destroys its function — xerostomia, fibrosis, dysphagia and aspiration are common and permanent. The survival statistics do not capture this, and for this cancer group more than any other in the chapter the quality of the cure is as important as its probability.

**Prevention.** Tobacco cessation — STRONG: about 50 per cent risk reduction for oral, oropharyngeal and hypopharyngeal cancer within five to nine years, about 40 per cent for larynx, returning to near never-smoker levels by twenty years. This is the highest-yield intervention and it requires no technology. WHO records that over 60 per cent of smokers intend to quit and that counselling and medication can more than double quit success, with cessation services offering full or partial cost coverage in 31 countries. Never starting tobacco or betel quid — STRONG. Alcohol reduction — STRONG for never starting, CONTESTED for cessation, with both positions printed as PDQ states them. Betel quid and smokeless tobacco cessation — STRONG on the causal evidence; oral submucous fibrosis, caused by areca nut, is a pre-malignant condition affecting millions in South Asia and is itself a major source of morbidity. Human papillomavirus vaccination — MODERATE on mechanism and surrogate endpoint, and the cancer endpoint is unproven, and that must be stated honestly. PDQ records that vaccination against types 16 and 18 prevents about 90 per cent of oral type 16 and 18 infections within four years, and that no studies show reduced oropharyngeal cancer risk, rating the evidence for the cancer endpoint as no studies available. The reasoning for expecting benefit is strong: type 16 causes the cancer at an odds ratio of 15.1 for tonsil, the vaccine prevents oral infection by about 90 per cent, and the cervical cancer endpoint has now been demonstrated. But oropharyngeal cancer has a latency of decades and the vaccinated cohorts are not yet old enough. This is a genuine limitation and it is frequently overstated in public discussion. A further honest point: in most countries vaccination was introduced for girls only, and oropharyngeal cancer predominantly affects men, roughly three to four to one, so gender-neutral vaccination, now adopted in many countries, is the policy change that bears on this cancer, and it came late. Treating oral pre-malignant lesions — MODERATE: excision of erythroplakia and dysplastic leukoplakia, with no randomised evidence that it reduces cancer incidence and field change limiting it. Screening — CONTESTED, with one important positive trial. There is no routine population programme in high-income countries, and the USPSTF found insufficient evidence, grade I, for oral cancer screening by primary care clinicians. Against that, the Kerala cluster-randomised trial of oral visual inspection by trained health workers in tobacco and alcohol users reported a reduction in oral cancer mortality in that high-risk subgroup over long follow-up: the single positive randomised trial of oral cancer screening, conducted in a very high-incidence population using visual inspection alone. The specific hazard ratios could not be retrieved and are not quoted. The result supports targeted visual screening in high-risk, high-incidence populations and does not support general population screening. The harms are biopsy of benign lesions and **overdiagnosis of leukoplakia that would never have transformed, for which no percentage has been published.** Dental care and oral hygiene — WEAK.

**Treatment.** Salvage surgery cures some recurrences after chemoradiotherapy, and the proportion is not given. For localized oral cavity cancer, wide local excision with neck dissection is curative and is the primary treatment; free-flap reconstruction improves function enormously and requires microsurgical capability, and a simpler reconstruction or primary closure is adequate for smaller defects. Radiotherapy is curative alone for early laryngeal cancer: for T1 glottic cancer it cures over 90 per cent and preserves the voice, which is a better functional outcome than surgery, and it requires a linear accelerator. Concurrent chemoradiotherapy with cisplatin follows. **Cisplatin is a listed medicine, with head and neck cancer as a radiosensitiser among its listed indications**, off-patent, at a trivial generic cost of tens of dollars a course: the standard radiosensitiser and the single most important drug in curative head and neck cancer treatment. Carboplatin, listed and off-patent, serves where renal function or hearing precludes cisplatin. Attempts to substitute cetuximab for cisplatin in virus-positive disease reduced survival in the De-ESCALaTE and RTOG 1016 randomised trials†, an important negative result, because cetuximab is better tolerated and the substitution was expected to work. Induction chemotherapy for larynx preservation uses docetaxel, cisplatin and fluorouracil, all three listed and off-patent. Cetuximab is not listed; biosimilars are emerging, and it adds a survival benefit to radiotherapy in patients unfit for cisplatin and is inferior to cisplatin where cisplatin can be given. Pembrolizumab is a selected medicine on the list, for other listed indications. Nivolumab's listing for this cancer needs checking against the 24th List (2025)†. Neither is off-patent, and pembrolizumab costs US$1,530.35 per 4 mL unit and US$6,121.41 per four-unit pack at the United States cash price, October 2026, and US$150,000 to 200,000 a year at United States list. In recurrent or metastatic head and neck squamous carcinoma pembrolizumab monotherapy produces

objective responses in roughly 17 to 19 per cent overall, higher in PD-L1-high tumours, with a durable tail, and added to platinum-fluorouracil chemotherapy it improved overall survival in the first-line setting in KEYNOTE-048; nivolumab improved survival over chemotherapy in platinum-refractory disease in CheckMate 141 at an objective response of roughly 13 per cent. Those are modest response rates with a meaningful survival gain in a minority, the characteristic pattern. Palliative radiotherapy serves pain and bleeding. Supportive and functional care — percutaneous or surgical gastrostomy for nutrition during and after chemoradiotherapy, tracheostomy for airway obstruction, speech and swallowing rehabilitation, dental assessment and extraction before radiotherapy to prevent osteoradionecrosis, and saliva substitutes and fluoride for xerostomia — are not optional adjuncts: without them, curative treatment is not survivable or not tolerable.

**Simple means.** Head and neck cancer has one of the strongest simple-means profiles for early detection in this chapter and one of the weakest for treatment of advanced disease. Looking in the mouth comes first. The oral cavity is directly visible with a torch and a tongue depressor, and oral cancer and its pre-malignant lesions — leukoplakia, erythroplakia, submucous fibrosis, a non-healing ulcer — can be seen and felt by any trained health worker in under a minute, with no equipment. The Kerala cluster-randomised trial showed that visual inspection by trained non-specialist health workers reduced oral cancer mortality in tobacco and alcohol users. **In a population where oral cancer is common, this is the cheapest effective cancer screening that exists — cheaper even than visual inspection with acetic acid for the cervix, because it needs no speculum and no vinegar.** Against that, 26 per cent of United States cases are localized at diagnosis, which means that in a country with abundant medical resources the majority of a visible cancer is being found late. The barrier is not technology. Tobacco, betel quid and alcohol cessation need no technology, at a 40 to 50 per cent risk reduction within a decade for tobacco. Excision of a small oral lesion, or wide local excision of a small tongue or buccal cancer, under local or general anaesthesia with basic instruments, is curative at a five-year survival near 89 per cent. Primary closure or a simple local flap avoids the need for microsurgery. Tracheostomy is a basic operation that prevents death by asphyxiation from an obstructing laryngeal or hypopharyngeal tumour, and it is the single most immediately life-saving simple procedure in this entry. A feeding gastrostomy or a nasogastric tube allows nutrition when swallowing fails, and malnutrition is a major cause of death here and is preventable with a tube. Oral morphine matters, with the same caveat as in entry 9: head and neck cancer pain is severe and has a neuropathic component, and a patient who cannot swallow needs sublingual, rectal or subcutaneous morphine, and the rectal route requires no equipment. Mouth care, saline rinses and simple analgesia serve radiation mucositis, and dental extraction before radiotherapy prevents osteoradionecrosis and requires only a dentist and forceps. Where nothing simple exists: curative treatment of locally advanced disease requires chemoradiotherapy with a linear accelerator and cisplatin, or major resection with reconstruction. The cisplatin is cheap and listed; the linear accelerator is not, and radiotherapy is unavailable to a large fraction of the world's head and neck cancer patients, which matters disproportionately here, because radiotherapy alone cures over 90 per cent of early glottic cancer and preserves the voice. Free-flap reconstruction, speech rehabilitation and the full supportive-care package that makes cure tolerable have no simple-means version. And for metastatic disease the checkpoint inhibitors cost over US$150,000 a year at United States list, for a 13 to 19 per cent response rate.

**Gaps.** GLOBOCAN reports six separate head and neck sites and this entry aggregates them; the component sites differ in cause, treatment and prognosis, so the combined figures are of limited use, and SEER's oral cavity and pharynx grouping is a different aggregation again, not directly comparable. PDQ gives no population attributable fraction for human papillomavirus in oropharyngeal cancer, so the 70 per cent figure is literature-derived. The Kerala trial hazard ratios could not be retrieved, so the single positive randomised trial of oral cancer screening is cited qualitatively only. PDQ rates the evidence that vaccination prevents oropharyngeal cancer as no studies available, so the benefit is inferred from surrogate endpoints and is genuinely unproven. PDQ finds the evidence that alcohol cessation reduces risk inadequate while the evidence that alcohol causes the cancer is solid, and that asymmetry is real. Virus-positive against virus-negative survival figures are literature-derived. Overdiagnosis of oral pre-malignant lesions is unquantified. Functional outcome after cure — voice, swallowing, eating — is not captured in any of the survival statistics quoted and no compa-

rable quantitative source for it was retrieved, which for this cancer group is a substantial omission.

## 26. Nasopharyngeal carcinoma

**What it is.** Cancer arising at the very top of the throat, behind the nose. It is rare across most of the world and common in southern China, Southeast Asia and parts of North Africa and the Arctic — one of the most sharply geographically restricted cancers known. It is caused by Epstein-Barr virus in combination with inherited susceptibility and diet, and unlike the other head and neck cancers it is treated with radiotherapy rather than surgery.

**Measured.** GLOBOCAN 2022 gives 120,434 cases; GLOBOCAN 2024 gives 119,750 cases and 62,060 deaths. SEER publishes no separate page for nasopharyngeal carcinoma; it is folded into oral cavity and pharynx, at a five-year relative survival of 69.9 per cent overall, localized 88.7, regional 69.7 and distant 36.0 per cent. Nasopharynx-specific survival therefore comes from the clinical literature: stage I to II roughly 90 per cent; stage III roughly 75 to 80 per cent; stage IVA roughly 65 to 70 per cent; metastatic stage IVB median survival roughly two to three years with chemotherapy, markedly better than for other metastatic head and neck cancers; and overall five-year survival in endemic centres with modern intensity-modulated radiotherapy exceeding 80 per cent. The age distribution is unusual: incidence rises from adolescence, peaks around age 50 to 59 and then falls, unlike most epithelial cancers which rise monotonically with age, with a secondary juvenile peak in some endemic populations and a male-to-female ratio of roughly two to three to one. Geography is the defining feature and the gradient is extreme. Age-standardised incidence in southern China — particularly Guangdong province and among Cantonese-speaking populations — reaches roughly 20 to 30 per 100,000 in men, against under 1 per 100,000 in most of Europe and North America: a thirtyfold or greater gradient. Intermediate rates occur in Southeast Asia, among Inuit populations of Greenland and Alaska, and in North Africa, where there is a distinct juvenile peak. Incidence has been falling substantially in endemic southern China over recent decades, with reductions of roughly 30 to 40 per cent in age-standardised rates reported, attributed to reduced consumption of salt-preserved fish, improved living conditions and reduced smoking: one of the clearest examples in this chapter of a cancer declining because an exposure declined, with no medical intervention. Migrant studies are informative: incidence falls in Chinese populations who migrate to low-incidence countries and remains above the host population rate for generations, which indicates both a genetic and an environmental component and allows neither to be dismissed.

**Where it starts.** The attributable fraction for undifferentiated nasopharyngeal carcinoma, the form that predominates in endemic regions, is essentially 100 per cent. Epstein-Barr virus DNA and virus-encoded RNA are present in the tumour cells in virtually every case, and clonal viral episomes are present in the pre-invasive lesions, which establishes that infection precedes transformation. **That is the most complete viral attribution of any cancer in this chapter — more complete than human papillomavirus in cervical cancer, at about 95 per cent, and far more complete than *H. pylori* in gastric cancer.** The keratinising squamous form, which predominates in low-incidence Western populations, is less consistently virus-associated and is more tobacco- and alcohol-related. de Martel and colleagues, 2020, gave figures for four agents not including this virus, so no published attributable case count is quoted here; on the near-100 per cent attribution for the endemic form and GLOBOCAN 2024 incidence of 119,750, the implied figure is in the region of 100,000 cases annually, and that is an inference. The crucial point is this: the virus infects more than 90 per cent of adults worldwide† and nasopharyngeal carcinoma is rare, so the virus is necessary and very far from sufficient. The attributable fraction being near 100 per cent does not mean the virus explains the disease. The geographic concentration does the explaining, and the virus is the common factor on which the other causes act. Read in the net: the configuration that persists is the one where all the conditions fit together, and naming the commonest condition does not name the fit. This is a reading, not a mechanism. Salt-preserved fish and other salt-preserved foods, particularly consumed during weaning and early childhood, contain volatile nitrosamines that are carcinogenic and that also reactivate the latent virus in vitro. The association is consistent across case-control studies in endemic regions, at odds ratios generally in the region of 2 to 7 for high childhood consumption, and the declining incidence in southern China has tracked declining consumption; IARC has evaluated Chinese-style salted fish

as carcinogenic to humans, Group 1†. On genetic susceptibility, HLA class I alleles are the strongest determinants: HLA-A2, HLA-B46 and HLA-B17 are associated with increased risk and certain HLA-A11 alleles with reduced risk, and genome-wide association studies have confirmed the HLA region as the dominant locus. Family history confers roughly a four- to tenfold increased risk in first-degree relatives in endemic populations. The HLA association points directly at antigen presentation of viral peptides, which is a coherent and unusually specific mechanistic story. Tobacco smoking has a modest independent effect, more relevant to the keratinising form and to non-endemic populations, at relative risks generally in the region of 1.5 to 2†. IARC has evaluated occupational formaldehyde as causing nasopharyngeal carcinoma, Group 1, on evidence that remains debated, and wood dust exposure likewise. Nasopharyngeal carcinoma has a low to moderate point-mutation burden, below or around the adult reference of 1.8 per megabase. The driving events are the viral latent genes — LMP1, LMP2, EBNA1 — plus recurrent somatic alterations in CYLD, TRAF3 and NFKBIA, all converging on NF-κB activation, with CDKN2A loss and TP53 mutation. Notably it shows frequent genomic alterations in antigen-presentation and immune-evasion genes and high PD-L1 expression, which is the basis for its checkpoint-inhibitor responsiveness despite a low mutation burden: **a third clear counterexample, alongside Hodgkin lymphoma and renal cell carcinoma, to mutation burden as a general predictor of immunotherapy response.** Not known: why a virus carried by over 90 per cent of humanity causes cancer in a specific population in a specific place; the relative contributions of HLA genotype, viral strain variation — endemic-region-specific high-risk variants have been identified and this is an active line — and salt-preserved fish; why the age-incidence curve peaks and then falls; why the juvenile peak occurs in North Africa and not in China.

**Cure status.** Stage I to II: CURABLE — five-year overall survival roughly 90 per cent†, with radiotherapy alone or with concurrent chemoradiotherapy, and radiotherapy alone curative for stage I. Stage III to IVA, locally advanced, the majority at presentation: CURABLE in roughly 65 to 80 per cent (five-year overall survival)†, with induction chemotherapy followed by concurrent chemoradiotherapy. That is a markedly better outcome for locally advanced disease than any other head and neck cancer, and it is why nasopharyngeal carcinoma is treated separately. Metastatic, stage IVB: CONTROLLABLE — median survival roughly two to three years with platinum-gemcitabine chemotherapy, and longer with the addition of a checkpoint inhibitor, which is an unusually good prognosis for metastatic head and neck cancer. A small subset with oligometastatic disease treated with chemotherapy plus local radiotherapy achieves long-term survival and may be cured. Recurrent local disease: CONTROLLABLE. Re-irradiation or nasopharyngectomy cures some, and both carry substantial morbidity in previously irradiated tissue. Early detection works here, and uniquely among the cancers in this chapter there is an effective, cheap, blood-based early-detection test validated in a prospective screening study. Surgery has almost no role in primary treatment: the nasopharynx is anatomically inaccessible and the tumour is exquisitely radiosensitive. That is the key practical fact about this cancer — it is the one major head and neck cancer where surgery is not the answer and radiotherapy is, which inverts the simple-means calculation. One honest note is necessary: cure costs a great deal functionally. Radiotherapy to the nasopharynx irradiates the brainstem, temporal lobes, cranial nerves, pituitary, inner ear, salivary glands and carotid arteries, and the late effects — xerostomia, hearing loss, hypopituitarism, cranial neuropathy, temporal lobe necrosis, carotid stenosis and stroke, trismus, dysphagia and second cancers — are common and permanent. Intensity-modulated radiotherapy reduced them substantially and is the reason outcomes improved; conventional two-dimensional radiotherapy, which is what is available in many endemic low-resource settings, causes far more late damage at a similar cure rate.

**Prevention.** Avoiding salt-preserved fish, especially in infancy and during weaning — MODERATE, and it appears to have worked. Incidence in endemic southern China has fallen by roughly 30 to 40 per cent over recent decades, tracking declining consumption alongside general improvements in living conditions. The evidence is ecological and observational and there is no trial, and it is nonetheless one of the few cancers in this chapter where a population-level decline is plausibly attributable to a specific dietary change. Tobacco cessation — MODERATE. An Epstein-Barr vaccine does not exist, and that is the central prevention gap. A vaccine would address nasopharyngeal carcinoma, Burkitt lymphoma, a third of Hodgkin lymphoma, virus-positive gastric cancer and post-transplant lymphoproliferative disorder — plausibly over 200,000 cancers a year — as well as infectious mononucleosis.

Candidates targeting gp350 and gH/gL are in early-phase trials and nothing is available. **This is arguably the largest unrealised cancer-prevention opportunity in this chapter after tobacco control.** Screening with plasma Epstein-Barr virus DNA — STRONG in endemic high-incidence populations, and this is the single most important fact in this entry. A large prospective screening study in Hong Kong, published in the *New England Journal of Medicine* in 2017, screened over 20,000 asymptomatic middle-aged Chinese men with plasma viral DNA by polymerase chain reaction. Screen-detected cancers were shifted dramatically towards early stage — roughly 70 per cent were stage I or II against roughly 20 per cent in a historical unscreened cohort — and three-year progression-free survival in the screened group was markedly superior, roughly 97 per cent against 70 per cent. Serology for IgA antibodies to viral capsid antigen and EBNA1 has been used for screening in southern China for decades and also produces a stage shift. The harms: the false-positive rate on a single plasma DNA test is appreciable, which is why a repeat test at four weeks is used to improve specificity before nasendoscopy, and false positives lead to nasendoscopy and magnetic resonance imaging, which are uncomfortable and costly and not dangerous. **Overdiagnosis appears to be low, because there is no large reservoir of indolent subclinical disease comparable to thyroid or prostate — no autopsy series shows occult nasopharyngeal carcinoma at any meaningful prevalence**. No overdiagnosis percentage has been published, and the absence of an indolent reservoir is the reason this screening programme does not carry the overdiagnosis problem that dominates the breast, prostate and thyroid entries. The grade is STRONG in endemic high-incidence populations and not justified in low-incidence populations, where the positive predictive value would collapse. This is the clearest example in this chapter of a cancer screening programme that works well, with a cheap test, in a defined high-risk population, without a significant overdiagnosis penalty, and it is worth setting against the breast, prostate and thyroid entries, where the same cannot be said.

**Treatment.** Re-irradiation or nasopharyngectomy cures some local recurrences, and the proportion is not given. Radiotherapy is the primary curative modality, and intensity-modulated radiotherapy is the standard. It is curative alone for stage I, and it substantially reduced xerostomia and other late effects compared with conventional radiotherapy at equal or better tumour control, which is the main reason survival improved. It requires a linear accelerator with inverse planning capability, and that is the binding constraint worldwide. Concurrent chemoradiotherapy with cisplatin treats stage II to IVA; **cisplatin is listed, with nasopharyngeal cancer as a radiosensitiser among its listed indications**, off-patent, at a trivial generic cost of tens of dollars a course. Induction chemotherapy before chemoradiotherapy for locally advanced disease uses gemcitabine with cisplatin, or docetaxel-cisplatin-fluorouracil, and all four drugs are listed and all off-patent; induction chemotherapy improved survival in randomised trials in endemic populations. Adjuvant metronomic capecitabine after chemoradiotherapy is a notable and unusual result: capecitabine is listed and off-patent, oral and inexpensive, and a randomised trial in endemic disease showed that one year of low-dose oral capecitabine after chemoradiotherapy improved failure-free survival. A cheap off-patent oral drug adding benefit to an already curative regimen is well suited to low-resource settings. Platinum-gemcitabine chemotherapy treats metastatic disease, both listed, both off-patent and cheap, and superior to platinum-fluorouracil. Pembrolizumab is a selected medicine on the list, for other listed indications. Nivolumab's listing for this cancer needs checking against the 24th List (2025)†. Neither is off-patent. Camrelizumab, toripalimab and tislelizumab, PD-1 inhibitors developed and approved in China specifically including for this disease, are not listed; toripalimab added to gemcitabine-cisplatin improved progression-free and overall survival in first-line metastatic disease in JUPITER-02†. PD-1 inhibitor monotherapy in recurrent or metastatic disease produces objective responses in roughly 20 to 30 per cent, and combined with chemotherapy in the first line the response rate exceeds 75 per cent†. An important access point: the Chinese-developed inhibitors are priced far below the Western originators in their home market, reported at a fraction of the United States price, which is directly relevant to the endemic populations that need them. Virus-specific cytotoxic T-lymphocyte therapy is experimental and requires cell-processing facilities. Salvage nasopharyngectomy or re-irradiation treats local recurrence. Supportive care — dental assessment and extraction before radiotherapy, management of xerostomia, hearing assessment, pituitary function monitoring and swallowing rehabilitation — matters, with lifelong surveillance for late effects required in a young patient population.

**Simple means.** Nasopharyngeal carcinoma inverts the usual pattern in this chapter: its early detection is achievable simply and cheaply, and its curative treatment is not achievable simply at all. Plasma viral DNA by polymerase chain reaction, or viral IgA serology, as a screening test in endemic populations, is a blood test: no imaging, no endoscopy, no specialist for the screening step itself, producing a large stage shift and markedly better survival with low overdiagnosis. Polymerase chain reaction requires a laboratory, which is a genuine but modest requirement, and serology requires even less. In an endemic region this is a highly cost-effective intervention. Avoiding salt-preserved fish during weaning and childhood is a dietary change with no cost, plausibly responsible for a 30 to 40 per cent incidence decline in southern China†. Nasendoscopy with a flexible or rigid scope and a biopsy forceps is needed for diagnosis, with a histopathologist; a rigid nasendoscope is inexpensive and durable, and it is the one piece of equipment that cannot be dispensed with for diagnosis. Cisplatin, gemcitabine, fluorouracil and capecitabine are all off-patent listed drugs costing tens to low hundreds of dollars a course, and oral capecitabine in particular, with randomised evidence of benefit as adjuvant metronomic therapy, needs only a tablet and a blood count. Oral morphine serves pain; nasogastric or gastrostomy feeding carries the patient through the mucositis of radiotherapy, when swallowing is impossible; tracheostomy serves airway compromise rarely. Myringotomy or grommet insertion is a minor procedure that restores hearing in the middle-ear effusion this cancer commonly causes by blocking the Eustachian tube, and that effusion is often the presenting complaint. **There is no simple means of curing nasopharyngeal carcinoma, because the cure is radiotherapy and surgery has essentially no role.** Unlike oral cavity cancer, endometrial cancer, skin cancer or thyroid cancer, all of which can be cured with a scalpel in a district hospital, nasopharyngeal carcinoma cannot be cured without a linear accelerator, and a general surgeon with basic instruments can do nothing curative for it. The disease is concentrated in populations where radiotherapy access is often limited. Conventional two-dimensional radiotherapy, where that is all that exists, still cures a large proportion at a much higher cost in permanent late damage than intensity-modulated radiotherapy, and the gap between what is achievable with and without modern planning is wide here and it is a quality-of-cure gap more than a cure-rate gap. So the honest summary is: the screening is simple and excellent, the chemotherapy is cheap and listed, and the irreplaceable component is a machine.

**Gaps.** SEER publishes no separate nasopharyngeal carcinoma page, so all stage-specific survival figures are literature-derived, which is the largest data gap in this entry. A published Epstein-Barr-attributable case count was not retrievable, and the 100,000 figure above is an inference from a near-100 per cent attribution. The screening study's figures — 70 against 20 per cent early stage, and 97 against 70 per cent three-year progression-free survival — are widely cited and could not be read off the paper itself, so the key screening evidence carries no primary verification. Endemic incidence rates, the incidence decline, the salt-fish odds ratios, the HLA associations and the familial relative risks are all literature-derived. No PDQ prevention summary specific to nasopharyngeal carcinoma was retrieved, so unlike most entries here the risk-factor effect sizes carry no evidence grade. Overdiagnosis has not been quantified, though the absence of an occult reservoir argues it is low. No Epstein-Barr vaccine exists, and that is the principal prevention gap. The relative contributions of HLA genotype, viral strain and diet are not resolved. Chinese inhibitor pricing is literature-derived.

## 27. Testicular cancer

**What it is.** Cancer of the testis, almost always a germ cell tumour arising from the sperm-producing cells. It is the commonest cancer of young men. It is also the most curable disseminated solid cancer that exists: widely metastatic testicular cancer is cured in the large majority of patients with off-patent chemotherapy, which no other metastatic solid tumour in this chapter can claim.

**Measured.** GLOBOCAN 2022 gives 72,040 cases; GLOBOCAN 2024 gives 70,714 cases and 9,240 deaths, so deaths are 13 per cent of incidence, the lowest ratio of any malignancy in this chapter apart from thyroid cancer at 5 per cent, and unlike thyroid cancer this is not an artefact of overdiagnosis. Five-year relative survival in the United States is 94.6 per cent. SEER's page publishes no stage-specific survival and no stage distribution, so those figures come from the clinical literature: stage I, confined to the testis, five-year survival roughly

99 per cent, with cure essentially universal; stage II, retroperitoneal nodes, roughly 95 per cent; stage III good-risk roughly 90 to 95 per cent; stage III intermediate-risk roughly 75 to 80 per cent; stage III poor-risk, with high markers, non-pulmonary visceral metastases or a mediastinal primary, roughly 50 to 70 per cent. Seminoma has a better prognosis than non-seminoma at equivalent stage. Median age at diagnosis 33, the second-youngest in this chapter after acute lymphoblastic leukaemia, and it is the commonest solid malignancy in men aged 15 to 40, which is why its late effects matter so much: survivors have fifty years of life ahead. United States incidence is rising about 0.7 per cent a year and the death rate about 2.3 per cent a year. That rising death rate is anomalous and worth flagging: for a cancer with 94.6 per cent five-year survival the absolute numbers are very small, at 630 projected United States deaths in 2026, so the percentage trend rests on few events and is unstable. It should not be read as a deterioration in treatment efficacy, and no established explanation exists. Incidence is highest in Northern and Western Europe — Norway, Denmark, Switzerland and Germany have the world's highest rates — and lowest in Africa and Asia; rates in men of African ancestry are roughly a quarter to a fifth of those in men of European ancestry, and the difference persists in the United States across the same healthcare system, indicating a constitutional rather than an access basis. Incidence has roughly doubled in many Western countries since the 1960s and the cause of that increase is not known†.

**Where it starts.** Cryptorchidism is the strongest and best-established risk factor, at a relative risk of roughly four- to eightfold. The risk applies to the contralateral normally descended testis as well, which indicates that cryptorchidism is a marker of an underlying developmental abnormality rather than purely a consequence of the testis being in the wrong place. Orchidopexy before puberty reduces but does not eliminate the risk and makes the testis examinable. A personal history of testicular cancer gives roughly a twelve- to twentyfold increased risk in the contralateral testis, with a cumulative incidence of a second primary of roughly 2 to 5 per cent†. Family history gives roughly a four- to sixfold increased risk in brothers and roughly fourfold in sons of affected men, with no single high-penetrance gene and many common variants identified, KITLG carrying an unusually large effect for such a locus. Germ cell neoplasia in situ is the precursor lesion and is present adjacent to essentially all germ cell tumours; it is detectable only by testicular biopsy and progresses to invasive cancer in roughly 50 per cent within five years†. Infertility and poor semen quality are associated with increased risk, consistent with the testicular dysgenesis syndrome hypothesis, which groups cryptorchidism, hypospadias, poor semen quality and testicular cancer as outcomes of disturbed fetal testicular development. Disorders of sex development and androgen insensitivity carry substantially increased risk, HIV a modest increase in seminoma risk, and height a consistent association at relative risks in the region of 1.1 to 1.2 per 5 cm, by an unknown mechanism†. What is not established matters here, because it is widely assumed: trauma, vasectomy, athletic activity, heat exposure and testicular torsion are not established causes, and tobacco and alcohol have no established role, which makes testicular cancer one of the very few cancers in this chapter where smoking is not a risk factor. Germ cell tumours have among the lowest point-mutation burdens of any cancer, far below the adult reference of 1.8 per megabase, characterised instead by near-universal gain of chromosome 12p, usually as an isochromosome, aneuploidy, and KIT mutations in a subset of seminomas; TP53 mutation is rare, and that is the leading explanation for the extraordinary chemosensitivity, because an intact p53 pathway means cisplatin-induced DNA damage triggers apoptosis efficiently. **The combination of a low mutation burden and an intact apoptotic response is the molecular reason a metastatic solid tumour can be cured by chemotherapy, and it is the clearest demonstration in this chapter that curability is a property of tumour biology rather than of treatment intensity.** Not known: why incidence has roughly doubled in Western countries since the 1960s, where in-utero exposure to endocrine-disrupting chemicals is the leading hypothesis and is unproven; why rates differ so much by ancestry; why germ cell tumours are so uniquely chemosensitive in a way that cannot be reproduced in other cancers.

**Cure status.** Germ cell neoplasia in situ: CURABLE by orchidectomy or low-dose radiotherapy, with surveillance an alternative. Stage I: CURABLE, essentially universally — five-year survival roughly 99 per cent†. Orchidectomy alone cures roughly 70 to 80 per cent of stage I non-seminoma and 80 to 85 per cent of stage I seminoma, and of those who relapse almost all are cured by subsequent chemotherapy; active surveillance after orchidectomy is now the preferred management precisely because the salvage rate is so high, which avoids giving

adjuvant treatment to the majority who do not need it. Stage II: CURABLE — roughly 95 per cent†. Stage III good-risk: CURABLE — roughly 90 to 95 per cent with three or four cycles of BEP chemotherapy†. Stage III poor-risk: CURABLE in roughly 50 to 70 per cent†. **Even with high-volume liver, brain and bone metastases and markedly raised tumour markers, cure is the goal and is achieved in the majority, and no other metastatic solid tumour in this chapter is treated with curative intent at that stage.** Relapsed after first-line chemotherapy: CURABLE in roughly 20 to 60 per cent depending on risk group, with salvage chemotherapy or high-dose chemotherapy with autologous stem cell support; late relapse, more than two years out, and platinum-refractory disease are the poor groups. A residual mass after chemotherapy is frequently cured by retroperitoneal lymph node dissection, because residual masses may contain viable tumour or teratoma that chemotherapy cannot eradicate. Platinum-refractory disease, and the rare primary mediastinal non-seminoma with poor response, a small minority: RELIEF ONLY. It is reliably curable when caught early and reliably curable when caught late, which is the more remarkable fact, and that is why there is no screening programme: the cure rate is so high at every stage that earlier detection would add little, and the test would generate large numbers of benign findings. The dominant clinical problem, as in Hodgkin lymphoma, is the cost of cure in a young population. Survivors carry excesses of second malignancies, at relative risks in the region of 1.5 to 2 overall and higher after radiotherapy, with leukaemia after etoposide and solid tumours after radiotherapy; cardiovascular disease; cisplatin-induced permanent sensorineural hearing loss and tinnitus; peripheral neuropathy; Raynaud phenomenon; nephrotoxicity; hypogonadism; metabolic syndrome; and infertility. Bleomycin causes pulmonary fibrosis, which can be fatal. The field's research agenda is accordingly dominated by de-escalation — fewer cycles, surveillance instead of adjuvant therapy, carboplatin instead of radiotherapy in seminoma, and avoiding radiotherapy altogether — the same pattern as Hodgkin lymphoma and for the same reason.

**Prevention.** Orchidopexy for cryptorchidism before puberty — MODERATE: it reduces risk, does not eliminate it, and places the testis where it can be examined and where a tumour will be noticed. The optimal timing is in infancy and earlier surgery appears to confer greater risk reduction, and the evidence is observational. There is no other established prevention: no modifiable exposure of consequence has been identified, and tobacco, alcohol, diet and obesity have no established role, which makes testicular cancer unusual in this chapter. If the endocrine-disruptor hypothesis is correct, reducing fetal exposure would be preventive; that is a hypothesis with no interventional evidence and should not be presented as established. There is no screening programme and no recommendation for one: the USPSTF recommends against screening asymptomatic adolescent and adult males, grade D. The reasoning is clear and is a useful counterpoint to other entries: the cure rate is extremely high at all stages, so screening cannot add much; the disease is uncommon, so the positive predictive value of any test would be low; and examination generates frequent benign findings — epididymal cysts, varicoceles, hydroceles — leading to ultrasound and anxiety. **Overdiagnosis in the classical sense is not the issue, because there is no large reservoir of indolent testicular cancer in autopsy series**; the issue is simply that screening has nothing to add. Self-examination and awareness are WEAK on evidence, and the practical point stands: a painless testicular lump in a young man needs immediate assessment, and delay in presentation, which is common from embarrassment or from being misdiagnosed as epididymitis, is the one avoidable factor that worsens outcome. The intervention is awareness, not a programme.

**Treatment.** Radical inguinal orchidectomy is the first and sometimes only treatment. It provides the diagnosis and cures the majority of stage I disease, and it is a short operation through a groin incision, performable with basic instruments under spinal or general anaesthesia. Sperm banking should be offered before it. BEP chemotherapy — bleomycin, etoposide and cisplatin — is the curative regimen for metastatic disease, and **every one of its three drugs is listed and off-patent**; cisplatin's listed indications include testicular germ cell tumours. The drug cost of three to four cycles at generic prices is in the region of a few hundred dollars. **This is the single most important fact in this entry, and arguably one of the most important in the chapter: widely metastatic testicular cancer is cured in roughly 90 per cent of good-risk and the majority of poor-risk patients by three cheap off-patent Essential Medicines.** The regimen has been essentially unchanged since the late 1970s, and no targeted agent, no antibody, no immunotherapy and no cell therapy

is involved. Complete response with durable cure runs at roughly 90 to 95 per cent in good-risk and 50 to 70 per cent in poor-risk metastatic disease†. Etoposide with cisplatin serves good-risk patients in whom bleomycin is to be avoided; both listed and off-patent. Single-dose carboplatin as adjuvant therapy for stage I seminoma is listed and off-patent: a single infusion reduces relapse, and it has replaced adjuvant radiotherapy because it avoids the second-cancer risk. Retroperitoneal lymph node dissection serves residual masses after chemotherapy and is an alternative to chemotherapy in some stage I to II non-seminoma; it is a major abdominal operation, and nerve-sparing technique preserves ejaculation. Salvage chemotherapy uses paclitaxel, ifosfamide, cisplatin, vinblastine and mesna, all listed and all off-patent. High-dose chemotherapy with autologous stem cell support for relapsed disease uses carboplatin and etoposide, both listed and off-patent, and the cost is in the stem cell infrastructure. Radiotherapy is curative for stage I to IIA seminoma and is now largely abandoned in favour of surveillance or single-dose carboplatin, because of the second-cancer and cardiovascular risk in young men with a fifty-year life expectancy: a clear and deliberate de-escalation. Checkpoint inhibitors have been disappointing in germ cell tumours, with low response rates in platinum-refractory disease, consistent with the very low mutation burden. There is no effective targeted or immunological therapy for refractory germ cell tumour, and this small group of young men who are not cured by chemotherapy represents a genuine and neglected unmet need. Testosterone replacement for post-treatment hypogonadism is off-patent and inexpensive. Tumour marker monitoring — alpha-fetoprotein, beta-human chorionic gonadotrophin and lactate dehydrogenase — uses cheap, widely available blood tests that are central to management: they establish risk group, monitor response and detect relapse earlier than imaging, and beta-human chorionic gonadotrophin can be measured with a urine pregnancy test strip in extremis, which is a genuinely useful piece of practical knowledge.

**Simple means.** Testicular cancer has the best simple-means profile of any metastatic solid cancer in this chapter. Radical inguinal orchidectomy is a short operation through a groin incision under spinal or general anaesthesia with basic surgical instruments; it makes the diagnosis and cures the majority of stage I disease, roughly 70 to 85 per cent, outright†, so for a young man with a localized testicular tumour a district hospital with a general surgeon can deliver a cure. BEP chemotherapy from three off-patent Essential Medicines, at a drug cost of a few hundred dollars, cures the majority of metastatic disease. The requirements are intravenous access, an antiemetic, hydration and magnesium for cisplatin nephrotoxicity, a blood count before each cycle and a creatinine. Cisplatin needs careful hydration, which is the main technical demand and requires fluids and attention rather than technology, and bleomycin needs awareness of pulmonary toxicity, which is assessed clinically. **No other metastatic solid tumour in this chapter can be cured with means this modest.** Diagnosis is possible by examination and scrotal ultrasound: a painless firm testicular mass in a young man is clinically distinctive, and ultrasound is cheap, portable, needs no contrast and no radiation and is highly accurate, so this is one of the few cancers in this chapter where a hand-held probe is close to diagnostic. Tumour markers are inexpensive standard laboratory tests that do most of the work of risk stratification and follow-up that would otherwise require repeated imaging, and beta-human chorionic gonadotrophin is detectable on a urine pregnancy test strip costing cents. Sperm banking requires a container and a freezer, and in a disease with 95 per cent survival and a median age of 33 that is not a luxury. Orchidopexy in infancy for cryptorchidism is a standard paediatric operation with basic instruments that reduces cancer risk and makes the testis examinable. Testosterone replacement is off-patent, cheap, intramuscular or transdermal. Awareness that a painless testicular lump in a young man requires immediate assessment needs no technology at all, and delay from embarrassment or from misdiagnosis as epididymitis is a recognised and avoidable cause of advanced presentation. Oral morphine serves pain in advanced disease. Where nothing simple exists: retroperitoneal lymph node dissection for a post-chemotherapy residual mass is a major vascular operation requiring specialist expertise, and omitting it when indicated causes relapse from viable residual tumour; high-dose chemotherapy with stem cell support requires apheresis and a transplant unit; and for the small number of young men with platinum-refractory disease there is nothing effective at all, simple or otherwise. Those are the exceptions. The central fact stands: **testicular cancer is the clearest proof in this chapter that curing widely metastatic cancer does not require expensive drugs.** The barrier to curing it

worldwide is access to orchidectomy, cisplatin and competent supportive care — not patents, and not price.

**Gaps.** SEER's page publishes no stage-specific survival and no stage distribution, so all stage-specific figures are literature-derived. No PDQ prevention summary for testicular cancer was retrieved, so the risk-factor effect sizes carry no evidence grade, unlike most entries here. The cryptorchidism, familial, contralateral and precursor-progression figures and the incidence gradients are all literature-derived. The roughly doubled incidence in Western countries since the 1960s is unexplained and the endocrine-disruptor hypothesis has no interventional evidence. The rising United States death rate rests on very few events and has no established explanation; it may be statistical noise and should not be over-interpreted. Second-cancer and late-effect figures are literature-derived despite being central to management. Platinum-refractory germ cell tumour has no effective treatment and is a genuinely neglected unmet need in a young population.

## 28. Sarcomas of soft tissue and bone

**What it is.** Cancers of the connective tissues — muscle, fat, blood vessels, nerve sheath, cartilage and bone — rather than of the linings and glands that produce the common carcinomas. They comprise more than a hundred distinct diagnoses, several defined by a single characteristic chromosomal translocation. They are uncommon, they affect all ages including children, and they are the cancers for which specialist referral makes the largest difference to outcome.

**Measured.** GLOBOCAN does not report soft tissue sarcoma or bone sarcoma as categories in the site list that supplies the rest of this chapter, which is a significant limitation: the global burden of sarcoma as a group cannot be read off that table. Kaposi sarcoma is reported separately, at 35,813 cases in 2022 and 34,230 cases with 10,727 deaths in 2024, and mesothelioma separately, at 30,633 cases in 2022 and 27,350 cases with 22,715 deaths in 2024. Sarcomas are generally estimated at roughly 1 per cent of adult cancers and roughly 10 to 15 per cent of childhood cancers†, which against GLOBOCAN 2024's total implies in the region of 150,000 to 250,000 cases worldwide annually; that is an inference and is marked as one. For soft tissue sarcoma in the United States, projections for 2026 are 13,910 new cases and 5,400 deaths, 0.7 per cent of cancer cases and 0.9 per cent of cancer deaths. Five-year relative survival is 65.7 per cent overall: localized, 57 per cent of cases, 83.3 per cent; regional, 18 per cent, 58.2 per cent; distant, 17 per cent, 17.0 per cent; unknown, 8 per cent, 62.7 per cent. Median age 63. Incidence has not significantly changed and the death rate is falling about 0.6 per cent a year, with modelled five-year survival rising from about 63 per cent in 1975 to about 69 per cent in 2023: one of the smallest long-term survival improvements of any cancer in this chapter. SEER's bones and joints page was not retrieved, so the bone sarcoma figures come from the literature: osteosarcoma, the commonest bone sarcoma, peaking in adolescence, five-year survival roughly 65 to 70 per cent localized and roughly 20 to 30 per cent with metastases at presentation; Ewing sarcoma, a childhood and young-adult tumour, roughly 70 to 80 per cent localized and 20 to 30 per cent metastatic; chondrosarcoma, adult and usually low grade, roughly 75 to 80 per cent overall and far worse for dedifferentiated forms; and chordoma, rare, axial and slow-growing, median survival roughly seven years. Among the soft tissue subtypes: localized gastrointestinal stromal tumour five-year survival above 90 per cent, with metastatic disease at a median survival of roughly five years on imatinib against roughly eighteen months before it; liposarcoma, leiomyosarcoma and undifferentiated pleomorphic sarcoma are the commonest adult types, with outcome driven by grade and size; rhabdomyosarcoma, predominantly paediatric, roughly 70 per cent for localized embryonal disease and far worse for alveolar and metastatic disease; angiosarcoma, aggressive, roughly 30 to 40 per cent; and desmoid tumour, which is locally infiltrative, does not metastasise, and spontaneously regresses in a substantial proportion. Kaposi sarcoma is the dominant sarcoma globally by volume and is concentrated in sub-Saharan Africa, where it was among the commonest cancers in men in several countries at the height of the HIV epidemic and remains so in parts of Eastern and Southern Africa; endemic non-HIV Kaposi sarcoma has long been recognised in equatorial Africa. Mesothelioma incidence tracks historical asbestos use and is still rising in countries that used asbestos late.

**Where it starts.** Sarcomas have the highest proportion of cases with an identifiable germline or iatrogenic cause of any group in this chapter, and simultaneously the least known about the sporadic majority. Prior therapeutic radiotherapy is the best-established acquired cause: radiation-induced sarcoma arises in the irradiated field after a latency of typically ten to twenty years, with an absolute risk in the region of 0.1 to 0.2 per cent of irradiated patients†. It is most often osteosarcoma, undifferentiated pleomorphic sarcoma or angiosarcoma, and it carries a worse prognosis than the sporadic equivalent, with angiosarcoma of the breast after breast-conserving radiotherapy the classic example. This is an iatrogenic cancer, and it is one of the reasons for the radiotherapy de-escalation described in entries 22 and 27. Chronic lymphoedema gives angiosarcoma in a chronically lymphoedematous limb, classically after axillary dissection for breast cancer. The germline predisposition syndromes account for a substantial minority: Li-Fraumeni syndrome, with germline TP53 mutation, gives soft tissue sarcoma, osteosarcoma, breast cancer, brain tumours and adrenocortical carcinoma at a lifetime cancer risk approaching 90 per cent†; hereditary retinoblastoma, with germline RB1 mutation, gives a very large increase in osteosarcoma risk, markedly amplified by radiotherapy to the orbit; neurofibromatosis type 1 gives malignant peripheral nerve sheath tumour at a lifetime risk of roughly 8 to 13 per cent; familial adenomatous polyposis gives desmoid tumours, which are a major cause of morbidity and death after colectomy; and hereditary leiomyomatosis and renal cell cancer, Werner syndrome, Rothmund-Thomson syndrome and germline succinate dehydrogenase mutations follow. Human herpesvirus 8 causes Kaposi sarcoma, and the attributable fraction is essentially 100 per cent: the virus is present in the tumour cells in every case, in all four epidemiological forms — classic Mediterranean, endemic African, HIV-associated and iatrogenic post-transplant. de Martel and colleagues, 2020, gave case counts for four agents not including this one; on near-100 per cent attribution and GLOBOCAN 2024's 34,230 Kaposi sarcoma cases, the implied figure is roughly 34,000 cases annually, and that is an inference. HIV co-infection is the critical amplifier: incidence in untreated HIV infection is raised several thousandfold, and it falls dramatically with antiretroviral therapy. Asbestos causes mesothelioma, is IARC Group 1, and the attributable fraction is high — generally estimated at roughly 80 per cent or more in men in industrialised countries — with a latency of twenty to fifty years. Mesothelioma is the clearest single-exposure cancer in this chapter after tobacco and lung cancer, and it is wholly preventable by not using asbestos. Vinyl chloride monomer causes hepatic angiosarcoma, is IARC Group 1, and is a historical occupational cancer now largely controlled; Thorotrast, arsenic and anabolic steroids likewise cause hepatic angiosarcoma. Chronic immunosuppression gives post-transplant Kaposi sarcoma and other sarcomas. Sarcomas divide into two genetic classes and the division is the most useful thing to know about them. The translocation-driven sarcomas carry a single defining fusion gene on a quiet genomic background with a very low mutation burden: Ewing sarcoma with EWSR1-FLI1, synovial sarcoma with SS18-SSX, myxoid liposarcoma with FUS-DDIT3, alveolar rhabdomyosarcoma with PAX3 or PAX7 to FOXO1, dermatofibrosarcoma protuberans with COL1A1-PDGFB, inflammatory myofibroblastic tumour with ALK fusions, and infantile fibrosarcoma with ETV6-NTRK3. These are mostly tumours of children and young adults, and their mutation burden is among the lowest measured in human cancer: Gröbner and colleagues, in *Nature* in 2018, found an overall paediatric rate of 0.13 mutations per megabase against the adult reference of 1.8, and Ewing sarcoma sits at the bottom of even that range. The complex-karyotype sarcomas carry massive aneuploidy, chromothripsis, TP53 and RB1 loss and no defining fusion: leiomyosarcoma, undifferentiated pleomorphic sarcoma, dedifferentiated liposarcoma, osteosarcoma and angiosarcoma, mostly adult tumours, with osteosarcoma in particular showing extreme structural rearrangement and chromothripsis on a moderate point-mutation burden. Gastrointestinal stromal tumour is a third category, driven by activating KIT mutations in roughly 75 to 80 per cent or PDGFRA mutations in roughly 10 per cent, with succinate dehydrogenase deficiency in most of the remainder, and that single-driver biology is why imatinib works. The practical consequence is that the translocation-driven sarcomas have essentially no mutational burden for checkpoint inhibitors to exploit, and immunotherapy has largely failed in sarcoma as a class; the exceptions — undifferentiated pleomorphic sarcoma, dedifferentiated liposarcoma and alveolar soft part sarcoma — are the ones with either higher burden or distinctive immune features. Not known: **the cause of the great majority of sporadic sarcomas.** For a group this heterogeneous and this often arising in children, the aetiological void is almost complete: there is no tobacco, no diet, no obesity, no infection outside Kaposi sarcoma and no identified environmental exposure for the sporadic majority.

Also unknown: why the characteristic translocations occur; why they are so cell-type and age specific; why a single fusion gene is sufficient to produce a malignant tumour in these cases when most cancers require multiple hits.

**Cure status.** Desmoid tumour, aggressive fibromatosis: SELF-LIMITING in roughly 20 to 30 per cent, which regress spontaneously without any treatment†; the remainder: CONTROLLABLE. It does not metastasise. Active surveillance is now the recommended first-line management, having replaced immediate surgery, and the shift to observation is a genuine and recent reversal of practice. HIV-associated Kaposi sarcoma: CONTROLLABLE by antiretroviral therapy alone, which is lifelong — restoring immune function causes regression in a large proportion of cases without any cytotoxic chemotherapy. **This is the only cancer in this chapter that routinely regresses on treatment of an underlying infection other than gastric mucosa-associated lymphoid tissue lymphoma on *H. pylori* eradication, and it is the single most important practical fact in this entry for global burden, because Kaposi sarcoma is the commonest sarcoma in the world.** Localized soft tissue sarcoma: CURABLE — five-year relative survival 83.3 per cent, by wide surgical excision with a clear margin, with radiotherapy to reduce local recurrence in high-grade or large deep tumours. The margin is everything: an inadequate first operation, performed by a non-specialist who did not suspect sarcoma, substantially worsens outcome and is the commonest avoidable error in sarcoma care. Regional soft tissue sarcoma: CURABLE in 58.2 per cent (five-year relative survival). Metastatic soft tissue sarcoma with resectable lung-only metastases: CURABLE in roughly 25 to 35 per cent (five-year survival after complete pulmonary metastasectomy); sarcoma is one of the cancers where metastasectomy is standard rather than exceptional. Metastatic soft tissue sarcoma otherwise: RELIEF ONLY — 17.0 per cent. Localized osteosarcoma and Ewing sarcoma: CURABLE in roughly 65 to 80 per cent with neoadjuvant chemotherapy, surgery and, for Ewing sarcoma, radiotherapy. Both were almost uniformly fatal before multi-agent chemotherapy was introduced in the 1970s, and survival rose from under 20 per cent to roughly 70, and both have seen essentially no further improvement in forty years, which is a notable plateau. Metastatic osteosarcoma and Ewing sarcoma with resectable lung-only deposits: CURABLE in roughly 20 to 30 per cent†. Metastatic osteosarcoma and Ewing sarcoma otherwise: RELIEF ONLY. Metastatic gastrointestinal stromal tumour: CONTROLLABLE, and the transformation is large — before imatinib, median survival was roughly eighteen months and chemotherapy was ineffective; on imatinib, median survival is roughly five years and a minority remain controlled for over a decade. Adjuvant imatinib for three years after resection of high-risk localized disease improves survival. Low-grade chondrosarcoma: CURABLE by excision. Dedifferentiated chondrosarcoma: RELIEF ONLY. Mesothelioma: RELIEF ONLY — median survival roughly twelve to eighteen months with chemotherapy, extended to roughly eighteen months with nivolumab and ipilimumab in non-epithelioid disease. Trimodality therapy in highly selected epithelioid pleural mesothelioma produces longer survival in some series and is not curative in the great majority. Mesothelioma is not curable at any stage and it is entirely preventable. Localized soft tissue and bone sarcoma is reliably curable when caught early, with the crucial proviso that caught early must mean caught and operated on correctly the first time. A sarcoma excised piecemeal or shelled out by a surgeon who thought it was a lipoma or a haematoma has a substantially worse outcome, and that is the dominant modifiable determinant of outcome in sarcoma. **The single most valuable intervention in sarcoma care is referral before the first operation.**

**Prevention.** Not using asbestos — STRONG, and mesothelioma is almost entirely preventable. Asbestos is IARC Group 1 and accounts for the large majority of mesothelioma; more than sixty countries have banned it and many large producers and users have not. Every mesothelioma occurring now reflects an exposure twenty to fifty years ago, and every mesothelioma occurring in fifty years' time reflects an exposure happening now. That is the clearest avoidable cancer in this chapter after tobacco-related disease. Antiretroviral therapy for HIV — STRONG for Kaposi sarcoma: incidence in people with HIV fell dramatically with effective therapy and established disease frequently regresses on therapy alone. Since Kaposi sarcoma is the commonest sarcoma globally and is concentrated in sub-Saharan Africa, where WHO records 64 per cent of the 41.0 million people living with HIV, scale-up of antiretroviral therapy is quantitatively the most important sarcoma prevention that exists. Minimising therapeutic radiotherapy dose and field, especially in children and young adults — MODERATE, against an absolute radiation-induced sarcoma risk of roughly 0.1 to 0.2 per

cent of irradiated patients at ten to twenty years†; this is a principal justification for de-escalation in Hodgkin lymphoma, testicular seminoma, retinoblastoma and childhood cancer generally, and avoiding orbital radiotherapy in hereditary retinoblastoma is the sharpest example, because the osteosarcoma risk in germline RB1 carriers is hugely amplified by radiation. Occupational control of vinyl chloride — STRONG, a historical success. Surveillance in germline predisposition syndromes — MODERATE: whole-body magnetic resonance imaging in Li-Fraumeni syndrome detects tumours early and has been associated with improved survival in cohort studies, with no randomised evidence, and annual clinical examination and imaging for malignant transformation in neurofibromatosis type 1 plexiform neurofibromas is recommended on risk grounds. There is no population screening for sarcoma and no rationale for one: the incidence is far too low, so any test would have a catastrophically low positive predictive value, and there is no pre-malignant lesion to intercept. Overdiagnosis is not a significant issue with one real exception: incidental detection of small lipomatous tumours, enchondromas and nerve sheath tumours on imaging done for other reasons is very common, and distinguishing an atypical lipomatous tumour from a benign lipoma, or an enchondroma from a low-grade chondrosarcoma, is genuinely difficult. That generates biopsies and operations on lesions that would never have caused harm. **No overdiagnosis percentage has been published for incidental lipomatous and cartilaginous lesions**, and it is an unquantified and growing harm of expanding imaging use.

**Treatment.** Wide surgical excision with a clear margin is the curative treatment for localized sarcoma, and the quality of the first operation is the dominant determinant of outcome. Limb-sparing surgery has replaced amputation for most extremity sarcomas with equivalent survival, and referral to a specialist centre before biopsy and before any excision is the single most important process measure in sarcoma care. Radiotherapy, preoperative or postoperative, reduces local recurrence in high-grade deep soft tissue sarcoma and is essential in Ewing sarcoma, and it requires a linear accelerator. Doxorubicin, with or without ifosfamide, is the standard chemotherapy for soft tissue sarcoma, and both are listed and off-patent, with mesna, listed and off-patent, required with ifosfamide to prevent haemorrhagic cystitis. Objective response to doxorubicin monotherapy in metastatic soft tissue sarcoma is roughly 15 to 20 per cent; adding ifosfamide raises response and has not clearly improved overall survival, at a generic cost of a few hundred dollars a course. For osteosarcoma, the MAP regimen of high-dose methotrexate, doxorubicin and cisplatin, with calcium folinate rescue, has all four components listed and all off-patent, and methotrexate's listed indications include osteosarcoma and cisplatin's include it too. That regimen raised localized osteosarcoma survival from under 20 per cent to roughly 65 to 70 per cent and has not been improved upon in forty years†; the entire curative regimen is off-patent and cheap, and high-dose methotrexate requires rescue, hydration, urinary alkalinisation and level monitoring, which is the technical demand. For Ewing sarcoma, vincristine, doxorubicin and cyclophosphamide alternating with ifosfamide and etoposide has every drug listed and every one off-patent, with vincristine's listed indications including Ewing sarcoma, and it cures roughly 70 to 80 per cent of localized disease†. For rhabdomyosarcoma, vincristine, dactinomycin and cyclophosphamide are all listed and all off-patent, and dactinomycin's listed indications include rhabdomyosarcoma. Imatinib for gastrointestinal stromal tumour is listed and off-patent, at United States generic cash prices, October 2026, of US$1.49 to 5.37 per 400 mg tablet and US$44.75 to 161.09 for thirty, which is US$540 to 1,960 a year at 400 mg daily. The originator price was in the region of US$90,000 to 145,000 a year at United States list by the time of generic entry in 2016†. Objective response or durable stable disease runs at roughly 80 per cent in metastatic disease, with median overall survival roughly five years against roughly eighteen months before it, and adjuvant imatinib for three years after resection of high-risk disease improves overall survival. That is the same drug and the same price story as in entry 20, and gastrointestinal stromal tumour is the second disease it transformed. Sunitinib, regorafenib, ripretinib and avapritinib are not listed. Pemetrexed with cisplatin treats mesothelioma: cisplatin is listed and off-patent, and pemetrexed is not listed and is off-patent with generics available. Nivolumab with ipilimumab improved survival over chemotherapy in non-epithelioid mesothelioma in CheckMate 743; nivolumab's listing for this cancer needs checking against the 24th List (2025)†, ipilimumab is not listed, and neither is off-patent. Antiretroviral therapy for HIV-associated Kaposi sarcoma is the first-line treatment, is listed, off-patent, and available at generic prices in the region of US$30 to 75 a year in global procurement programmes†. For more advanced Kaposi sarcoma, pe-

gylated liposomal doxorubicin, listed, and paclitaxel, listed and off-patent, are effective, and bleomycin with vincristine, both listed and off-patent, are the older and cheapest option and remain widely used in Africa. Trabectedin, eribulin, pazopanib, tazemetostat, larotrectinib and entrectinib, and atezolizumab for alveolar soft part sarcoma, are none of them listed except atezolizumab, which is listed for lung cancer, and all are on patent except where generics have emerged. Larotrectinib and entrectinib produce objective responses above 70 per cent in NTRK-fusion tumours including infantile fibrosarcoma, where they have allowed limb-sparing treatment in infants who would previously have been amputated: a small group with a very large benefit. Mifamurtide for osteosarcoma is approved in Europe, is not listed, and has marginal and contested benefit. Denosumab for giant cell tumour of bone is not listed and produces dramatic radiological response in a benign but locally destructive tumour. Pulmonary metastasectomy is standard in sarcoma and curative in a minority.

**Simple means.** Antiretroviral therapy for HIV-associated Kaposi sarcoma comes first: oral tablets, listed, off-patent, available at US$30 to 75 a year through global procurement, causing regression of the commonest sarcoma in the world with no cytotoxic drug. **In terms of cancer burden addressed per dollar, that is among the most important interventions in this chapter, and it is already a public health priority for other reasons.** Where cytotoxic therapy is needed, bleomycin and vincristine are off-patent listed drugs costing tens of dollars, and they are effective and widely used in African settings. Observation for desmoid tumour is the recommended first-line management and costs nothing, because a substantial proportion regress spontaneously. Wide excision of a localized extremity soft tissue sarcoma with a cuff of normal tissue is a conventional operation requiring basic instruments and anaesthesia, and it is curative in roughly 83 per cent of localized cases. Amputation, where limb-sparing excision is not feasible and no radiotherapy is available, is a definitive and curative operation achievable in any district hospital, and for a high-grade extremity sarcoma with no access to radiotherapy amputation may be the correct choice rather than an inadequate excision with a high local recurrence rate. That is an uncomfortable and honest point. **Recognising a sarcoma before operating on it is the single highest-value simple means in this entry and it costs nothing**: a deep soft tissue mass larger than about 5 cm, or any enlarging deep mass, should be imaged and biopsied with a needle along a planned track rather than shelled out, and bone pain with a lytic or sclerotic lesion and periosteal reaction in an adolescent is osteosarcoma until proven otherwise. Those are diagnostic rules rather than technologies, and getting them wrong is the commonest avoidable harm in sarcoma care worldwide. Core needle biopsy requires a needle and a histopathologist, and the binding constraint is pathology: sarcoma subtyping requires immunohistochemistry and increasingly molecular confirmation of the characteristic fusion, and misdiagnosis rates in non-specialist settings are high. Without reliable pathology the correct chemotherapy cannot be chosen, and the regimens differ completely between osteosarcoma, Ewing sarcoma and rhabdomyosarcoma. The paediatric bone and soft tissue sarcoma regimens are entirely off-patent: every drug in MAP, in the Ewing regimen and in the rhabdomyosarcoma regimen is listed and off-patent. A full curative course costs in the region of a few hundred to low thousands of dollars, and it cures 65 to 80 per cent of localized osteosarcoma, Ewing sarcoma and embryonal rhabdomyosarcoma. As with childhood acute lymphoblastic leukaemia, the drugs are not the barrier. What is the barrier: high-dose methotrexate needs rescue, hydration, alkalinisation and level monitoring; the regimens cause prolonged neutropenia requiring transfusion and antibiotic support; and treatment runs for many months, so abandonment is a major cause of failure. Imatinib for gastrointestinal stromal tumour is one oral tablet daily, off-patent, listed, at US$540 to 1,960 a year at United States generic prices, October 2026, and less in generic-supplying markets, with no infusion and no cold chain: a metastatic sarcoma controlled for years by a cheap daily tablet. Amputation with simple prosthetics, oral morphine, which matters especially in bone sarcoma where pain is severe, and orthopaedic fixation or bracing for an impending pathological fracture complete the list. Not using asbestos is prevention requiring no technology, only a decision. Where nothing simple exists: limb-sparing reconstruction with endoprostheses or allografts, radiotherapy, which is essential in Ewing sarcoma and in high-grade soft tissue sarcoma margins, pulmonary metastasectomy, and the specialist pathology on which correct treatment selection depends. And for metastatic complex-karyotype sarcoma and for mesothelioma there is nothing effective at all: doxorubicin’s response rate of 15 to 20 per cent and mesothelioma’s twelve- to eighteen-month median survival are the honest figures. **The structural problem in sarcoma is**

**different from the other entries in this chapter: the drugs are cheap and off-patent, and the diagnosis is difficult, the first operation determines the outcome, and both require expertise that is concentrated in a small number of centres. Sarcoma is the clearest case in this chapter where the scarce resource is skill rather than money or technology.**

**Gaps.** GLOBOCAN does not report soft tissue or bone sarcoma as categories, so there is no reliable global incidence or mortality figure for sarcoma as a group, and the inference above is labelled as one. That is the largest data gap of any entry in this chapter. SEER's bones and joints page was not retrieved, so all bone sarcoma survival figures are literature-derived. No PDQ prevention summary for sarcoma was retrieved, so the risk-factor effect sizes carry no evidence grade. All subtype-specific survival figures, the germline syndrome risks, the radiation-induced sarcoma absolute risk, the desmoid spontaneous regression rate, the gastrointestinal stromal tumour survival on imatinib and the metastasectomy outcomes are literature-derived. A published human herpesvirus 8-attributable case count for Kaposi sarcoma was not retrievable. The aetiology of the sporadic majority is unknown, and for a group that includes many childhood cancers that is a substantial void. Osteosarcoma and Ewing sarcoma survival have not improved in roughly forty years despite extensive trial activity, an unexplained plateau. Overdiagnosis of incidental lipomatous and cartilaginous lesions is real, growing and entirely unquantified. The dominant determinant of outcome — the quality of the first operation and the accuracy of the pathology — is not captured in any of the survival statistics quoted.

---

# Childhood cancer

Childhood cancer is a cross-cutting subject as well as a set of entries, and the material that runs through all four paediatric entries below is set out once here. The individual entries follow.

## 29. Childhood cancer as a class

**What it is.** Cancer in children is a different set of diseases from cancer in adults, not a younger version of the same thing. It arises in developing tissues rather than in surfaces worn down by decades of exposure, it carries far fewer mutations, it is not caused by tobacco or diet or obesity, and it is much more often curable. The commonest types are the leukaemias, brain tumours, lymphomas, and the embryonal solid tumours — neuroblastoma, Wilms tumour, medulloblastoma and retinoblastoma — which have their own entries below.

**Measured.** WHO estimates that about 400,000 children and adolescents aged 0 to 19 develop cancer each year worldwide. **Survival is the central fact: more than 80 per cent of children with cancer are cured in high-income countries, and in most low- and middle-income countries less than 30 per cent are cured**. That roughly threefold divergence, in a group of diseases largely curable with off-patent drugs, is the largest single inequity documented in this chapter. WHO's Global Initiative for Childhood Cancer targets at least 60 per cent survival for all children with cancer by 2030, roughly double the current global rate, which WHO estimates would save an additional one million lives over the decade. WHO names the commonest childhood cancers as the leukaemias, brain tumours and solid tumours such as neuroblastoma and Wilms tumour, with lymphomas, bone cancer and thyroid cancer more common in adolescence. SEER's childhood cancer page could not be retrieved, so United States aggregate childhood figures are absent here; the type-specific SEER figures available in this chapter are acute lymphoblastic leukaemia at 73.2 per cent overall, with a median age of 18 and 52.1 per cent of cases under 20, and acute myeloid leukaemia at 33.4 per cent. The others are Hodgkin lymphoma at 89.3 per cent with a median age of 38, brain and central nervous system tumours at 32.9 per cent, and soft tissue sarcoma at 65.7 per cent. Childhood cancer mortality in high-income countries fell by roughly 70 per cent between 1970 and 2020, driven almost entirely by cooperative-group clinical trials using off-patent cytotoxic drugs. The age pattern peaks in the first five years of life, with the embryonal tumours and acute lymphoblastic leukaemia, troughs in middle childhood, and

rises again in adolescence with bone sarcoma, Hodgkin lymphoma, germ cell tumours and thyroid cancer.

**Where it starts. Paediatric tumours carry roughly fourteen times fewer somatic mutations than adult tumours.** Gröbner and colleagues, in *Nature* in 2018, analysed 961 tumours from children, adolescents and young adults across 24 molecular cancer types and reported an overall somatic mutation frequency of **0.13 mutations per megabase, against the adult pan-cancer reference of 1.8 mutations per megabase**. The paper describes this as an overall rate rather than a median, and the figure is not in the abstract. Three consequences follow, and they run through every childhood cancer entry in this chapter. First, childhood cancers are driven by single structural or epigenetic events — fusion genes, translocations, aneuploidy, histone mutations, imprinting defects — rather than by accumulated point mutations from exposure, and that is why they occur in children at all: they do not require decades of mutational accumulation. Second, **there is almost no mutational burden for checkpoint inhibitors to exploit, and checkpoint blockade has broadly failed across paediatric oncology.** That is the clinical consequence and it is observed rather than predicted: the successful immunotherapies in children — dinutuximab in neuroblastoma, blinatumomab and CD19-directed cell therapy in acute lymphoblastic leukaemia — all target a lineage antigen rather than a neoantigen. Third, the absence of a tobacco, diet, alcohol or obesity signature is not a gap in research; it may reflect the fact that these exposures have not had time to act. Gröbner and colleagues also found that **7.6 per cent of children with cancer carry an unambiguous predisposing germline variant** (given as 7 to 8 per cent in the paper, 7.6 per cent in its main text), against WHO's figure of about 10 per cent, and the two are consistent. And they found that nearly 50 per cent of paediatric neoplasms harbour a potentially druggable event, 52 per cent of primary tumours after normalising for cancer incidence. On causation WHO's summary is the honest one and is quoted directly: most childhood cancers do not have a known cause, very few are linked to environmental or lifestyle factors, and childhood cancer generally cannot be prevented or found through screening. What is established: germline predisposition in 7 to 10 per cent of cases — Li-Fraumeni syndrome, retinoblastoma, neurofibromatosis types 1 and 2, Beckwith-Wiedemann syndrome and the Wilms tumour loci, DICER1, Fanconi anaemia, ataxia-telangiectasia, Down syndrome, familial neuroblastoma, rhabdoid tumour predisposition and constitutional mismatch repair deficiency; ionising radiation, the best-established environmental cause, including in-utero exposure and therapeutic irradiation; chronic infections, particularly in low- and middle-income countries, where WHO names HIV, Epstein-Barr virus and malaria as risk factors, the agents behind endemic Burkitt lymphoma, HIV-associated Kaposi sarcoma and lymphoma, and the juvenile North African nasopharyngeal peak; prior chemotherapy and radiotherapy for a first cancer; and Down syndrome, with a roughly twentyfold increase in childhood acute lymphoblastic leukaemia and a large increase in megakaryoblastic acute myeloid leukaemia. WHO recommends vaccination against hepatitis B and human papillomavirus to reduce later cancer risk; these prevent adult cancers in people vaccinated as children rather than childhood cancers, and the distinction should be kept clear. Not known: **the cause of the great majority of childhood cancer**, as WHO states explicitly. For childhood acute lymphoblastic leukaemia the delayed-infection hypothesis is the leading account and is unproven; for the embryonal tumours the initiating events occur in utero or in early development and nothing is known about what triggers them; for brain tumours, nothing. That is the largest aetiological void in this chapter and it is a void in the field.

**Cure status.** High-income settings: CURABLE — more than 80 per cent of children with cancer are cured. Most low- and middle-income settings: CURABLE — and less than 30 per cent are cured. The label is the same in both strata, and the stratum is named because the honest answer to whether this is curable differs by where the child lives, which is the point. **The difference is not biological.** The same diseases, with the same genetics, are cured at over 80 per cent in one place and under 30 per cent in another, using drugs that are almost all off-patent and listed. The determinants of the gap, drawn from the individual entries in this chapter: diagnostic delay and advanced presentation, of which retinoblastoma presenting with proptosis rather than a white pupil is the sharpest example; absence of reliable histopathology, where the regimens for osteosarcoma, Ewing sarcoma and rhabdomyosarcoma are completely different; no blood or platelet supply for the intensive phases, without which acute myeloid leukaemia induction kills by haemorrhage regardless of drug cost; no inpatient capacity for febrile neutropenia; interrupted drug supply over the two to three years

that acute lymphoblastic leukaemia maintenance requires; no radiotherapy, without which medulloblastoma cannot be cured; and treatment abandonment. **Treatment abandonment is specific to paediatric oncology in low-income settings and is a leading cause of death; it is a failure of social and financial support rather than of medicine, and it is measurable and addressable**. The second dominant problem, where cure is achieved, is the cost of cure. A cured child has sixty or seventy years ahead. Survivors carry substantial excesses of second cancers, cardiac disease from anthracyclines, hearing loss from cisplatin, infertility from alkylators, growth and endocrine failure from cranial and spinal irradiation, cognitive impairment from central-nervous-system-directed treatment, and renal impairment. In the large survivorship cohorts a majority of adult survivors of childhood cancer have at least one chronic health condition attributable to treatment. That is why de-escalation — risk-stratified therapy, omission of radiotherapy, reduced anthracycline dose, surveillance instead of adjuvant treatment — dominates the paediatric trial agenda, exactly as in Hodgkin lymphoma and testicular cancer.

**Prevention.** WHO states plainly that childhood cancer generally cannot be prevented or found through screening, and that is the honest headline and it differs from almost every other entry in this chapter. What does work: avoiding unnecessary diagnostic and therapeutic ionising radiation in pregnancy and childhood — STRONG, and the only established environmental cause across the class. HIV prevention and antiretroviral therapy — STRONG for Kaposi sarcoma and HIV-associated lymphoma in children; the therapy is listed, off-patent, US$30 to 75 a year at global procurement prices, and causes established Kaposi sarcoma to regress. Malaria control — MODERATE for endemic Burkitt lymphoma, on ecological evidence only, and nets and antimalarials are cheap and justified anyway; WHO records 282 million malaria cases and 610,000 deaths in 2024, with about 75 per cent of African Region deaths in children under five in its key facts, against 76 per cent then 75 per cent in two adjacent paragraphs of the body of the same page; both are printed. Minimising treatment intensity in curable childhood cancers — STRONG for preventing second cancers and late effects: this is prevention of iatrogenic disease and it is the main prevention activity in paediatric oncology. Genetic counselling and surveillance in predisposition syndromes — MODERATE, on cohort evidence with no randomised trials: whole-body imaging in Li-Fraumeni syndrome, renal ultrasound in Beckwith-Wiedemann syndrome and the Wilms tumour syndromes, and ophthalmological examination in familial retinoblastoma all detect tumours early, and avoiding radiotherapy in germline RB1 carriers is strongly indicated because of the amplified osteosarcoma risk. Hepatitis B and human papillomavirus vaccination in childhood — STRONG, and they prevent adult cancers of the liver, cervix and oropharynx rather than childhood cancers. There is no population screening for any childhood cancer, and one attempt is the most instructive failure in the whole screening literature: urinary catecholamine screening of infants for neuroblastoma, set out in entry 30. It detected large numbers of tumours, did not reduce neuroblastoma mortality, and was abandoned. The lesson is the same as for thyroid cancer, prostate cancer and the myeloma and chronic lymphocytic leukaemia precursors: a detectable lesion with a high rate of spontaneous regression or indolence makes screening harmful rather than helpful. The one exception is not a technology, and it is the red reflex test for retinoblastoma, set out in entry 33.

**Treatment.** The drugs that cure childhood cancer are, almost without exception, off-patent and listed. Drawing the regimens together from the individual entries, all of the following are in the antineoplastic section of the Essential Medicines List and all are off-patent: vincristine, dactinomycin, cyclophosphamide, ifosfamide, doxorubicin, daunorubicin, etoposide, cisplatin, carboplatin, methotrexate, mercaptopurine, tioguanine, cytarabine, asparaginase, pegaspargase, bleomycin, dacarbazine, melphalan, procarbazine, vinblastine, calcium folinate, prednisolone, prednisone, dexamethasone, hydroxyurea, all-trans retinoic acid, arsenic trioxide, mesna, allopurinol, rasburicase, filgrastim and zoledronic acid. The total drug cost for a full curative course of most childhood cancer protocols is in the region of a few hundred to a low thousands of dollars at generic prices. The modern expensive agents that matter in paediatrics: dinutuximab for neuroblastoma, not listed and on patent; blinatumomab, listed and on patent at US$180,000 a course at United States list; CD19-directed cell therapy, not listed, at a reported US$475,000 an infusion at United States list; larotrectinib and entrectinib for NTRK fusions, not listed; and selumetinib for neurofibromatosis type 1 plexiform neurofibroma, not listed. Radiotherapy is essential in medulloblastoma, Ewing sarcoma and several others and is being minimised wherever possible because of late effects. Surgery

is curative or essential in Wilms tumour, neuroblastoma, retinoblastoma, hepatoblastoma and sarcoma. Supportive care — transfusion, antibiotics, antifungals, antiemetics, nutrition and central venous access — is not adjunctive. It is what makes the cheap curative drugs survivable, and its absence is the main reason cure rates differ threefold between settings.

**Simple means.** The drugs are cheap, off-patent and listed, and that is the single most important fact about childhood cancer worldwide: a curative course costs hundreds of dollars. What cannot be dispensed with: a histopathology service that can distinguish the tumour types, because the regimens differ completely; a laboratory that can do a blood count; a blood and platelet supply; inpatient beds for febrile neutropenia; and continuity of treatment for months to years. What is specific to children and is addressable with no technology at all is preventing treatment abandonment: accommodation for families, travel costs, food, income replacement, and someone who follows up a child who misses an appointment. In several documented programmes these measures alone raised cure rates substantially. **That is the highest-yield simple intervention in paediatric oncology and it is not medical.** Nutrition matters, because malnourished children tolerate chemotherapy worse and have higher treatment-related mortality, and feeding is cheap. Oral morphine for children is essential and frequently unavailable, and the palliative care figures in section G apply with particular force to children. The honest statement: the curative treatment of childhood cancer is not achievable by truly simple means, because it needs a hospital, a laboratory, a blood bank and months of continuity. It does not need expensive drugs, patented agents or advanced technology. The gap between an 80 per cent and a sub-30 per cent cure rate is made of organisation, supportive care and social support rather than of pharmacology.

**Gaps.** SEER's childhood cancer page could not be retrieved, so United States aggregate childhood cancer figures are absent. GBD 2023 childhood cancer figures were not retrieved; a GBD study of cancer in children and adolescents aged 0 to 19 exists and could not be retrieved in primary form. WHO's 400,000 annual cases and the over-80 against under-30 per cent survival figures are stated without a confidence interval or a data year on the retrieved fact sheet. The cause of most childhood cancer is unknown, which is WHO's own statement. Late-effect prevalence in survivors and the 70 per cent mortality decline from 1970 to 2020 are literature-derived. Treatment abandonment rates are reported in the paediatric oncology literature and no single global figure was retrieved.

## 30. Neuroblastoma

**What it is.** A cancer of the developing sympathetic nervous system, arising in the adrenal gland or alongside the spine, almost entirely in young children. It is the commonest cancer of infancy. It is also the most biologically bizarre cancer in this chapter: some neuroblastomas disappear on their own without any treatment, and others are among the most lethal cancers in children, and the difference is largely determined by the tumour's genetics at the outset.

**Measured.** It is the commonest extracranial solid tumour of childhood and the commonest cancer of infancy, at roughly 6 to 10 per cent of all childhood cancer, with a median age at diagnosis of roughly 17 to 18 months and 90 per cent of cases under age 5†. Five-year survival is bimodal and the aggregate figure is uninformative: low-risk disease above 95 per cent, intermediate-risk roughly 90 to 95 per cent, high-risk roughly 50 per cent with maximal modern multimodality therapy, and MYCN-amplified metastatic disease in older children at the lower end of that. High-risk disease accounts for roughly half of all cases and the great majority of deaths, and neuroblastoma causes roughly 10 to 15 per cent of all childhood cancer deaths, disproportionate to its incidence. All figures in this entry are literature-derived: SEER publishes a neuroblastoma page which was not retrieved, and GLOBOCAN does not report neuroblastoma.

**Where it starts.** Essentially nothing environmental is established: no exposure, maternal factor, diet or infection has been established as a cause. Germline predisposition accounts for roughly 1 to 2 per cent: germline ALK and PHOX2B mutations cause familial neuroblastoma, and it also occurs in Hirschsprung disease, congenital central hypoventilation syndrome and Beckwith-Wiedemann syndrome. Germline ALK is the main one and it is actionable. The mutation burden is very low, consistent with the paediatric rate of 0.13 mutations per megabase against the adult 1.8: neuroblastoma is among the most quietly mutated cancers known. The dominant driver is MYCN amplification, present in roughly 20 to 25 per cent of cases and the single strongest adverse prognostic marker in paediatric oncology. Other

recurrent events are ALK mutation or amplification in roughly 8 to 10 per cent, ATRX loss, TERT rearrangement and segmental chromosomal aberrations — loss of 1p and 11q, gain of 17q — while whole-chromosome gains without segmental changes mark the favourable, often spontaneously regressing tumours. Not known: **why some neuroblastomas regress spontaneously and completely, and others kill.** The spontaneous regression of stage 4S disease — widespread disease in infants involving liver, skin and marrow that disappears without treatment — is one of the most striking phenomena in oncology and it is not explained. Also unknown: what causes the initiating event, which occurs in utero; why MYCN amplification is so catastrophic; why high-risk disease relapses after apparently complete response.

**Cure status.** Stage 4S or MS disease in infants, and localized disease in infants without MYCN amplification: SELF-LIMITING — a substantial proportion regress completely without any treatment, and observation alone is the recommended management for selected infants. This is one of the very few genuine uses of SELF-LIMITING in this chapter. Low-risk disease: CURABLE above 95 per cent, frequently with surgery alone or observation†. Intermediate-risk disease: CURABLE at roughly 90 to 95 per cent, with moderate chemotherapy and surgery†. High-risk disease — metastatic in children over 18 months, or any MYCN-amplified disease: CURABLE in roughly 50 per cent (five-year survival), and only with the most intensive multimodality therapy in all of paediatric oncology: induction chemotherapy, surgery, high-dose chemotherapy with autologous stem cell rescue, radiotherapy, anti-GD2 immunotherapy and isotretinoin maintenance†. Relapsed high-risk neuroblastoma: RELIEF ONLY, among the worst outcomes in paediatric oncology. The early-detection question is inverted here: catching it earlier made outcomes worse rather than better. Risk is determined by biology at the outset, and screening found the tumours that were going to regress.

**Prevention.** No prevention exists. Screening was attempted, failed and was abandoned, and this is the single most instructive negative result in the cancer screening literature, so it belongs here in full. Urinary catecholamine metabolite screening of infants, measuring vanillylmandelic and homovanillic acid, was introduced as a national programme in Japan from 1984 and trialled in Germany, Quebec and elsewhere. **It worked as a test**: it detected large numbers of neuroblastomas, and incidence in the screened age group roughly doubled. **It did not reduce neuroblastoma mortality.** The Quebec and German studies both showed no mortality reduction, and the German study screened roughly 1.5 million children†. The explanation: screening detected the favourable, hyperdiploid, non-MYCN-amplified tumours that would have regressed spontaneously or never presented, while the high-risk MYCN-amplified tumours that cause the deaths developed and presented between screening rounds. The harm was concrete: infants with tumours that would have regressed were given surgery and chemotherapy, and treatment-related deaths occurred in children who had been destined to be well. Japan suspended its national programme in 2004†. **The overdiagnosis fraction approached the entirety of the additional detected disease, and it has never been published as a percentage.** These figures are literature-derived, and the conclusion is not in dispute and the programme was discontinued on this evidence. The general lesson applies directly to the thyroid, prostate, myeloma and chronic lymphocytic leukaemia entries in this chapter: a sensitive test applied to a population with a large reservoir of indolent or self-regressing disease produces diagnoses, treatment and harm without reducing mortality. The grade is recommend against, on demonstrated harm.

**Treatment.** Relapsed high-risk neuroblastoma is not curable in most patients, and the proportion rescued is not given. Observation for stage 4S and low-risk infant disease is the correct treatment and it costs nothing. Surgery is curative for localized low-risk disease. Multi-agent chemotherapy uses cyclophosphamide, doxorubicin, vincristine, cisplatin, carboplatin, etoposide and ifosfamide, all listed and all off-patent, at a total course cost in the low hundreds to low thousands of dollars. High-dose chemotherapy with autologous stem cell rescue uses melphalan, listed and off-patent, and the cost is in the stem cell infrastructure. Radiotherapy treats the primary site in high-risk disease. **Dinutuximab, the anti-GD2 monoclonal antibody, is not on the Essential Medicines List and is on patent**. Adding it with granulocyte-macrophage colony-stimulating factor and interleukin-2 to isotretinoin maintenance improved two-year event-free survival from roughly 46 to 66 per cent in the pivotal trial†, one of the largest single advances in high-risk neuroblastoma, at a United States course cost in the region of US$100,000 to 300,000†. It is severely painful to administer, requiring an opioid infusion. Isotretinoin maintenance reduces relapse after high-dose

therapy; it is not in the antineoplastic section of the list, where tretinoin is listed for acute promyelocytic leukaemia, and isotretinoin is off-patent and inexpensive. Crizotinib, lorlatinib and ceritinib for ALK-mutated disease are not listed and are on patent, and lorlatinib has produced responses in ALK-driven relapsed neuroblastoma and is the clearest targeted success in this disease. Iodine-131 MIBG therapy exploits the catecholamine uptake pathway and requires a nuclear medicine facility with radiation containment. GD2-directed cell therapy and bispecific approaches are experimental.

**Simple means.** Observation for stage 4S and low-risk infant disease is doing nothing, correctly, for a disease that regresses by itself. Surgical excision of a localized abdominal or paraspinal mass with basic instruments is curative for low-risk localized disease, which is a substantial fraction of all cases. Diagnosis is cheap: urinary catecholamine metabolite measurement is an inexpensive test, abdominal ultrasound detects the mass, and the diagnosis is usually straightforward in a child with an abdominal mass, bone pain and periorbital bruising. Histopathology with MYCN status determines treatment, and MYCN testing is the one genuinely necessary molecular test: without it risk cannot be assigned and treatment cannot be rationally chosen. Off-patent listed chemotherapy cures 90 to 95 per cent of intermediate-risk disease†. Oral morphine matters, because neuroblastoma bone pain is severe and dinutuximab-related pain is extreme. High-risk neuroblastoma has no simple-means answer and it accounts for half the cases and almost all the deaths: the curative package requires stem cell rescue, radiotherapy, MIBG therapy, and an antibody costing over US$100,000 a course in the United States, that is not listed. In a setting with off-patent chemotherapy and surgery alone, low- and intermediate-risk neuroblastoma — roughly half of cases — is curable, and high-risk neuroblastoma is not. That is the honest division.

**Gaps.** All figures in this entry are literature-derived: SEER's neuroblastoma page was not retrieved and GLOBOCAN does not report neuroblastoma. Why some neuroblastomas regress spontaneously is unexplained, and it is the central scientific question. Dinutuximab is not listed despite being the main recent advance in high-risk disease. The screening trial figures are literature-derived. No prevention exists and no aetiology is known. Relapsed high-risk neuroblastoma has no effective treatment.

## 31. Wilms tumour

**What it is.** A cancer of the developing kidney, occurring almost entirely in young children. It presents as a large painless abdominal mass. It is among the most curable cancers in this chapter, cured in roughly 90 per cent of children in high-income countries, and it was the first solid tumour of childhood for which multi-agent chemotherapy was shown to work, which makes it the founding success of cooperative-group paediatric oncology.

**Measured.** It is the commonest renal tumour of childhood and roughly 5 to 6 per cent of all childhood cancer, with a median age at diagnosis of roughly three to four years and roughly 10 per cent bilateral†. Five-year survival is roughly 90 per cent overall in high-income countries, above 95 per cent for favourable-histology localized disease, roughly 75 to 85 per cent for stage IV favourable histology, and roughly 50 to 60 per cent for anaplastic histology†. Survival in low-income settings is markedly lower, reported in the region of 25 to 50 per cent in several African series†, for the reasons set out in entry 29 — late presentation, abandonment, absent supportive care — rather than because of tumour biology. All figures are literature-derived: SEER publishes a Wilms tumour page which was not retrieved, and GLOBOCAN does not report Wilms tumour. Survival rose from under 30 per cent in the 1950s to roughly 90 per cent now, achieved entirely with off-patent drugs and surgery through successive cooperative-group trials.

**Where it starts.** Nothing environmental is established. Germline predisposition accounts for roughly 10 to 15 per cent, higher than in most childhood cancers†. WAGR syndrome, from WT1 deletion, with Wilms tumour, aniridia, genitourinary anomalies and intellectual disability, carries a Wilms tumour risk of roughly 45 to 60 per cent†; Denys-Drash and Frasier syndromes, from WT1 point mutations, carry a very high risk; Beckwith-Wiedemann syndrome, from an imprinting defect at 11p15, carries roughly 5 to 10 per cent†; hemihypertrophy and isolated overgrowth raise risk; and germline TRIM28, REST, DIS3L2, DICER1 and Li-Fraumeni follow, with familial Wilms tumour rare. Nephrogenic rests — persistent embryonal kidney tissue — are the precursor lesion, present in roughly 40 per cent of unilateral and nearly all bilateral cases†. The mutation burden is very low, consistent with the paediatric

rate of 0.13 mutations per megabase against the adult 1.8. The disease is driven by developmental and epigenetic lesions rather than by point mutations from exposure: WT1 mutation, loss of imprinting at 11p15 affecting IGF2, CTNNB1 and AMER1 mutation, and mutations in the microRNA-processing genes DROSHA, DGCR8 and DICER1†. It is a disease of failed differentiation rather than of accumulated damage. Not known: the cause of the sporadic majority; why nephrogenic rests persist and why only a minority transform; the trigger for the imprinting defect.

**Cure status.** Localized favourable histology, stages I to III: CURABLE above 90 to 95 per cent, with nephrectomy and chemotherapy, plus radiotherapy for stage III. Stage IV favourable histology, usually lung metastases: CURABLE in roughly 75 to 85 per cent†. Pulmonary metastases frequently resolve completely with chemotherapy and whole-lung irradiation, and cure with widespread metastases is routine. Bilateral disease, stage V: CURABLE with nephron-sparing surgery after chemotherapy, with cure and preserved renal function the goal. Anaplastic, unfavourable histology: CURABLE in roughly 50 to 60 per cent, worse with diffuse anaplasia and advanced stage†. Relapsed favourable-histology disease: CURABLE in roughly 50 per cent with salvage therapy†, unusually good for a relapsed childhood solid tumour. It is reliably curable when caught early and also when caught late: metastatic Wilms tumour is cured in the large majority, which makes it, after testicular cancer and Hodgkin lymphoma, the clearest example in this chapter of a metastatic solid tumour cured by off-patent chemotherapy. The dominant problem in high-income settings is the late cost of cure: renal insufficiency after nephrectomy, especially bilateral; cardiac toxicity from doxorubicin; second malignancy after radiotherapy; and in girls, uterine damage from abdominal irradiation affecting later pregnancy. Successive trials have accordingly reduced treatment for the lowest-risk groups, and some now receive no chemotherapy at all after nephrectomy.

**Prevention.** No prevention exists. Surveillance in predisposition syndromes — MODERATE: three- to four-monthly renal ultrasound until age five to seven is recommended in children with Beckwith-Wiedemann syndrome, WAGR syndrome, Denys-Drash syndrome, hemihypertrophy and other high-risk syndromes, and it detects tumours at a smaller size and lower stage. The evidence is cohort-based rather than randomised, and because the cure rate is already above 90 per cent with standard presentation the incremental benefit is in reducing treatment intensity rather than in preventing death. Ultrasound is cheap, portable and harmless, which makes the balance favourable. There is no population screening and no rationale: the incidence is far too low and the cure rate at presentation is already around 90 per cent, so screening has almost nothing to add. Overdiagnosis is not an issue, because Wilms tumour does not regress spontaneously and nephrogenic rests, while common, are not detectable by imaging at a useful scale.

**Treatment.** The proportion of bilateral disease cured with nephron-sparing surgery after chemotherapy is not given. Most are cured. Nephrectomy is the central curative treatment. A transabdominal radical nephrectomy in a child is a conventional operation requiring basic instruments, anaesthesia and blood availability, and avoiding tumour rupture during surgery matters a great deal, because rupture upstages the tumour and mandates whole-abdomen radiotherapy. Two standards coexist and both are correct. North American practice performs nephrectomy first and then chemotherapy based on stage and histology; European practice gives preoperative chemotherapy and then nephrectomy. Both achieve roughly 90 per cent survival, the European approach downstaging tumours and reducing rupture and the North American approach preserving accurate initial staging. In settings where surgical expertise is limited the preoperative-chemotherapy approach has practical advantages, because it shrinks the tumour first. **Vincristine and dactinomycin are both listed and both off-patent, and dactinomycin's listed indications include nephroblastoma**. That two-drug regimen cures the large majority of localized favourable-histology disease, given over weeks to months, intravenously, at a total drug cost in the region of tens to low hundreds of dollars. Doxorubicin, listed, off-patent and cheap, is added for higher stages. Cyclophosphamide, etoposide, carboplatin and ifosfamide, all listed and all off-patent, serve anaplastic histology and relapse. Radiotherapy to the flank or whole abdomen for stage III, and to the whole lung for pulmonary metastases, requires a linear accelerator and is being minimised because of late effects. Nephron-sparing surgery serves bilateral disease after chemotherapy. Supportive care covers transfusion, antibiotics, antiemetics and nutrition. **There is no expensive targeted agent and no immunotherapy in standard Wilms tumour treatment. The**

**entire curative armamentarium is off-patent and listed.** That is unusual and it should be said plainly.

**Simple means.** Wilms tumour has one of the strongest simple-means profiles of any cancer in this chapter. Radical nephrectomy in a child is a standard general or paediatric surgical operation requiring basic instruments, anaesthesia and blood, and combined with vincristine and dactinomycin it cures over 90 per cent of localized favourable-histology disease†. Vincristine with dactinomycin is two off-patent listed drugs at a total cost of tens to low hundreds of dollars, curing the majority, and they are intravenous and given as short injections rather than prolonged infusions, which makes delivery in an outpatient clinic feasible. Preoperative chemotherapy to shrink a very large tumour before operating is particularly well suited to settings where tumours present late and large and where surgical expertise is limited, because it reduces the risk of intraoperative rupture. Diagnosis is possible by abdominal examination and ultrasound: a large smooth painless abdominal mass in a well-looking toddler that does not cross the midline is clinically distinctive, and ultrasound is cheap, portable, needs no contrast and no radiation and distinguishes a renal from an adrenal or hepatic mass, which is the key distinction from neuroblastoma. A chest radiograph detects lung metastases. This is one of very few cancers in this chapter diagnosable to a treatable standard with a hand and an ultrasound probe. Renal ultrasound surveillance in syndrome-predisposed children is cheap, portable and harmless. Oral morphine, nutrition and transfusion follow. Where nothing simple exists: radiotherapy for stage III disease and for pulmonary metastases, and nephron-sparing surgery for bilateral disease, both requiring resources that are not simple; anaplastic histology requires intensified chemotherapy and worse outcomes follow without it; and the whole package requires reliable histopathology, because anaplastic histology changes the treatment entirely and because distinguishing Wilms tumour from neuroblastoma, clear cell sarcoma of the kidney and rhabdoid tumour determines which regimen is used. The central fact is strong: **Wilms tumour is cured in roughly 90 per cent of children by an operation a district surgeon can perform and two drugs that cost tens of dollars.** Where that does not happen, and survival in parts of Africa is reported at 25 to 50 per cent, the cause is late presentation, treatment abandonment and absent supportive care, not the price or availability of the medicines.

**Gaps.** All figures are literature-derived: SEER's Wilms tumour page was not retrieved and GLOBOCAN does not report it. The low-income-setting survival figures are literature-derived and the range is wide and poorly characterised. The syndrome-specific risks are literature-derived. There is no randomised evidence for syndrome surveillance. The cause of sporadic Wilms tumour is unknown. The North American and European approaches differ — nephrectomy first against chemotherapy first — and both are standard, which is a genuine and long-standing disagreement between two major cooperative groups with equivalent outcomes. Late effects on renal function and on later pregnancy after abdominal irradiation are literature-derived.

## 32. Medulloblastoma

**What it is.** A malignant tumour of the cerebellum, at the back of the brain, and the commonest malignant brain tumour of childhood. It blocks the flow of cerebrospinal fluid, so children present with headache, vomiting and unsteadiness. It seeds along the spinal cord, which is why treatment has to cover the whole brain and spine, and that is the source of almost all of the lasting damage it causes.

**Measured.** It is roughly 20 per cent of all childhood brain tumours and the commonest malignant paediatric central nervous system tumour, at roughly one to two cases per million children a year. The peak age is five to nine years, roughly 70 per cent occur under age 10, and the male predominance is roughly 1.5 to 2 to 1†. Five-year survival depends almost entirely on molecular subgroup, and the 2021 WHO classification reorganised the disease around four of them. WNT-activated disease, roughly 10 per cent of cases and in older children, has five-year survival above 90 to 95 per cent and is the subgroup in which de-escalation trials are active. SHH-activated TP53-wildtype disease, roughly 15 per cent, in infants and adults, runs at roughly 70 to 80 per cent. SHH-activated TP53-mutant disease, roughly 5 per cent, in children 4 to 17 and frequently with germline TP53 mutation, runs at roughly 40 per cent. Group 3, roughly 25 per cent, in infants and young children, frequently MYC-amplified and metastatic at diagnosis, runs at roughly 40 to 50 per cent and is the worst subgroup.

Group 4, roughly 35 per cent and the commonest, runs at roughly 75 to 80 per cent†. Overall five-year survival in high-income countries is roughly 70 to 75 per cent for standard-risk and roughly 50 to 60 per cent for high-risk disease, with infants under three doing worst, partly because craniospinal irradiation is avoided in them. All figures are literature-derived: SEER folds medulloblastoma into brain and other nervous system, at 32.9 per cent overall five-year survival, which does not describe medulloblastoma, and GLOBOCAN does not report it separately.

**Where it starts.** Nothing environmental is established. Germline predisposition accounts for roughly 5 to 6 per cent, and identifying it changes management†. Li-Fraumeni syndrome, from germline TP53 mutation, gives SHH/TP53-mutant disease, and critically, radiotherapy in a germline TP53 carrier carries a very high risk of radiation-induced second malignancy, so the diagnosis should change the treatment plan. Gorlin syndrome, from PTCH1 or SUFU mutation, gives SHH disease usually in infants, and again radiotherapy causes a very high rate of basal cell carcinomas in the irradiated field in these children and should be avoided. Familial adenomatous polyposis gives WNT disease. Germline BRCA2, PALB2, ELP1 — recently identified and relatively common in SHH disease — and Fanconi anaemia follow. The mutation burden is low, consistent with the paediatric rate of 0.13 mutations per megabase against the adult 1.8, and the disease is driven by pathway activation and structural events: CTNNB1 mutation in WNT disease, PTCH1, SMO or SUFU mutation or GLI2 amplification in SHH disease, MYC amplification with GFI1 or GFI1B enhancer hijacking in Group 3, and KDM6A, SNCAIP and PRDM6 alterations with isochromosome 17q in Group 4†. Medulloblastoma is one of the clearest demonstrations that childhood cancers are diseases of developmental pathway dysregulation rather than of mutational accumulation. Not known: the cause of the sporadic majority; the cell of origin for Groups 3 and 4, where WNT disease arising from the lower rhombic lip and SHH disease from granule neuron precursors are both established and Groups 3 and 4 are not settled; why the subgroups differ so much in age distribution and metastatic propensity.

**Cure status.** WNT-activated, standard risk: CURABLE above 90 to 95 per cent†. De-escalation trials — reduced craniospinal radiotherapy dose, reduced chemotherapy — are active precisely because these children are cured and are being harmed by the cure. Group 4 and SHH/TP53-wildtype, standard risk: CURABLE in roughly 75 to 80 per cent†. Group 3, MYC-amplified, and metastatic disease: CURABLE in roughly 40 to 50 per cent†. SHH/TP53-mutant: CURABLE in roughly 40 per cent†. Infants under three: CURABLE in roughly 40 to 60 per cent, using intensive chemotherapy with or without high-dose therapy and stem cell rescue, specifically to avoid craniospinal irradiation in a developing brain. Relapsed medulloblastoma: RELIEF ONLY — relapse after craniospinal irradiation is almost always fatal, among the worst outcomes in paediatric oncology. Early detection partly applies, and the dominant determinant is subgroup rather than timing. There is no screening and no pre-symptomatic phase that could be found. What does matter is recognising raised intracranial pressure before the child is in extremis: early-morning headache and vomiting in a child, with ataxia or a head tilt, is medulloblastoma or another posterior fossa tumour until proven otherwise, and delay leads to presentation with coning, blindness from papilloedema, or death from acute hydrocephalus. The cost of cure is the central problem, and in medulloblastoma it is more severe than in any other curable childhood cancer. Craniospinal irradiation in a developing child causes permanent loss of intelligence: reported losses run at roughly two to four points of measured intelligence quotient per year of follow-up, with greater loss at younger ages at treatment. It also causes growth hormone deficiency and short stature, hypothyroidism and other pituitary failure, hearing loss compounded by cisplatin, spinal growth arrest, stroke, and second malignancies in the irradiated field including meningioma, glioma and thyroid cancer. A child cured of medulloblastoma at age four frequently has lifelong cognitive and endocrine disability. **The whole modern research programme in medulloblastoma is about giving less radiation to the children who can be cured without it, and this is the clearest case in the chapter where the harm of successful treatment drives the research agenda.**

**Prevention.** No prevention exists. There is no screening and no rationale: the incidence is roughly one to two per million children, no test exists and no pre-symptomatic phase is detectable. Surveillance in predisposition syndromes — MODERATE: brain imaging surveillance is part of Li-Fraumeni and Gorlin syndrome protocols. The real prevention activity is prevention of treatment-induced harm, and it is substantial. Avoiding or reducing cran-

iospinal irradiation — STRONG on the harm-reduction endpoint: infants are treated with chemotherapy-only or chemotherapy-plus-focal-radiotherapy strategies specifically to protect the developing brain, and risk-adapted reduction of craniospinal dose in WNT-subgroup and standard-risk disease is the subject of active trials. Avoiding radiotherapy entirely in germline TP53 and Gorlin syndrome carriers — STRONG, because radiation-induced second cancers in these children are frequent and often fatal. Proton beam therapy instead of photons — MODERATE: it reduces dose to the cochlea, pituitary, thyroid, heart and vertebral growth plates, which should reduce late effects, and the long-term comparative evidence is still accruing and it is available to a very small fraction of children worldwide.

**Treatment.** Relapse after craniospinal irradiation is not curable in most patients, and the proportion rescued is not given. Maximal safe surgical resection affects outcome, and relief of hydrocephalus is frequently the immediate life-saving act; it requires neurosurgical capability and imaging. Cerebrospinal fluid diversion — an external ventricular drain, a ventriculoperitoneal shunt or an endoscopic third ventriculostomy — is the emergency intervention: a child with acute obstructive hydrocephalus from a posterior fossa tumour will die or be blinded without it, and a shunt or a drain buys the time to do everything else. Craniospinal irradiation with a boost to the posterior fossa is essential for cure in children over three, because the disease seeds the whole neuraxis. **It is the single most effective and the single most damaging component of treatment.** It requires a linear accelerator with the capacity to plan a craniospinal field, which is technically demanding. Chemotherapy uses cisplatin, carboplatin, vincristine, cyclophosphamide, etoposide, lomustine and methotrexate; cisplatin, whose listed indications include low-grade glioma, carboplatin, vincristine, whose listed indications include low-grade glioma, cyclophosphamide, etoposide and methotrexate are all listed and all off-patent, and lomustine is not listed and has been subject to very large United States price increases, as entry 17 records. The standard regimens are built almost entirely from off-patent listed drugs at a total drug cost in the low hundreds to low thousands of dollars. High-dose chemotherapy with autologous stem cell rescue is used in infants to avoid irradiation and in some high-risk protocols. Vismodegib and sonidegib for SHH-subgroup disease are not listed and are on patent, and they are active in relapsed disease, with a specific and serious caution: hedgehog inhibitors cause irreversible premature growth plate fusion in growing children, so their use in paediatric medulloblastoma is restricted. That is an unusual and instructive toxicity — a drug that works and cannot be given to the patients who would benefit. No molecularly targeted approach is established for Group 3 or MYC-amplified disease, and that is the principal unmet need. Supportive care: dexamethasone, listed and off-patent at an indicative 24 cents a 4 mg tablet in the UNICEF Supply Catalogue, October 2026, for peritumoural oedema and raised intracranial pressure; anticonvulsants; antiemetics, cisplatin being among the most emetogenic drugs in use; audiological monitoring; growth hormone and thyroxine replacement, with levothyroxine listed for hypothyroidism, off-patent and a few dollars a year; and long-term neuropsychological and endocrine follow-up.

**Simple means.** Cerebrospinal fluid diversion is the highest-value simple intervention in this entry. A ventriculoperitoneal shunt or a burr-hole external ventricular drain can be placed with basic neurosurgical instruments and it is immediately life-saving in obstructive hydrocephalus, and where a shunt is all that can be offered it still prevents death by coning and preserves vision. Dexamethasone is listed, off-patent, cents a dose, oral or injectable, and reduces peritumoural oedema and raised intracranial pressure within hours, relieving headache and vomiting and restoring consciousness; as in entry 17 it is the most valuable single drug available simply. Off-patent listed chemotherapy — cisplatin, vincristine, cyclophosphamide, etoposide and carboplatin — costs in the low hundreds of dollars. Levothyroxine is listed, off-patent and a few dollars a year, and treating the hypothyroidism that follows craniospinal irradiation is cheap and transformative; growth hormone is expensive and not listed. Recognising the clinical picture costs nothing: early-morning headache with vomiting, ataxia, a head tilt or a squint in a child, with or without papilloedema on fundoscopy, is a posterior fossa tumour until excluded, and fundoscopy needs an ophthalmoscope. The diagnosis is frequently missed for months, with the child treated for migraine or gastroenteritis. Oral morphine, antiemetics, nursing care and family support follow. The honest statement is stark: **medulloblastoma cannot be cured without a linear accelerator capable of craniospinal irradiation, and it cannot be diagnosed without computed tomography or magnetic resonance imaging.** Neither has a simple-means substitute. A district hospital

can relieve the hydrocephalus and keep a child comfortable; it cannot cure medulloblastoma. And the irradiation that cures also permanently damages the child's brain, hearing, growth and endocrine function, so medulloblastoma is simultaneously the childhood cancer most dependent on advanced technology for cure and the one in which the cure does the most harm. There is no version of this that is simple.

**Gaps.** All figures are literature-derived: SEER folds medulloblastoma into brain and other nervous system and GLOBOCAN does not report it. Subgroup frequencies and subgroup-specific survival are literature-derived. The intelligence loss figures after craniospinal irradiation are literature-derived despite being central to treatment decisions. The 2021 classification reorganised the disease into molecular subgroups, which makes survival figures published before and after it non-comparable, and most quoted figures mix the two. Group 3 and MYC-amplified disease has no effective targeted therapy and is the principal unmet need. Relapsed medulloblastoma after craniospinal irradiation is almost uniformly fatal and there is no established salvage therapy. Hedgehog inhibitors work in SHH disease and cannot be given to growing children, an unresolved practical problem. The cause of sporadic medulloblastoma is unknown. Proton therapy's comparative late-effect benefit is not yet established with long-term data, and it is available to very few children.

## 33. Retinoblastoma

**What it is.** A cancer of the developing retina, occurring almost entirely in children under five. It is the commonest eye cancer of childhood. It is caused by loss of both copies of a single gene, RB1 — the first tumour suppressor gene ever identified, and the disease from which the two-hit model of cancer genetics was derived. In high-income countries almost every child survives; in low-income countries a large proportion die, and the difference is almost entirely one of how late the child presents.

**Measured.** Roughly 8,000 children worldwide develop retinoblastoma each year, at roughly one in 15,000 to 20,000 live births, which is roughly 2 to 4 per cent of all childhood cancer†. The median age at diagnosis is roughly 18 months for bilateral hereditary disease and roughly 24 to 30 months for unilateral disease†. Roughly 40 per cent is hereditary, from a germline RB1 mutation, and usually bilateral or multifocal; roughly 60 per cent is sporadic and unilateral†. **Survival shows the largest divergence of any cancer in this chapter.** In high-income countries five-year survival is above 95 to 98 per cent and death from retinoblastoma is now rare. In low-income countries, particularly in sub-Saharan Africa and parts of Asia, five-year survival is reported in the region of 30 to 50 per cent, and in some series below 30 per cent†. The reason is stage at presentation: in high-income countries children present with a white pupil or a squint while the tumour is intraocular and curable, and in low-income countries a large proportion present with proptosis, the eye pushed forward by extraocular tumour, by which time the disease is frequently metastatic and usually fatal. A global multicentre study of presentation found the proportion presenting with extraocular disease ranging from near zero in high-income countries to a majority in low-income countries. All figures are literature-derived: GLOBOCAN does not report retinoblastoma and SEER publishes a page which was not retrieved.

**Where it starts.** RB1, and the attribution is essentially complete. Biallelic inactivation of RB1 is present in the great majority of retinoblastomas, germline in roughly 40 per cent and somatic in the remainder, and a small minority, roughly 2 per cent, are MYCN-amplified with intact RB1, which are unilateral, present very young and are histologically distinctive. Germline RB1 mutation carriers have a penetrance above 90 per cent for retinoblastoma; roughly 25 per cent of germline cases are inherited from an affected parent and roughly 75 per cent are new germline mutations†. Carriers are at risk of bilateral and multifocal disease and of a second primary tumour outside the eye, and they have a roughly 5 per cent risk of trilateral disease, an intracranial midline tumour, usually pineoblastoma, which is frequently fatal. **Second malignancies in germline carriers are the single most important long-term fact**: survivors of hereditary retinoblastoma carry a markedly increased lifetime risk of second cancers, principally osteosarcoma, soft tissue sarcoma and melanoma, at a cumulative incidence reported in the region of 25 to 40 per cent by age 50†. External beam radiotherapy to the orbit amplifies that risk substantially, with reported relative risks for radiation-associated sarcoma in the irradiated field several-fold above the already elevated baseline. That is why external beam radiotherapy has been largely abandoned

in retinoblastoma. The mutation burden is very low, and retinoblastoma is, with chronic myeloid leukaemia, among the closest things in oncology to a single-gene cancer: loss of RB1 plus few additional events on a quiet genome, consistent with the paediatric rate of 0.13 mutations per megabase against the adult 1.8. Recurrent secondary events include MYCN and MDM4 gain, BCOR mutation and loss of 16q, and the disease requires remarkably little beyond RB1 loss†. Nothing environmental is established: no maternal, dietary or exposure risk factor is established, and advanced paternal age has been associated with new germline mutations. Not known: why RB1 loss produces a retinal tumour specifically and in a narrow developmental window, when the gene is expressed throughout the body; why the disease does not occur after about age five, even in germline carriers whose cells continue to lack one copy; the cell of origin, where cone precursors are the leading candidate and it is not settled.

**Cure status.** Intraocular retinoblastoma: CURABLE above 95 to 98 per cent survival in high-income countries†. Cure of the child is close to universal, and the clinical question is whether the eye and the vision can also be saved. Small tumours are cured by focal therapy — laser photocoagulation, cryotherapy or plaque brachytherapy — with vision preserved; larger tumours require systemic or intra-arterial chemotherapy to shrink them first; and advanced intraocular disease requires enucleation, removal of the eye, which cures the child and loses the eye. Extraocular retinoblastoma with orbital extension: CURABLE in roughly 30 to 50 per cent, with intensive chemotherapy, surgery, radiotherapy and sometimes high-dose therapy with stem cell rescue. Metastatic retinoblastoma without central nervous system involvement: CONTROLLABLE. High-dose chemotherapy with stem cell rescue cures some. Central nervous system metastatic disease and trilateral retinoblastoma: RELIEF ONLY — almost uniformly fatal. It is reliably curable when caught early, more completely than almost any cancer in this chapter, and the converse is equally stark. **Retinoblastoma is the clearest case in this chapter where the entire difference between a 98 per cent and a sub-30 per cent survival rate is the delay between the first visible sign and the first medical assessment.** The tumour biology does not differ between Boston and Bamako. The presentation does. The dominant long-term problem in germline carriers is the second cancer risk, at a cumulative incidence of roughly 25 to 40 per cent by age 50 and amplified by radiotherapy†: a child cured at 18 months has a substantial chance of developing osteosarcoma or melanoma as a young adult, and lifelong surveillance is required.

**Prevention.** Genetic counselling and prenatal or preimplantation genetic testing in families with a germline RB1 mutation — STRONG, and retinoblastoma is one of the few cancers where this is routine practice. In a family with a known mutation, affected pregnancies can be identified, and newborns at risk can be examined under anaesthesia from birth on a defined schedule, so that tumours are found at a size treatable by focal therapy with vision preserved. That changes the outcome from enucleation to vision-sparing cure. Avoiding external beam radiotherapy in germline carriers — STRONG: the radiation-amplified second cancer risk is large enough that external beam radiotherapy has been largely abandoned, one of the clearest and most justified treatment de-escalations in oncology. No primary prevention of sporadic retinoblastoma exists. On screening this is the important case, because retinoblastoma is the one childhood cancer where a form of screening works. There is no population screening programme and no justification for one in a general population of this incidence. Targeted surveillance of at-risk newborns — children of germline carriers, siblings of affected children — by serial examination under anaesthesia is standard, effective and preserves vision, and that is surveillance of known high risk rather than population screening. And awareness-raising about leukocoria, a white pupil instead of a red reflex, is the single most effective intervention in this disease worldwide, and it is not a medical technology at all. A white reflex can be seen in a photograph taken with a flash. Public awareness campaigns, routine red reflex examination of every newborn and infant by any health worker with an ophthalmoscope or even a torch, and parental education have all been associated with earlier presentation. The red reflex test is part of routine newborn examination in many countries and costs nothing beyond an ophthalmoscope: where it is done, children present intraocular, and where it is not, they present with proptosis. The harms: a positive red reflex test is far more often a cataract, a retinal detachment, Coats disease or a benign finding than a retinoblastoma, so referrals are mostly false alarms. Given the consequence of a missed retinoblastoma, that is a strongly favourable trade. **No overdiagnosis problem exists: retinoblastoma does not regress and is not indolent.** The grades are STRONG for red

reflex examination and leukocoria awareness, STRONG for genetic counselling and at-risk newborn surveillance, and population screening is not applicable.

**Treatment.** High-dose chemotherapy with stem cell rescue cures some metastatic retinoblastoma without central nervous system involvement, and the proportion is not given. Enucleation cures intraocular retinoblastoma. It is a short operation requiring basic instruments and anaesthesia, and the specimen provides the histology that determines whether adjuvant chemotherapy is needed. It is the correct treatment for advanced intraocular disease and it is definitively curative, and in settings without access to chemotherapy or focal therapy, prompt enucleation is the intervention that saves the child's life. Performing it early, before extraocular extension, is what distinguishes a 98 per cent from a sub-30 per cent survival rate. Focal therapy — laser photocoagulation, cryotherapy, episcleral plaque brachytherapy — serves small tumours and preserves the eye and vision, and requires an ophthalmologist with specific equipment. Systemic chemoreduction uses carboplatin, vincristine and etoposide, and all three are listed and all off-patent, with vincristine's listed indications including retinoblastoma, at a total drug cost in the region of tens to low hundreds of dollars a course. Chemoreduction shrinks tumours to a size treatable by focal therapy and has substantially reduced the need for enucleation and for radiotherapy, with one caution: etoposide carries a leukaemia risk, which matters particularly in germline carriers who are already cancer-prone. Intra-arterial chemotherapy — ophthalmic artery infusion of melphalan, topotecan or carboplatin — delivers high local drug concentration with minimal systemic exposure and has further improved eye salvage, and it requires interventional neuroradiology to pass a microcatheter into the ophthalmic artery of an infant and is available in a small number of centres. Intravitreal chemotherapy for vitreous seeding uses melphalan, listed and off-patent, or topotecan, in a technically simple injection with a specific safe-injection technique to avoid tumour spread along the needle track. Adjuvant chemotherapy after enucleation for high-risk histological features — optic nerve or choroidal invasion — uses off-patent listed drugs. External beam radiotherapy is effective and largely abandoned because of the second cancer risk in germline carriers, and is still used in some extraocular and salvage settings. High-dose chemotherapy with autologous stem cell rescue serves metastatic disease without central nervous system involvement. An ocular prosthesis after enucleation is a cosmetic shell, cheap and important: the social consequences of an empty socket in a child are substantial, and a prosthesis is a simple manufactured item. Lifelong second-cancer surveillance in germline carriers requires clinical examination, awareness of bone pain, skin surveillance for melanoma, and avoiding further radiation exposure throughout life.

**Simple means.** Retinoblastoma has, alongside keratinocyte skin cancer, the most favourable simple-means profile in this chapter, and the widest gap between what is possible and what is delivered. **The red reflex test comes first.** An ophthalmoscope, or in a dark room a torch, held at arm's length from an infant's eyes: a normal eye reflects red and a retinoblastoma reflects white. The test takes seconds, costs nothing beyond the instrument, requires no specialist, and detects retinoblastoma at a stage where the child's life and often the eye can be saved, and it can be taught to any health worker in minutes. **Per unit of cost, that is arguably the most effective cancer early-detection intervention described anywhere in this chapter.** Leukocoria awareness among parents requires no equipment at all, only information: a white pupil in a flash photograph is a recognised presenting sign, and public awareness campaigns have brought children to attention earlier. Enucleation with basic instruments is a short operation under general anaesthesia performable in a district hospital, and it cures intraocular retinoblastoma. For a child with advanced intraocular disease and no access to chemotherapy or focal therapy, prompt enucleation is the life-saving treatment and it is wholly achievable by simple means. The barrier is frequently not surgical capability but parental refusal — understandably, since the operation removes a child's eye — and in several documented series refusal or delay of enucleation is a leading cause of death, so counselling and family support are part of the treatment and they are not technological. Carboplatin, vincristine and etoposide are three off-patent listed drugs at tens to low hundreds of dollars a course, which shrink tumours and save eyes. An ocular prosthesis is a simple manufactured shell, locally producible, with a substantial social benefit. Oral morphine serves pain in advanced disease. Where nothing simple exists: intra-arterial chemotherapy, plaque brachytherapy and laser therapy — the techniques that save the eye and the vision rather than merely the child — all require specialist ophthalmological or interventional radiology capability; metastatic and central nervous system disease

requires high-dose therapy with stem cell rescue; and trilateral retinoblastoma is essentially untreatable. **But the central and uncomfortable fact about retinoblastoma is this: the difference between a 98 per cent survival rate and a sub-30 per cent survival rate is not made of intra-arterial chemotherapy or plaque brachytherapy. It is made of a torch, a trained health worker who looks at a child's eyes, a parent who knows that a white pupil is an emergency, and a surgeon willing and able to remove an eye promptly. Every one of those is simple. Retinoblastoma is the sharpest example in this chapter of a curable cancer killing children for want of means that are already simple and already cheap.**

**Gaps.** All figures are literature-derived: GLOBOCAN does not report retinoblastoma and SEER's page was not retrieved. The 8,000 annual global cases, the high-income against low-income survival figures and the extraocular presentation proportions are literature-derived, and these are the key figures of the entry, so their absence from primary verification is a real limitation. The second cancer cumulative incidence in germline carriers and the radiation amplification of that risk are literature-derived despite determining lifelong management. No PDQ prevention summary for retinoblastoma was retrieved, so no evidence grades are attached. No randomised evidence exists for red reflex screening, which is recommended universally on the strength of the stage-shift argument and the negligible cost; the evidence is observational and ecological. Why RB1 loss produces a retinal tumour in a narrow developmental window is unexplained. Trilateral retinoblastoma has no effective treatment. Rates of enucleation refusal and its contribution to mortality are reported in regional series and no global figure was retrieved.

---

# Benign neoplasms of clinical importance

## 34. Uterine fibroids

**What it is.** Benign tumours of the smooth muscle of the womb. They are the commonest tumour of any kind in women, they are not cancer and they essentially never become cancer, and they are nonetheless one of the largest single causes of surgery and of iron-deficiency anaemia in women worldwide. They cause heavy bleeding, pain, pressure and infertility, and they shrink after the menopause.

**Measured.** The cumulative incidence of fibroids by age 50 is roughly 70 per cent in white women and above 80 per cent in black women, as measured by systematic ultrasound screening of asymptomatic women, and clinically significant symptomatic fibroids affect roughly 25 to 30 per cent of women of reproductive age†. A second source line names the Baird ultrasound-screened cohort and gives about 70 per cent in white women and about 80 to 90 per cent in black women. The two source lines disagree. The first reads "above 80 per cent" and carries a dagger. The second reads "80 to 90 per cent" and names its source, which was not opened again. Both are printed. Incidence rises through the reproductive years and peaks in the forties. The ancestry difference is one of the largest in this chapter: black women develop fibroids earlier, in greater number and larger size, have more severe symptoms, and undergo hysterectomy at roughly two to three times the rate of white women, and the difference is not explained by access, body mass index or parity. In black women the fibroids often appear in the twenties. Vitamin D deficiency, genetic ancestry, hair relaxer use and allostatic load (the accumulated wear of chronic stress) have all been proposed as explanations, and none is established. Fibroids are the leading indication for hysterectomy: in the United States roughly 200,000 to 300,000 hysterectomies a year are performed for them, and they account for roughly a third to 40 per cent of all hysterectomies†. A second source line calls fibroids the leading indication for hysterectomy worldwide, at about 30 to 40 per cent of hysterectomies in many countries†. The two source lines differ in scope, the United States against many countries, and in the lower bound, a third against 30 per cent. Both are printed. GLOBOCAN and SEER do not report benign neoplasms, so there is no figure for fibroids in the sources that supply the rest of this chapter. GBD does report uterine fibroids as a cause of disability, and GBD 2023's years-lived-with-disability table ranks gynaecological diseases tenth overall at 28.6 million, interval 19.5 to 40.0 million, with no fibroid-specific row retrieved. An earlier edition does give figures: GBD 2019 gave roughly

230 million women affected worldwide, about 0.6 to 0.8 million DALYs (disability-adjusted life years) and negligible deaths. Mortality is essentially zero directly: the mortality attributable to fibroids is surgical mortality and the consequences of severe anaemia, and in settings without safe blood transfusion or safe surgery, death from fibroid-related haemorrhage and anaemia does occur. Malignant transformation does not happen: uterine leiomyosarcoma is a distinct disease rather than a transformed fibroid. The risk that a clinically diagnosed fibroid is in fact a leiomyosarcoma is low and contested, with estimates clustering around one in 350 to one in 1,000 for women undergoing surgery for presumed fibroids and wide variation by age. That became practically important because of power morcellation.

**Where it starts.** Oestrogen and progesterone dependence is established: fibroids grow during reproductive life, enlarge in pregnancy, shrink after the menopause and do not occur before puberty. African ancestry gives roughly two- to threefold higher incidence with markedly earlier onset and greater severity. Early menarche and nulliparity raise risk, and parity is protective with risk falling with each birth, by about 20 to 30 per cent for each term pregnancy†. Obesity raises risk, at roughly 20 per cent per 10 kg of weight gain in some cohorts†. Family history gives roughly two- to threefold increased risk in first-degree relatives. Heritability is estimated at about 26 to 69 per cent depending on the study, and twin studies support a substantial genetic component. A second source line puts the risk for a first-degree relative at about 2.5 times†, which lies inside the range above. Hypertension and vitamin D deficiency are associated and causality is not established; vitamin D deficiency is more prevalent in women of African ancestry and has been proposed as a partial explanation for the ancestry difference, and that is a hypothesis rather than an established mechanism. Vitamin D is plausible because of its antifibrotic effects. Hair relaxer and phthalate exposure are CONTESTED. High red meat intake with low fruit and vegetable intake is weakly associated. Extended lactation is protective. Combined oral contraceptives and depot progestogens are associated with reduced risk on mixed evidence, and they are also used as treatment. Smoking is associated with reduced risk, presumably through anti-oestrogenic effects, and that is not a reason to smoke. Roughly 70 per cent of fibroids carry MED12 mutations; others carry HMGA2 rearrangements, frequently from a t(12;14) translocation, FH mutations, which in germline form cause hereditary leiomyomatosis and renal cell cancer where fibroids are a feature, or COL4A5 and COL4A6 deletions†. HMGA2 rearrangements are found in about 10 to 20 per cent of fibroids†. Fibroids are clonal neoplasms, each arising from a single cell, so a woman with multiple fibroids has multiple independent tumours, and the mutation burden is very low, as expected for a benign clonal lesion. Not known: the cause of the ancestry difference, which is large, consistent and unexplained; why fibroids are so common and leiomyosarcoma so rare, given a shared tissue of origin; what determines whether a fibroid stays small and silent or grows to the size of a term pregnancy. Also not known: what initiates the founding somatic mutation; why individual fibroids in the same uterus grow at different rates, and why some regress without treatment; and why some fibroids cause heavy bleeding and others do not, since submucosal location matters and does not explain everything. The link to infertility and miscarriage is established for submucosal and large intramural fibroids and uncertain for small intramural ones.

**Cure status.** Perimenopausal symptomatic fibroids: SELF-LIMITING — fibroids regress after the menopause as oestrogen falls, and a woman approaching the menopause with symptomatic fibroids can often be managed expectantly until they shrink. That is a legitimate strategy and it is the only condition in this chapter for which SELF-LIMITING applies by virtue of a predictable physiological endpoint. Symptomatic fibroids treated by hysterectomy: CURABLE, definitively and permanently — the organ and the problem are removed and fibroids cannot recur. Symptomatic fibroids treated by myomectomy: CURABLE of the fibroids removed — about 15 per cent of women have recurrence at five years and 25 to 50 per cent at ten years, because myomectomy removes the existing tumours and not the propensity to form new ones, which arise as new clonal growths rather than as regrowth of the old. Symptomatic fibroids treated by uterine artery embolisation: CONTROLLABLE — the fibroids are shrunk rather than removed and bleeding is controlled effectively, with re-intervention in about 15 to 30 per cent at five years. Symptomatic fibroids managed medically: CONTROLLABLE — bleeding and symptoms can be controlled for years with a levonorgestrel intrauterine system, tranexamic acid, hormonal contraception or GnRH-pathway drugs, without removing anything. Asymptomatic fibroids require no treatment at all, and most fibroids are asymptomatic: the large majority of the women who have fibroids by age

50 never need anything done. A necessary distinction from the malignant entries: the goal is not survival, which is not threatened, but relief of bleeding, pain, pressure and infertility, and preservation of fertility where it is wanted. The treatment decision is accordingly driven almost entirely by what the woman wants rather than by a survival calculation, and that is unlike every other entry in this chapter.

**Prevention.** There is no established effective primary prevention. Parity, combined oral contraceptives and, unusably, smoking are associated with reduced risk, and none is a prevention strategy. Weight control — WEAK. Vitamin D supplementation — CONTESTED: biologically plausible, supported by observational association and small trials showing reduced fibroid growth, with no adequate randomised evidence of a clinically important effect. A second source line grades vitamin D sufficiency as CONTESTED and WEAK. The two source lines disagree on the grade, CONTESTED here and CONTESTED and WEAK there, and both are printed. Combined oral contraceptives and depot medroxyprogesterone — WEAK: the associations with reduced incidence are weak, and the drugs are used for symptom control and not for prevention. Extended lactation is likewise protective and not prescribable as prevention. Treating iron-deficiency anaemia does not prevent fibroids. It prevents their main consequence — STRONG, and the most neglected element of care. There is no screening and no rationale for one, and that is worth stating because ultrasound finds fibroids constantly. Systematic ultrasound screening of asymptomatic women finds fibroids in the majority, and finding them confers no benefit: they are not pre-cancerous, they do not require treatment when asymptomatic, and knowing about them generates anxiety, follow-up imaging and in some cases intervention on a lesion that would never have caused a symptom. **Incidental detection of asymptomatic fibroids on pelvic ultrasound and imaging done for other reasons is extremely common and is a genuine, substantial and unquantified overdiagnosis problem. No overdiagnosis percentage has been published, and the reason is simply that the condition is so common that the concept is rarely applied to it.** The power morcellation controversy is the one place where fibroids intersect with cancer, and both sides are genuinely held. Laparoscopic hysterectomy and myomectomy for large fibroids required the tissue to be cut up to remove it through small incisions, and if the lesion was in fact an unsuspected leiomyosarcoma, morcellation disseminated it through the abdomen and worsened the prognosis substantially. The United States Food and Drug Administration issued a safety communication in 2014 and a boxed warning, estimating the risk of unsuspected uterine sarcoma in women undergoing hysterectomy or myomectomy for presumed fibroids at roughly one in 350†. Critics argued that estimate was too high, derived from referral-centre populations and from studies with ascertainment bias, and that figures in the region of one in 1,000 to one in 2,000 were more appropriate for the general population of women having fibroid surgery, particularly younger women. The consequence of the warning was a shift from laparoscopic to open abdominal surgery, which carries higher rates of wound complications, infection, venous thromboembolism and longer recovery, and several analyses argued that the net harm from more open surgery exceeded the harm prevented from fewer morcellated sarcomas. Current practice uses contained morcellation in a bag, avoids morcellation in older women and in anyone with suspicious features, and counsels explicitly about the risk. Both figures are printed because the disagreement is real: roughly one in 350 against roughly one in 1,000 to one in 2,000. The underlying problem is that there is no reliable preoperative test to distinguish a fibroid from a leiomyosarcoma, and that remains true.

**Treatment.** Expectant management for asymptomatic fibroids is correct for the majority and free. Size alone is not an indication for treatment, which corrects historical practice. Watchful waiting is also appropriate for mild symptoms approaching the menopause. **Tranexamic acid is listed, for haemorrhage not elsewhere classified and for postpartum haemorrhage**, off-patent, and costs cents a tablet. It reduces menstrual blood loss by roughly a third, is taken only during menstruation, and is one of the most cost-effective interventions in this entire chapter for a condition affecting hundreds of millions of women. A second source line gives the reduction as about 40 to 50 per cent†, against roughly a third here. The two source lines disagree on the reduction, and both are printed. That line places tranexamic acid in section 10.2 of the Essential Medicines List, core, under medicines affecting coagulation, and gives its cost as tens of US dollars a year, against cents a tablet here. The two source lines differ in how far their figures were checked, and state the price on different bases, a year against a tablet. That line calls tranexamic acid cheap, effective, under-used and safe

in this use. In gastrointestinal bleeding, by contrast, the HALT-IT trial found no mortality benefit and more thromboembolism. Mefenamic acid and ibuprofen are off-patent and cheap and reduce bleeding modestly and relieve pain. A second source line puts the reduction in blood loss at about 20 to 40 per cent†, and notes relief of painful periods (dysmenorrhoea). A levonorgestrel-releasing intrauterine system is listed as a contraceptive, and a single device insertion lasts five to eight years, reducing menstrual blood loss by roughly 80 to 90 per cent and matching hysterectomy for quality of life in many women with heavy bleeding; it is less effective when the uterine cavity is distorted by submucosal fibroids, and it costs in the region of US$10 to 20 at public-sector procurement prices, and far more in private markets. That is the single most important non-surgical treatment and it is a one-visit procedure. A second source line gives the reduction in menstrual blood loss as about 70 to 95 per cent†, against roughly 80 to 90 per cent here. The two source lines disagree, and both are printed. That line records the device as on the Essential Medicines List and gives its cost as tens of US dollars, so a few dollars a year, against US$10 to 20† here. The two source lines differ in how far their figures were checked. That line calls the device outstanding value. Combined oral contraceptives and oral or injectable progestogens are listed, off-patent and cheap and control bleeding. **Ferrous salts are listed, off-patent and cost cents**, at a UNICEF indicative price of US$1.43 on one catalogue page and US$1.60 on another per bottle of 100 tablets of iron 60 mg, October 2026, which is about 1.4 to 1.6 US cents a tablet. Fibroid-related iron deficiency anaemia is extremely common and is the main systemic consequence of fibroids, and oral iron treats it: cheap, simple and frequently neglected. Iron may also be given intravenously. The anaemia is often the actual cause of the symptoms women present with, and iron is frequently the highest-value single intervention. A second source line gives about US$2 to 15 a year for oral iron, set beside the UNICEF indicative prices above, and records iron as on the Essential Medicines List. Goserelin, leuprorelin and triptorelin are all listed and shrink fibroids and induce amenorrhoea, used preoperatively to reduce size and correct anaemia; they cause menopausal symptoms and bone loss, so use is limited to a few months unless add-back hormone therapy is given. A second source line gives shrinkage of about 35 to 60 per cent over three to six months† and a limit of six months without add-back. It states that fibroids regrow within months of stopping, and gives the cost as thousands of US dollars a year. Elagolix, the relugolix combination and linzagolix are not listed and are on patent, oral and effective for bleeding and pain, allowing longer-term use than the agonists, at United States costs in the region of US$10,000 a year and above†. A second source line gives the cost of the antagonist combinations as about US$10,000 to 13,000 a year at United States list†, which lies inside the figure above, and reduction of blood loss in about 70 to 75 per cent†, with built-in add-back allowing longer use. Ulipristal acetate is effective and was restricted in Europe after cases of severe liver injury requiring transplantation, a genuine safety withdrawal worth recording. A second source line says it is restricted or withdrawn in several markets, and calls it a cautionary case. Myomectomy removes fibroids with the uterus preserved, by open, laparoscopic or hysteroscopic route depending on fibroid location; it preserves fertility, at a recurrence of roughly 15 to 30 per cent at five to ten years†. The cure status above gives recurrence of about 15 per cent at five years and 25 to 50 per cent at ten years, which is also the figure in the second source line. The two source lines disagree with the 15 to 30 per cent at five to ten years† given here, and both are printed. Hysteroscopic myomectomy for submucosal fibroids is highly effective for bleeding and for fertility, and is a day case. Myomectomy may also be robotic. Hysterectomy is a definitive cure, abdominal, vaginal or laparoscopic. Vaginal or laparoscopic routes are preferred over open surgery where feasible. Uterine artery embolisation blocks the blood supply and shrinks fibroids, with comparable symptom relief to surgery and faster recovery, a higher reintervention rate, and effects on fertility not fully established, so it is used cautiously in women wanting pregnancy. It is generally avoided in women planning pregnancy. The FEMME trial of 2020 found that myomectomy gave better fibroid-related quality of life than embolisation at two years, though both improved substantially. Focused ultrasound and radiofrequency ablation are non-invasive or minimally invasive with limited availability. The focused ultrasound is MRI-guided. Both have less long-term data and variable re-intervention rates. Endometrial ablation is an option for bleeding with small fibroids and no wish for fertility. On morcellation: power morcellation of an unsuspected leiomyosarcoma can disseminate the malignancy. That led to regulatory warnings and to contained morcellation in extraction bags, as set out under Prevention. A second source line gives the risk as about one in 350 to one in 10,000, varying widely, and calls the magnitude CONTESTED†. The upper end, one in 10,000, lies

outside the one in 1,000 to one in 2,000 given under Prevention, so the two source lines disagree. All the figures are printed.

**Simple means.** Fibroids are among the best-served conditions in this chapter by simple means, and the gap between what is cheap and what is done is correspondingly large. Tranexamic acid costs a few cents a tablet, is oral, is taken during menstruation only, is listed and off-patent, and reduces blood loss by roughly a third, with no device, no procedure, no cold chain and no monitoring. A second source line gives the reduction as about 40 to 50 per cent† at tens of US dollars a year. Those are the figures printed under Treatment, where the disagreement is set out. Oral iron costs cents, is listed and off-patent, and treats the anaemia that is the main systemic harm: the combination of tranexamic acid and ferrous sulphate costs pennies a month and addresses both the bleeding and its consequence. Iron, dietary and supplemental, treats the fatigue and breathlessness of the anaemia, at pennies. A levonorgestrel intrauterine system is a single insertion in an outpatient clinic lasting five to eight years, reducing blood loss by 80 to 90 per cent at a public-sector procurement cost in the region of US$10 to 20†. For a woman with heavy bleeding and a non-distorted cavity it is close to definitive management at trivial cost, and it also provides contraception. The second source line gives 70 to 95 per cent bleeding reduction† at a few dollars a year, the figures printed under Treatment. Abdominal hysterectomy and myomectomy are both conventional operations performable in a district hospital with basic instruments, anaesthesia and blood availability, and hysterectomy is definitively curative; for a woman with a very large fibroid uterus causing severe anaemia and pressure symptoms, abdominal hysterectomy is the correct and achievable treatment, and agonist pretreatment or iron repletion before surgery reduces operative risk. Combined oral contraceptives and injectable progestogens are listed, off-patent and cents, and control bleeding. NSAIDs are cheap and reduce both bleeding and pain. Continuous cheap combined oral contraceptives suppress bleeding. Diagnosis is possible by abdominal and pelvic examination and ultrasound: a firm irregular enlarged uterus is palpable, and ultrasound is cheap, portable, needs no contrast and no radiation and is diagnostic. Fibroids are among the easiest diagnoses in this chapter to make with simple means, and the difficulty is the opposite one, that they are found too easily and too often in women who have no symptoms. Expectant management until the menopause is free and correct for many women in their late forties. Watchful waiting is also the simple means of not intervening on asymptomatic fibroids. It avoids all surgical risk, and a significant number of hysterectomies have historically been done for size alone, without symptoms. Other simple means are heat for pain, exercise and weight management. Menstrual cups and washable pads are a practical way to manage heavy flow where disposable products are unaffordable. That is a real equity issue in low-income settings, where heavy bleeding causes absence from school and work. Measuring haemoglobin is a cheap test that identifies the treatable consequence. Where nothing simple exists: uterine artery embolisation, focused ultrasound and hysteroscopic resection of submucosal fibroids all require specific equipment, and hysteroscopic resection in particular is the best treatment for the submucosal fibroids that cause the heaviest bleeding and the most infertility, with no simple substitute. Large or submucosal fibroids causing severe symptoms need a procedure, and nothing simple shrinks them meaningfully. The GnRH antagonists that allow long-term medical control without surgery are on patent, expensive and not listed. And no simple means exists to distinguish a fibroid from a leiomyosarcoma preoperatively, which is the residue of the morcellation controversy. The central point stands: **for the commonest tumour in women, the two cheapest drugs in the pharmacy — tranexamic acid and iron — plus a US$10 to 20 intrauterine device at public-sector procurement prices, plus an operation a district surgeon can perform, cover the large majority of what needs to be done. The burden of fibroids worldwide is not a burden of expensive technology. It is a burden of untreated anaemia and unoperated symptomatic disease.**

**Gaps.** GLOBOCAN and SEER do not report benign neoplasms, so this entry has no figures from the sources that supply the rest of this chapter, and no fibroid-specific GBD 2023 row was retrieved. The prevalence figures, the hysterectomy volumes and the ancestry disparity in hysterectomy rates are literature-derived. The ancestry difference is large, consistent and entirely unexplained, and vitamin D is a hypothesis. The occult leiomyosarcoma risk is genuinely contested, roughly one in 350 against roughly one in 1,000 to one in 2,000, both printed, unresolved, and there is no preoperative test. Overdiagnosis of asymptomatic fibroids by incidental imaging is extremely common and entirely unquantified. Ulipristal's

liver toxicity led to regulatory restriction, a safety signal that emerged after approval. No effective primary prevention exists. Effects of uterine artery embolisation on subsequent fertility are not established. What initiates the founding somatic mutation is unknown. Fibroid growth is unpredictable, so prognosis for an individual woman cannot be given. The relationship between small intramural fibroids and fertility or miscarriage is unresolved, so advice on whether to remove them is uncertain. The racial disparity is a major research gap with clear equity implications. Morcellation sarcoma risk estimates vary by more than an order of magnitude in the second source line, which gives one in 350 to one in 10,000. Long-term comparative data between embolisation, ablation techniques and surgery are limited. Hysterectomy rates vary enormously between countries and systems for identical disease, which suggests substantial supply-driven treatment. Data from Africa, where symptomatic fibroids are a major surgical burden, are sparse relative to the problem.

## 35. Colonic adenomas

**What it is.** Benign glandular tumours of the lining of the large bowel. They are extremely common in older people, they are the lesion from which almost all colorectal cancer develops, and removing them prevents that cancer. They are the single most important benign neoplasm in medicine, because the entire rationale for colorectal cancer screening rests on finding and removing them.

**Measured.** Adenomas are found in roughly 25 to 40 per cent of asymptomatic people over 50 undergoing screening colonoscopy, and in a higher proportion of men than women; advanced adenomas, 10 mm or larger or with high-grade dysplasia or villous histology, are found in roughly 5 to 10 per cent; and prevalence rises steeply with age, with autopsy and colonoscopy series in people over 70 finding adenomas in roughly 50 per cent or more. The adenoma detection rate is the principal quality metric for colonoscopy, with a recommended minimum in the region of 25 to 30 per cent in a mixed screening population†, and the fact that the quality metric is a detection rate rather than a miss rate is itself informative: operators differ substantially in how many they find. **The great majority of adenomas never become cancer.** The commonly cited figure is that roughly 5 per cent progress to cancer over about ten years, with the risk concentrated in advanced adenomas, and for a small tubular adenoma under 5 mm the lifetime risk of progression is very low†. The dwell time — the interval from adenoma to invasive cancer — is estimated at roughly ten years for the conventional sequence, and that long interval is what makes screening every ten years viable; serrated lesions and Lynch syndrome adenomas progress faster. GLOBOCAN and SEER do not report benign neoplasms, so the relevant outcome data are in the colorectal screening trials, in entry 2 and below.

**Where it starts.** The risk factors are essentially those of colorectal cancer, which is expected since the adenoma is the precursor: physical activity relative risk 0.76, interval 0.72 to 0.81; obesity colon cancer relative risk 1.45, interval 1.02 to 2.07, in women above a body mass index of 29; smoking incidence relative risk 1.18, interval 1.11 to 1.25; and alcohol above 45 grams a day 1.41, interval 1.16 to 1.72. Smoking is more strongly associated with adenomas, and particularly with serrated lesions, than with cancer itself. Age dominates; male sex gives roughly 1.5-fold and family history of colorectal cancer or advanced adenoma roughly twofold. The hereditary syndromes define the extremes. Familial adenomatous polyposis, from germline APC mutation, produces hundreds to thousands of adenomas from adolescence and a near-100 per cent lifetime colorectal cancer risk without prophylactic colectomy, and it is the proof of the adenoma-carcinoma sequence. Lynch syndrome, from mismatch repair deficiency, carries a lifetime colorectal cancer risk of about 80 per cent, with fewer adenomas than polyposis and faster progression, which is why surveillance intervals are one to two years rather than ten. MUTYH-associated polyposis, serrated polyposis syndrome, Peutz-Jeghers syndrome and juvenile polyposis follow. The molecular pathways are two. The conventional adenoma-carcinoma sequence runs through APC loss, initiating, then KRAS mutation, then TP53 loss and chromosomal instability. The serrated pathway runs through BRAF mutation and CpG island methylation to microsatellite-unstable cancer, and sessile serrated lesions are flat, pale, right-sided and easy to miss at colonoscopy, which is now recognised as a major source of post-colonoscopy interval cancers. Mutation burden in an adenoma is low and accumulates through the sequence. Not known: **which individual adenoma will progress.** That is the central unanswered question and it is the reason all

adenomas are removed. There is no test that distinguishes the roughly 5 per cent that would become cancer from the 95 per cent that would not†, so the only available strategy is to remove them all, and that means roughly twenty polypectomies are performed for every cancer prevented. Also unknown: why the right colon and the serrated pathway behave differently; why adenoma prevalence differs so much by sex.

**Cure status.** Sporadic adenoma: CURABLE, completely and permanently, by polypectomy. Snare polypectomy or endoscopic mucosal resection removes the lesion in a single outpatient procedure, and the removed adenoma cannot progress. **That makes it the most straightforwardly curable neoplasm in this entire chapter.** SELF-LIMITING is not correct, because adenomas do not regress spontaneously in any meaningful proportion; the great majority are biologically inert over a lifetime, which is a different thing and is the source of the overtreatment problem below. Familial adenomatous polyposis: CURABLE only by prophylactic colectomy or proctocolectomy, because the propensity to form adenomas is in every cell of the colonic epithelium. The operation is performed in adolescence or early adulthood and it prevents a near-certain cancer, and desmoid tumours and duodenal adenomas then become the leading causes of morbidity and death — see entry 28 on desmoids. Lynch syndrome: CONTROLLABLE by one- to two-yearly colonoscopic surveillance with polypectomy, which reduces colorectal cancer incidence and mortality substantially, and some patients elect prophylactic colectomy. A malignant polyp — an adenoma containing invasive carcinoma that has been removed endoscopically: CURABLE by polypectomy alone if the margin is clear, the invasion is superficial and the histology is favourable, and otherwise segmental colectomy is required.

**Prevention.** This section is the heart of the entry, because adenoma removal is itself the prevention of colorectal cancer. Screening with polypectomy — STRONG, and the randomised evidence is as in entry 2. Flexible sigmoidoscopy: four randomised trials pooled, 458,002 people, colorectal cancer mortality rate ratio 0.74, interval 0.68 to 0.80, over eleven to seventeen years. Guaiac faecal occult blood testing: relative risk 0.78, interval 0.65 to 0.93, to 0.91, interval 0.84 to 0.98, at eleven to thirty years. Faecal immunochemical testing: no randomised trial, with a Taiwanese cohort of 5,417,699 people giving an adjusted relative risk of 0.90, interval 0.84 to 0.95, at six years. Colonoscopy: the NordICC randomised trial gives ten-year colorectal cancer risk of 0.98 per cent in those invited against 1.20 per cent in usual care, an 18 per cent reduction, risk ratio 0.82, interval 0.70 to 0.93. Colorectal cancer death was 0.28 against 0.31 per cent, risk ratio 0.90, interval 0.64 to 1.16, which is not significant, and all-cause death was 11.03 against 11.04 per cent. The number needed to invite was 455, interval 270 to 1,429, on 42.0 per cent uptake. Recommended ages: 50 to 75 Grade A, 45 to 49 Grade B, 76 to 85 selectively Grade C, stop at 86. NCI PDQ on polyp removal specifically is more cautious than is generally assumed, and it should be stated plainly: **PDQ rates the benefit magnitude of polyp removal as unknown, probably greater for polyps larger than 1.0 cm, rates the benefit evidence as fair, and rates the harms as solid at 7 to 9 events per 1,000 procedures**. The authority that grades colorectal risk factors as solid grades the benefit of polypectomy itself as fair with unknown magnitude. Harms, with figures: colonoscopy after a positive stool test gives about 17.5 serious bleeds and 5.4 perforations per 10,000; screening colonoscopy 14.6 bleeds and 3.1 perforations; colonoscopy after abnormal sigmoidoscopy 20.7 and 12.0; flexible sigmoidoscopy 0.5 and 0.2; and lifetime complications for screening from 45 to 75 are 10 to 16 per 1,000 adults screened. The overtreatment question is stated honestly here, because it differs from the breast, prostate and thyroid cases and is usually not discussed at all. Roughly 25 to 40 per cent of screened people over 50 have an adenoma, and roughly 5 per cent of adenomas progress to cancer over a decade, so the great majority of polypectomies remove lesions that would never have harmed the patient. In the classical overdiagnosis framing used for thyroid, prostate and breast cancer this would be described as massive overtreatment. It is not usually described that way, and there is a defensible reason: the intervention is a snare passed through an endoscope already in place, taking seconds, with a complication rate of a few per thousand, and it prevents a cancer in the one case in twenty. The harm per unnecessary intervention is very small and the benefit when it lands is very large, which is the opposite of the thyroid case, where the unnecessary intervention is a thyroidectomy with permanent consequences. The defence is not unlimited, and two real harms follow. First, the surveillance cascade: a person with a small adenoma is enrolled in repeat colonoscopy for years, with the complication risk repeated each time, on the basis of guidelines whose intervals rest on observational data. Second, in very elderly or

comorbid people, screening and polypectomy continue past the point where any benefit could accrue, and the recommendation to stop at 86 and screen 76 to 85 selectively is an attempt to address that. **No overdiagnosis percentage has ever been published for colonic adenomas, and the reason is that the framework has not been applied. The underlying number — roughly twenty polypectomies per cancer prevented — is nonetheless available and is stated here.** Aspirin — MODERATE for adenomas and CONTESTED on net benefit: colorectal cancer incidence hazard ratio 0.60, interval 0.47 to 0.76, at ten to nineteen years after starting, against 0.99 within ten years, a twenty-year death hazard ratio of 0.67, and major gastrointestinal bleeding odds ratio 1.58 with about fourteen extra bleeds per thousand people over ten years at very low doses. In Lynch syndrome, CAPP2 gave a hazard ratio of 0.65, interval 0.43 to 0.97, the clearest case for aspirin, in a group with an 80 per cent lifetime risk. Non-steroidal anti-inflammatory drugs — CONTESTED: PDQ rates the evidence inadequate for the colorectal cancer endpoint, with adenoma reduction only and no relative risk given, against solid harms of 4 to 5 upper gastrointestinal events per 1,000 a year and serious cardiovascular events up 50 to 60 per cent. Celecoxib reduces adenoma recurrence and increases cardiovascular events, and that trade-off ended its use for chemoprevention in the general population. Physical activity — MODERATE. Avoiding tobacco — MODERATE, and the association with serrated lesions is stronger. Limiting alcohol — MODERATE. Diet — CONTESTED, with the authorities disagreeing: PDQ states there is no reliable evidence that a low-fat, low-meat, high-fibre diet reduces colorectal cancer risk by a clinically important degree, and IARC classified processed meat Group 1 and red meat Group 2A in 2015 with a reported 18 per cent increase per 50 grams a day of processed meat. Both are printed, and randomised trials of dietary fibre supplementation and of low-fat diets have not reduced adenoma recurrence. Calcium and vitamin D — CONTESTED: some trials showed reduced adenoma recurrence with calcium, and the large vitamin D and calcium polyp prevention study was negative for vitamin D.

**Treatment.** Snare polypectomy at colonoscopy is the definitive treatment and removes the lesion in seconds. Cold snare polypectomy is now preferred over hot snare for lesions under 10 mm, because it has a lower delayed bleeding and perforation rate: a technique change, costing nothing, that reduced harm. Endoscopic mucosal resection and endoscopic submucosal dissection serve larger and flat lesions and avoid surgery for lesions that would previously have required colectomy. Segmental colectomy serves lesions not amenable to endoscopic removal and malignant polyps with unfavourable features. Prophylactic colectomy or proctocolectomy with an ileal pouch serves familial adenomatous polyposis. Surveillance colonoscopy follows at intervals determined by the number, size and histology of adenomas removed, typically three years after advanced adenomas and seven to ten years after one or two small tubular adenomas under current guidelines, and those intervals rest on observational data rather than randomised trials. Aspirin is listed, off-patent and costs cents a tablet, recommended for chemoprevention in Lynch syndrome at a hazard ratio of 0.65 and not recommended for the general population, because the bleeding harm offsets the benefit. **There is no drug treatment for sporadic adenomas and no expensive agent anywhere in this entry. The entire management is endoscopic and surgical.**

**Simple means.** There is no simple-means substitute for colonoscopy, and that is the central honest point of this entry. Finding and removing adenomas requires a colonoscope, a light source, a processor, a snare, a reprocessing chain for the instrument, sedation, and a trained operator with a documented detection rate. None of that is simple, and the capital and maintenance cost of an endoscopy service is the binding constraint on colorectal cancer prevention worldwide. What is simple is stool testing. A faecal immunochemical test kit costs a few dollars, is done by the patient at home, needs no bowel preparation, no sedation and no clinic visit, and has randomised evidence for guaiac testing and very large cohort evidence for immunochemical testing of colorectal cancer mortality reduction: relative risk 0.78 to 0.91 and adjusted relative risk 0.90, interval 0.84 to 0.95. It requires a laboratory to read it, which is a modest requirement, and it requires colonoscopy capacity for the positives, which is not. Stool testing is the single most transferable element of colorectal cancer prevention, and its limitation is that it is a cancer and advanced-adenoma detection test rather than an adenoma detection test, so it does not prevent cancer by finding precursors nearly as well as colonoscopy does. Flexible sigmoidoscopy uses a shorter, cheaper instrument, no sedation and no full bowel preparation, **and it has the strongest randomised evidence of any colorectal screening modality: a mortality rate ratio of 0.74, interval 0.68 to 0.80,**

**from four randomised trials in 458,002 people**. It reaches only the left colon, which is a real limitation given the rise in right-sided and serrated lesions, and it is substantially simpler than colonoscopy and the evidence for it is better. That is worth stating clearly: the modality with the best randomised evidence is also the simpler one. Digital rectal examination and rigid sigmoidoscopy detect low rectal lesions with almost no equipment, at poor sensitivity for anything higher. Aspirin in Lynch syndrome costs cents a tablet, is listed and off-patent, at a hazard ratio of 0.65. Physical activity, not smoking and limiting alcohol need no technology. Oral iron, listed and costing cents, treats the iron-deficiency anaemia that a bleeding adenoma or cancer causes, with the corollary that matters: iron-deficiency anaemia in an adult, particularly a man or a postmenopausal woman, requires investigation of the bowel rather than iron alone, and treating the anaemia without looking for the cause is a recognised and avoidable error. The honest statement: colonic adenomas are the one entry in this chapter where the preventive intervention is highly effective, entirely off-patent in drug terms because there are no drugs, and nonetheless unavailable to most of the world, because it is an endoscopic service rather than a medicine. There is no cheap substitute for a colonoscope. Stool testing and flexible sigmoidoscopy are the realistic simple approaches and both have randomised evidence behind them. **The gap in colorectal cancer prevention worldwide is a gap in endoscopy capacity, and no amount of drug pricing reform touches it.**

**Gaps.** GLOBOCAN and SEER do not report benign neoplasms, so adenoma prevalence figures are literature-derived. Adenoma prevalence, advanced adenoma prevalence, the progression rate and the dwell time are all literature-derived, and those are the numbers on which the whole screening rationale rests. PDQ rates the benefit of polyp removal as fair evidence with unknown magnitude, while screening programmes worldwide rest on it, and that is a genuine and underappreciated tension. No overdiagnosis percentage has ever been published for colonic adenomas, though the underlying ratio of roughly twenty polypectomies per cancer prevented is calculable and is stated above; the framework applied to thyroid, prostate and breast has simply not been applied here. Surveillance intervals rest on observational data. Which individual adenoma will progress is unknown and no test exists, which is the fundamental gap. Sessile serrated lesions are easy to miss and are now recognised as a major cause of post-colonoscopy interval cancers, and the magnitude of the miss rate varies by operator and is incompletely characterised. PDQ and IARC disagree on diet and on meat, and both are printed.

# Cross-cutting sections

## A. The autopsy evidence, and why it predicts overdiagnosis

This is the evidence that bears most directly on the overdiagnosis figures printed throughout the chapter. It comes from people who died of something else and whose organs were then examined systematically. It measures the reservoir of cancer that a sensitive test can find.

**Prostate.** Bell and colleagues, in the *International Journal of Cancer* in 2015, pooled 29 autopsy studies dated 1948 to 2013. Incidental prostate cancer at autopsy was present in 5 per cent of men under 30, interval 3 to 8, and 59 per cent of men over 79, interval 48 to 71, rising non-linearly at approximately 1.7-fold per decade. The intermediate age-group figures are not reported in the abstract and could not be retrieved; they lie on the curve between 5 and 59 per cent.

Lifetime risk of a *diagnosis* of prostate cancer in a high-screening country is in the region of 12 to 15 per cent, and lifetime risk of *dying* of it roughly 2 to 3 per cent†. Against an autopsy prevalence of 59 per cent in men over 79, the great majority of prostate cancer that exists is never diagnosed and never causes harm. The overdiagnosis estimate of 20 to 50 per cent of screen-detected cancers — 21 per cent in PLCO, 50 per cent in ERSPC, 22 to 42 per cent in CISNET models — is entirely consistent with a reservoir of that size. The autopsy data do not resolve which cancers matter; they establish that the reservoir is very large and that any sensitive test applied to older men will draw from it.

**Thyroid.** Furuya-Kanamori and colleagues, in the *Journal of Clinical Oncology* in 2016, pooled 35 studies, 42 data sets and 12,834 autopsies conducted between 1949 and 2007. Incidental differentiated thyroid cancer was present in 4.1 per cent on partial thyroid examination, interval 3.0 to 5.4, and 11.2 per cent on whole thyroid examination, interval 6.7 to 16.1. The authors give those two subgroup estimates rather than a single pooled figure, and the difference between them is itself the point: how much cancer is found depends on how hard the pathologist looks. The Finnish series from which the phrase “a normal finding” comes reported occult papillary carcinoma in a very high proportion of thyroids examined in fine serial section; the specific figure could not be retrieved in primary form, and the study is the historical origin of the recognition that subclinical papillary thyroid carcinoma is near-ubiquitous when sought thoroughly.

Annual thyroid cancer incidence in high-screening populations is a small fraction of 11.2 per cent. Two findings are direct consequences of a reservoir of that size meeting a sensitive imaging test. The first is the South Korean experience: a roughly fifteenfold rise in incidence between 1993 and 2011 with flat mortality, after ultrasound screening was added to health checks. The second is IARC’s 2016 estimate that more than half a million people were overdiagnosed in twelve high-income countries over two decades, about 470,000 women and 90,000 men. The thyroid autopsy data are the clearest demonstration in medicine that the amount of cancer found is a function of the intensity of looking.

**Breast.** Thomas and colleagues, in *BMC Cancer* in 2017, pooled 13 studies from 1948 to 2010 covering 2,363 autopsies. At autopsy, invasive breast cancer was present in 0.85 per cent, in-situ cancer in 8.9 per cent, atypical hyperplasia in 9.8 per cent, and any cancer or precursor lesion in 19.5 per cent. The authors do not report confidence intervals in the abstract and they could not be retrieved.

The reservoir of occult invasive breast cancer is small, at 0.85 per cent, which is why breast overdiagnosis estimates are far lower than the thyroid figures and why the dispute is gen-

uinely close. **The reservoir of in-situ cancer is ten times larger than the invasive reservoir, at 8.9 per cent, and almost all detected in-situ cancer is treated.** That is where the breast overdiagnosis problem principally sits, and the autopsy data support it. The 19.5 per cent figure for any cancer or precursor sits close to the Marmot panel's 19 per cent overdiagnosis estimate, which is a coincidence of numbers rather than a derivation, and it indicates the order of magnitude.

### The pattern across the three organs

| Organ | Occult cancer at autopsy | Lifetime risk of diagnosis | Published overdiagnosis estimate from screening |
|---|---|---|---|
| Prostate | 59 per cent, interval 48 to 71, in men over 79; 5 per cent, interval 3 to 8, under 30 | roughly 12 to 15 per cent† | 20 to 50 per cent of screen-detected cancers; PLCO 21, ERSPC 50, CISNET 22 to 42 |
| Thyroid | 11.2 per cent, interval 6.7 to 16.1, whole gland; 4.1 per cent, interval 3.0 to 5.4, partial | roughly 1 to 2 per cent† | approaching 90 per cent or more in high-screening settings; IARC about 560,000 overdiagnosed in 12 countries over 20 years |
| Breast | 0.85 per cent invasive; 8.9 per cent in situ; 19.5 per cent any cancer or precursor | roughly 12 to 13 per cent† | 19 per cent, Marmot 2012, against 30 per cent, Cochrane 2013 |

**The relationship across these three organs is direct: the size of the occult reservoir tracks the magnitude of the overdiagnosis problem.** Prostate and thyroid have large reservoirs and large overdiagnosis; breast has a small invasive reservoir and a contested, moderate overdiagnosis figure concentrated in in-situ disease. Read in the net: the test returns what is present at the depth it probes, and the reservoir is a property of the organ. This is a reading, not a mechanism.

The same reading is offered for the other screening results in this chapter, and it is a reading and not a finding, since most of the figures behind them carry a dagger. Neuroblastoma has a large reservoir of spontaneously regressing tumours in infants: screening doubled incidence, did not reduce mortality, and was abandoned. The myeloma precursor is present in roughly 3 per cent of people over 50 and over 5 per cent over 70, progressing at roughly 1 per cent a year†, so screening would label millions and offer nothing. The chronic lymphocytic leukaemia precursor is present in roughly 3 to 5 per cent of adults over 40 and over 10 per cent over 80, progressing at roughly 1 to 2 per cent a year†, and the same conclusion follows. Colonic adenomas are present in 25 to 40 per cent of people over 50, of which roughly 5 per cent progress over a decade†, so roughly twenty polypectomies are performed per cancer prevented — tolerated because the harm per unnecessary polypectomy is a few per thousand rather than a thyroidectomy. Lung cancer's NELSON overdiagnosis ceiling of 8.9 per cent is consistent with a modest reservoir, and the higher NLST-derived estimates remain disputed.

**Nasopharyngeal carcinoma is a control case. No occult reservoir is found at autopsy, and plasma Epstein-Barr virus DNA screening in endemic populations produces a large stage shift and better survival without a significant overdiagnosis penalty; no overdiagnosis percentage has been published.**

What the autopsy data do not show: they do not identify which lesion in a living person will progress. **No marker exists, in any of these organs, that reliably separates the indolent from the lethal at the time of detection.** That is the common root of every overdiagnosis controversy in this chapter, and it has not been solved for any of them.

---

## B. Where overdiagnosis has never been quantified

Overdiagnosis has been quantified for breast, prostate, thyroid, lung, melanoma and neuroblastoma, and the figures are printed in those entries. It has never been quantified for gastric cancer, liver cancer, kidney cancer, bladder cancer, cervical intraepithelial neoplasia, colonic adenoma, uterine fibroids, incidental meningioma, monoclonal gammopathy of unde-

termined significance or monoclonal B-cell lymphocytosis — several of which have reservoirs as large or larger.

**The absence of a figure is not evidence of the absence of harm.** For gastric cancer, national endoscopic programmes have run for decades with no randomised mortality trial and no published overdiagnosis estimate. For liver cancer, six-monthly surveillance of cirrhotic patients is widely recommended on one randomised trial. For kidney cancer, overdetection of small renal masses through imaging done for other reasons is unintended screening at scale, with the rising-incidence-and-falling-mortality pattern as its only quantification. For bladder cancer, there is no programme to quantify it in, and half of all United States diagnoses are already in situ. For cervical intraepithelial neoplasia, the treated entity is a precursor rather than a cancer, so the framing does not transfer, and over-treatment of lesions that would have regressed is the principal harm. For colonic adenoma, the framework has not been applied, and the underlying ratio is roughly twenty polypectomies per cancer prevented. For uterine fibroids, the condition is so common that the concept is rarely applied to it at all. For incidental meningioma, a substantial proportion never grow and intervening carries neurosurgical risk. And for the myeloma and chronic lymphocytic leukaemia precursors, the overdiagnosis fraction of a screening programme would approach the full population prevalence of the precursor.

In the kidney, fibroid and incidental-meningioma cases the harm from expanding imaging is real, growing and unmeasured.

---

## C. The preventable fraction of all cancer

Three WHO figures are in current circulation, they are not the same quantity, and they are frequently conflated. All three are given here with their bases, and one of them has a published derivation.

**The figure to use: 37.8 per cent of 2022 cases, about seven million.** A WHO and IARC analysis published in *Nature Medicine* in 2026 found that **37.8 per cent of the roughly 18.7 million new cancer cases diagnosed globally in 2022 were attributable to modifiable risk factors — about seven million cases**. By sex: **4.3 million cases in men, 45.4 per cent, against 2.7 million in women, 29.7 per cent**. By risk factor, as a share of all new cancer cases: **smoking 15.1 per cent, infections 10.2 per cent, alcohol consumption 3.2 per cent**. High body mass index, low physical activity, smokeless tobacco, air pollution and ultraviolet radiation are also named, and the retrieved report gives no percentages or case counts for them. The denominator, 18.7 million, is the GLOBOCAN 2022 total excluding non-melanoma skin cancer, which is the convention used throughout this chapter. The method is a population attributable fraction calculation: exposure prevalence combined with relative risks from the epidemiological literature, applied to GLOBOCAN 2022 incidence. That is the standard approach, and it carries the standard limitations, set out below.

**The two figures not used, and why.** First, WHO's *Preventing cancer* activity page states that between 30 and 50 per cent of all cancer cases are preventable†. The page does not explain how the estimate was derived and cites no methodology or source; what it offers instead is a list of the risk factors on which prevention can act — tobacco, alcohol, physical inactivity, diet and overweight, infections including hepatitis and human papillomavirus, environmental pollution including outdoor and household air pollution, occupational carcinogens such as asbestos, and radiation. It is a range offered without a derivation. It is the most widely quoted cancer prevention figure in the world and it is, as published, unsourced, so it is treated here as an order-of-magnitude statement and is not used. Second, the WHO cancer fact sheet states that approximately 38 per cent of cancers are preventable. That is a point estimate without a stated derivation on the page, and it corresponds closely to the 37.8 per cent figure above, which does have one. Where the two could be used interchangeably, this chapter uses the figure with the published derivation and the figure-by-figure breakdown.

**The infection-attributable component, independently measured.** de Martel and colleagues, in *The Lancet Global Health* in 2020, estimated 2.2 million infection-attributable cancer cases in 2018, about 13 per cent of all new cancer cases worldwide, at an age-

standardised incidence rate of 25.0 per 100,000 person-years. By agent: *Helicobacter pylori* about 810,000 cases at 8.7 per 100,000; human papillomavirus about 690,000 at 8.0; hepatitis B about 360,000 at 4.1; and hepatitis C about 160,000 at 1.7. By region, Eastern Asia at 37.9 and sub-Saharan Africa at 33.1 had the highest attributable rates and Northern Europe at 13.6 and Western Asia at 13.8 the lowest, with China accounting for about a third of all infection-attributable cases worldwide, driven by *H. pylori* and hepatitis B. The human papillomavirus attributable rate rises as income falls, from 6.9 in high-income countries to 16.1 in low-income countries. One important limitation: the retrieved summary reports four agents, so Epstein-Barr virus, human herpesvirus 8, HTLV-1 and *Schistosoma haematobium* are not among them, and no case counts for those agents could be retrieved. That affects the Hodgkin lymphoma, nasopharyngeal carcinoma, Kaposi sarcoma, non-Hodgkin lymphoma and bladder cancer entries, each of which flags it.

The sources differ on the infection-attributable share and are not reconciled: de Martel gives 13 per cent for 2018 and the WHO and IARC analysis gives 10.2 per cent for 2022. The WHO cancer fact sheet gives approximately 10 per cent of cancers diagnosed globally in 2022 in its body, while stating in its key facts, with no year, that infections cause approximately 30 per cent of cancer cases in low- and lower-middle-income countries. The 13 against 10 per cent difference reflects different years, agent lists and methods. The 30 per cent figure is a different scope, and the WHO page sets the two against each other without reconciling them.

## What the preventable fraction does and does not mean

**Attributable to modifiable risk factors is not the same as preventable now.** The 37.8 per cent figure assumes complete elimination of the exposures. Eliminating tobacco entirely would prevent 15.1 per cent of cancers, and no policy has ever eliminated tobacco anywhere: WHO records 1.2 billion tobacco users and smoke-free laws in 79 countries covering over a third of the world's population. The achievable fraction over any realistic horizon is substantially smaller than the attributable fraction.

**The attributable fractions are not additive in a simple way.** Tobacco and alcohol interact supra-multiplicatively in head and neck and oesophageal cancer: the combined population attributable risk is 89.4 per cent for oesophageal squamous carcinoma, and the relative risk for larynx with heavy use of both is thirty-sixfold. A case attributable to both is counted in a way that depends on the method.

**Latency means today's prevention yields results in decades.** Every mesothelioma now reflects asbestos exposure twenty to fifty years ago. Every human papillomavirus vaccination now prevents a cervical cancer in thirty years. The United States lung cancer mortality decline of 4.1 per cent a year now reflects smoking cessation that began in the 1960s.

**The 62 per cent that is not attributable to modifiable factors, which is the complement of the 37.8 per cent above, is the part this chapter repeatedly reports as unknown.** For breast cancer the established risk factors account for only a minority of cases. For prostate cancer no modifiable risk factor is established at all. For brain tumours, nothing beyond radiation. For childhood cancer, WHO states plainly that most has no known cause. For sarcoma, nothing for the sporadic majority. For pancreatic cancer the prevention summary could not be retrieved. These are the state of the field.

**The infection-attributable fraction is the most actionable component, because the interventions are cheap and proven.** Hepatitis B vaccination is listed at under a dollar a dose and would prevent 70 to 85 per cent of global hepatocellular carcinoma if universal; human papillomavirus vaccination is non-inferior at one dose; *H. pylori* eradication costs a few dollars of generic antibiotics at a relative risk of 0.66 and a number needed to treat of 124; hepatitis C direct-acting antivirals cost under US$50 a curative course in many low- and middle-income countries, according to the WHO fact sheet printed 28 July 2026; antiretroviral therapy costs US$30 to 75 a year in global procurement programmes; and praziquantel is listed at under a dollar. **The infection-attributable 10 per cent is where the gap between what is possible and what is delivered is widest, and the tools cost almost nothing.**

**The single largest unrealised prevention opportunity after tobacco control is an Epstein-Barr virus vaccine, which does not exist.** It would address nasopharyngeal carcinoma, Burkitt lymphoma, roughly a third of Hodgkin lymphoma, virus-positive gastric

cancer and post-transplant lymphoproliferative disorder — plausibly over 200,000 cancers annually†.

---

# D. Childhood cancer: mutation burden and its clinical consequence

The three quantities that run through every paediatric entry are collected here. The clinical detail is in entries 29 to 33.

**Gröbner and colleagues, in *Nature* in 2018, analysed 961 tumours from children, adolescents and young adults across 24 molecular cancer types.** The somatic mutation frequency was **0.13 mutations per megabase in paediatric tumours against 1.8 mutations per megabase in the adult pan-cancer reference — approximately fourteen times lower**. The paper describes this as an overall rate rather than a median, and the figure is not in the abstract. **Germline cancer predisposition was present in 7.6 per cent of children** (given as 7 to 8 per cent in the paper, 7.6 per cent in the main text), against WHO's figure of about 10 per cent, and the two are consistent. Nearly 50 per cent of paediatric neoplasms harboured a potentially druggable event, 52 per cent of primary tumours after normalising for cancer incidence.

Where the individual childhood cancers sit against that 0.13 per megabase paediatric rate and the 1.8 per megabase adult reference, as reported in the entries above:

| Entity | Burden | Dominant driver type |
|---|---|---|
| Childhood acute lymphoblastic leukaemia | at or below the paediatric average | structural: ETV6-RUNX1, hyperdiploidy, KMT2A, BCR-ABL1 |
| Ewing sarcoma | at the bottom of even the paediatric range | single fusion: EWSR1-FLI1 |
| Retinoblastoma | very low | biallelic RB1 loss, and little else |
| Neuroblastoma | very low | MYCN amplification, ALK, segmental aberrations |
| Wilms tumour | very low | WT1, 11p15 imprinting, microRNA processing genes |
| Medulloblastoma | low | pathway activation: WNT, SHH, MYC amplification |
| Paediatric acute myeloid leukaemia | very low | fusion genes; adult disease averages about 13 coding mutations |
| Osteosarcoma | moderate point burden, extreme structural rearrangement | TP53 and RB1 loss, chromothripsis |
| Adult reference | 1.8 per megabase | — |
| Adult melanoma, lung, bladder, keratinocyte skin | an order of magnitude or more above the adult reference | exposure signatures: ultraviolet, tobacco, APOBEC |

**Four consequences follow, and the second is the clinical one.**

First, childhood cancers are diseases of developmental pathway dysregulation — fusion genes, aneuploidy, histone mutations, imprinting defects — rather than of accumulated exposure damage, and that is why they occur in children at all: they do not require decades of mutational accumulation.

Second, **there is almost no mutational burden for checkpoint inhibitors to exploit, and checkpoint blockade has broadly failed across paediatric oncology.** That is the observed clinical consequence, not a prediction. The successful immunotherapies in children — dinutuximab against GD2 in neuroblastoma, blinatumomab and CD19-directed cell therapy in acute lymphoblastic leukaemia — all target a lineage antigen rather than a neoantigen, which may be why they work where checkpoint blockade does not.

Third, the absence of tobacco, alcohol, diet and obesity signatures is not a research gap in the sense that those exposures are not the main drivers; whether they have had time to act is not established.

Fourth, fewer drivers has not meant easier treatment. A single fusion gene is frequently undruggable — EWSR1-FLI1, PAX3-FOXO1, MYCN — and osteosarcoma and Ewing sarcoma survival have not improved in roughly forty years.

**A note on the general rule and its exceptions.** This chapter reports three clear counterexamples to mutation burden as a predictor of checkpoint-inhibitor response: Hodgkin lymphoma, with a low burden and a 65 to 85 per cent response rate driven by 9p24.1 PD-L1 and PD-L2 amplification†; renal cell carcinoma, with a low burden and a 40 to 60 per cent response to combinations by an unexplained mechanism†; and nasopharyngeal carcinoma, with a low burden, a 20 to 30 per cent monotherapy response and high PD-L1 expression†. **Mutation burden is a useful heuristic and not a law.**

**The survival divergence.** WHO: about 400,000 children and adolescents aged 0 to 19 develop cancer each year; more than 80 per cent are cured in high-income countries; less than 30 per cent are cured in most low- and middle-income countries; and the Global Initiative for Childhood Cancer target is at least 60 per cent survival for all children by 2030, roughly double the current global rate, which WHO estimates would save an additional one million lives over the decade. Childhood cancer mortality in high-income countries fell by roughly 70 per cent between 1970 and 2020, achieved almost entirely through cooperative-group clinical trials using off-patent cytotoxic drugs.

**The threefold divergence is not biological**, and entry 29 lists the determinants. Treatment abandonment is specific to paediatric oncology in low-income settings, is a leading cause of death, is driven by cost of travel, lost income, accommodation and loss of confidence, and is a failure of social and financial support rather than of medicine. The second problem, where cure is achieved, is the cost of cure, and it drives the whole paediatric trial agenda.

---

# E. Oral morphine and palliative care

Every entry in this chapter refers to oral morphine. The figures that justify that emphasis are collected here once.

WHO's palliative care fact sheet: **about 56.8 million people need palliative care each year, including 25.7 million in the last year of life; roughly 14 per cent of those who need palliative care receive it; and in 2018, 79 per cent of the world's population, mainly in low- and middle-income countries, used only 13 per cent of the morphine consumed for pain management**†. WHO's cancer fact sheet adds that palliative care can relieve symptoms in more than 90 per cent of patients with advanced cancer, and that over 80 per cent of patients in the terminal phase suffer moderate to severe pain.

**Oral morphine is a listed medicine, for pain, in oral liquid at 5 and 10 mg per 5 mL, immediate- release tablets at 10 mg, slow-release solid forms from 5 to 200 mg and slow-release granules**. It is off-patent and costs cents a dose. Injectable morphine at 10 mg/mL is available at a UNICEF indicative price of US$5.71 for a box of ten ampoules, which is about 57 cents an ampoule, read off the catalogue in October 2026; the catalogue returns different indicative prices for the same material on different pages, so these are indicative and dated rather than a price.

**The barrier is regulatory and organisational** — restrictive controlled-drug legislation, prescriber licensing, supply-chain registration and fear of diversion — rather than price, patents or technology. Across this chapter, oral morphine is the single intervention that appears in the simple-means section of every entry without exception, and it is the one most consistently unavailable.

---

# F. Price, and the two ends of one list

## F.1 Cure at early stage with nothing on patent

| Condition | Early-stage survival | Off-patent means that achieves it |
|---|---|---|
| Basal and squamous cell skin carcinoma | over 95 and over 90 per cent† | excision under local anaesthetic; curettage; cryotherapy; topical fluorouracil, listed |
| Melanoma, localized | 100.0 per cent | wide local excision with a scalpel and sutures |
| Endometrial cancer, localized | 94.9 per cent | total hysterectomy with bilateral salpingo-oophorectomy |
| Thyroid cancer, localized | 99.9 per cent | lobectomy or thyroidectomy; levothyroxine, listed |
| Colorectal cancer, localized | 91.3 per cent | colectomy; polypectomy for the precursor; fluorouracil, calcium folinate and oxaliplatin, all listed |
| Cervical cancer, localized | 91.8 per cent | thermal ablation or loop excision for the precursor; hysterectomy; cisplatin, listed |
| Breast cancer, localized | 100.0 per cent | mastectomy; tamoxifen, listed, US$80 to 250 for five years at generic international prices, 2024, against US$785 to 1,241 at United States cash prices, October 2026 |
| Testicular cancer, stage I | roughly 99 per cent† | inguinal orchidectomy |
| Kidney cancer, localized | 93.6 per cent | radical or partial nephrectomy |
| Wilms tumour, localized | above 95 per cent† | nephrectomy; vincristine with dactinomycin, both listed, tens of dollars |
| Retinoblastoma, intraocular | above 95 to 98 per cent† | enucleation; the red reflex test to find it; carboplatin, vincristine and etoposide, all listed |
| Bladder cancer, in situ and localized | 98.0 and 73.0 per cent | transurethral resection, which needs a resectoscope; intravesical bacille Calmette-Guérin or gemcitabine |
| Stomach cancer, localized | 78.1 per cent | gastrectomy; *H. pylori* eradication for the precursor, a few dollars |
| Gastric MALT lymphoma, early | 60 to 80 per cent cured by antibiotics alone† | *H. pylori* eradication — a very cheap cancer cure |
| Colonic adenoma | cured by polypectomy | snare polypectomy, which needs a colonoscope |
| Uterine fibroids | cured by hysterectomy; controlled medically | tranexamic acid and ferrous sulphate, cents; intrauterine system US$10 to 20 at public-sector procurement prices† |
| Oral cavity cancer, localized | 88.7 per cent | wide local excision; visual inspection of the mouth to find it |
| Sarcoma, localized soft tissue | 83.3 per cent | wide excision with a clear margin — the margin is everything |

## F.2 Cure at metastatic stage with nothing on patent

| Condition | Advanced-stage outcome | Off-patent regimen |
|---|---|---|
| Testicular cancer, metastatic | 90 to 95 per cent good-risk; 50 to 70 per cent poor-risk† | bleomycin, etoposide and cisplatin, all listed, a few hundred dollars |
| Hodgkin lymphoma, stage IV | 82.8 per cent | doxorubicin, bleomycin, vinblastine and dacarbazine, all listed |
| Acute promyelocytic leukaemia | over 90 per cent cured† | all-trans retinoic acid with arsenic trioxide, both listed; no chemotherapy needed in non-high-risk disease |
| Childhood acute lymphoblastic leukaemia | 90 to 94 per cent in high-income settings† | vincristine, steroids, asparaginase, methotrexate, mercaptopurine and intrathecal methotrexate, all listed, a few hundred to low thousands of dollars over two to three years |
| Wilms tumour, stage IV | 75 to 85 per cent† | vincristine, dactinomycin and doxorubicin, all listed |
| Diffuse large B-cell lymphoma | roughly 60 to 65 per cent cured; 45 to 50 per cent with CHOP alone† | R-CHOP, all components listed; CHOP fully off-patent; rituximab a biosimilar |
| Burkitt lymphoma | 85 to 90 per cent in children† | cyclophosphamide, vincristine, doxorubicin, methotrexate, ifosfamide, etoposide and cytarabine, all listed |
| Osteosarcoma, localized | 65 to 70 per cent† | high-dose methotrexate, doxorubicin and cisplatin, all listed |
| Ewing sarcoma, localized | 70 to 80 per cent† | vincristine, doxorubicin, cyclophosphamide, ifosfamide and etoposide, all listed |

## F.3 Not curable at any stage

Pancreatic cancer beyond resectable disease, metastatic five-year survival 3.4 per cent; glioblastoma, 5 to 7 per cent at five years and median survival about 15 months†; diffuse

midline glioma, median 9 to 12 months, with no treatment having improved survival in a randomised trial; anaplastic thyroid carcinoma, median 3 to 6 months, with the BRAF V600E exception†; mesothelioma, median 12 to 18 months and entirely preventable†; multiple myeloma, CONTROLLABLE, median over 7 to 10 years and no plateau; follicular lymphoma, CONTROLLABLE, median over 15 to 20 years; chronic lymphocytic leukaemia, CONTROLLABLE at 90.2 per cent five- year survival; chronic myeloid leukaemia, CONTROLLABLE with near-normal life expectancy; the roughly 50 per cent who stay in remission after stopping treatment in deep molecular remission are the one exception in this list; metastatic prostate, breast, lung, liver, oesophageal, gastric, cervical, head and neck, bladder, ovarian and endometrial cancer, CONTROLLABLE to RELIEF ONLY with the subgroup exceptions each entry records; adult T-cell leukaemia-lymphoma, acute type, median under a year; Richter transformation, median under a year with no established treatment; relapsed high-risk neuroblastoma and relapsed medulloblastoma, both near-uniformly fatal; and platinum-refractory germ cell tumour, with no effective treatment, in young men.

## F.4 The price range, in one place

| Intervention | Price | Source and status |
|---|---|---|
| *H. pylori* eradication — amoxicillin, clarithromycin or metronidazole, proton-pump inhibitor | a few dollars a one- to two-week course | generic; cures 60 to 80 per cent of early gastric MALT lymphoma and cuts gastric cancer incidence by a third to a half |
| Praziquantel, listed | under a dollar a dose | prevents schistosomal bladder cancer |
| Hepatitis B vaccine, listed | under a dollar a dose | prevents 70 to 85 per cent of global hepatocellular carcinoma if universal |
| Oral morphine, listed | cents a dose; injectable 57 cents an ampoule, UNICEF Supply Catalogue, indicative, October 2026 | reaches about 14 per cent of those who need palliative care† |
| Amoxicillin 250 mg dispersible, listed | about 5.4 cents a tablet, indicative, October 2026 | UNICEF catalogue |
| Dexamethasone 4 mg, listed | about 24 cents a tablet, indicative, October 2026 | UNICEF catalogue |
| Ferrous sulphate, iron 60 mg, listed | about 1.4 cents a tablet, indicative, October 2026 | UNICEF catalogue |
| Allopurinol, levothyroxine, prednisolone, tranexamic acid, all listed | cents a dose | generic |
| Antiretroviral therapy, listed | US$30 to 75 a year† | global procurement; causes Kaposi sarcoma regression |
| Generic tenofovir for hepatitis B, listed | US$30 to 60 a year† | global procurement; cuts hepatocellular carcinoma incidence about 50 per cent |
| Generic hepatitis C direct-acting antivirals, listed | under US$50 a curative course in many low- and middle-income countries, fact sheet printed 28 July 2026 | WHO hepatitis C fact sheet |
| Tamoxifen, listed | US$0.43 to 0.68 per 20 mg tablet; US$20.48 for 30; US$430.56 for 1,000 — five years at one tablet a day, for orientation only, US$785 to 1,241; the generic international price for five years, 2024, is US$80 to 250 | United States cash price, October 2026 data stamps |
| Generic imatinib, listed | US$1.49 to 5.37 per 400 mg tablet; US$44.75 to 161.09 for 30 — roughly US$540 to 1,960 a year | United States cash price, October 2026 data stamps |
| Levonorgestrel intrauterine system, listed | US$10 to 20, public-sector procurement† | literature-derived |
| Full curative courses: BEP, ABVD, CHOP, MAP, Ewing and childhood leukaemia protocols | a few hundred to low thousands of dollars | all-generic listed regimens |
| Originator sofosbuvir at launch | US$84,000 a twelve-week course, 2013 to 2014 | more than 1,680-fold above the generic price — the largest ratio in this chapter |
| Originator imatinib before generic entry | US$90,000 to 145,000 a year at United States list by the time of generic entry in 2016† | about 46- to 269-fold above the generic |
| Pembrolizumab, listed, on patent | US$1,530.35 per 4 mL unit; US$6,121.41 per four-unit pack; US$12,234.94 for eight units; about US$53,000 a year at 200 mg every three weeks | United States cash price, October 2026 data stamps; the United States list price is US$150,000 to 200,000 a year |

| Intervention | Price | Source and status |
|---|---|---|
| Blinatumomab, listed, on patent | US$180,000 a course at United States list† | literature-derived |
| BTK inhibitors, venetoclax, PARP inhibitors, CDK4/6 inhibitors, osimertinib, lenvatinib | US$100,000 to 200,000 a year† | United States list; mostly not listed |
| Dinutuximab, not listed | US$100,000 to 300,000 a course in the United States† | literature-derived |
| CD19 and BCMA CAR-T, not listed | US$400,000 to 525,000 per single infusion at United States list† | literature-derived; the price guide states only that pricing varies, and NCI's page gives no prices |

### F.5 Two statements the table makes unavoidable

**The Essential Medicines List now contains both ends of this range, and it should be said once with the figures. Pembrolizumab, at US$150,000 to 200,000 a year, and blinatumomab, at US$180,000 a course, both at United States list are on the same list as morphine at cents a dose and amoxicillin at 5.4 cents a tablet at the UNICEF Supply Catalogue indicative price, October 2026.** The committee's stated threshold for adding a cancer medicine is proven prolongation of life by at least four to six months. Pembrolizumab is a selected medicine for four indications: melanoma of the skin; metastatic colorectal cancer, restricted to mismatch-repair-deficient or microsatellite-instability-high tumours; metastatic cervical cancer with PD-L1 expression of 1 per cent or more, in combination with platinum-based chemotherapy; and metastatic non-small-cell lung cancer with oncogene-driver wildtype status and PD-L1 expression of 50 per cent or more, as monotherapy. Nivolumab is a therapeutic equivalent to it for melanoma and for malignant neoplasms of the bronchus and lung, which is a weaker status than selection. Blinatumomab is listed for B-cell acute lymphoblastic leukaemia.

**Which drugs are absent from the list.** Of the five absences this chapter was asked to record, two are not absences and three are. **Temozolomide is on the list**, for other specified gliomas of the brain, Ewing sarcoma of bone or articular cartilage, neuroblastoma not otherwise specified, and unspecified malignant neoplasms. **Daratumumab is on the list**, for plasma cell myeloma. **Venetoclax is not on the list in any form**: a query of the electronic list returns zero recommendations, zero medicines and zero therapeutic equivalents, and that absence is confirmed rather than inferred. **Dinutuximab is not listed**, despite being the main recent advance in high-risk neuroblastoma. **No CAR-T product is on the list**: not tisagenlecleucel, obecabtagene autoleucel, brexucabtagene autoleucel, axicabtagene ciloleucel, lisocabtagene maraleucel, idecabtagene vicleucel or ciltacabtagene autoleucel. To those three absences this chapter adds carfilzomib, ixazomib, pomalidomide, isatuximab, obinutuzumab, acalabrutinib, brentuximab vedotin, polatuzumab vedotin, enfortumab vedotin, ipilimumab, osimertinib, lomustine, pemetrexed, the ALK, ROS1, KRAS, FGFR, RET, NTRK, hedgehog, IDH and FLT3 inhibitors, the CDK4/6 and PARP inhibitors, the BCMA bispecifics, and dostarlimab. No rationale for any of these absences was retrievable.

---

## G. What is thin in this chapter

Stated plainly, because a reference work may carry gaps and may not carry unmarked ones.

**The material this chapter was built from carries no per-figure provenance marking.** Every figure taken from it therefore carries a dagger, unless it names a source and a year, in which case the source is named and was not opened again. Where a WHO fact sheet read off the page, or the retrieval of the 24th Essential Medicines List, or the GBD 2023 capstones, or the NordICC trial closed a figure, that figure was read off its source and the source is named in the entry.

**GBD 2023 site-level cancer figures could not be retrieved**, and that is the single largest gap. GBD 2023's Table 1 gives neoplasms as a group at 10,567.9 thousand deaths in 2023, interval 9,726.9 to 11,166.9 thousand, with malignant skin melanoma at 66.6 thousand and non-melanoma skin cancer at 63.9 thousand, and the remaining per-cause rows could not

be read: three fetches at successive offsets into the published table each terminated at the same point, which is a property of the table's layout rather than of any one host. So every other quantitative burden figure in this chapter is GLOBOCAN, with 2024 beside 2022, or SEER, or a WHO fact sheet. The GBD contribution — disability-adjusted life years, years of life lost, risk-factor attribution by its own method — is absent for the individual cancers.

**GLOBOCAN 2022 has been superseded by GLOBOCAN 2024**, published in 2026 at 20,636,441 cases and 9,762,507 deaths, with a projection of 34.4 million cases by 2050. Both are given throughout. Where the two differ materially — cervical cancer at 662,301 against 604,196 cases and 348,874 against 279,583 deaths — the difference is almost certainly a methodological revision rather than an epidemiological change over two years, and should not be read as a trend. The GLOBOCAN 2022 site figures are quoted from a tabulation of the IARC release rather than from the source paper's own tables, which were not retrievable in full.

**Several NCI PDQ prevention summaries could not be retrieved** — pancreatic, bladder, kidney, sarcoma, testicular, nasopharyngeal, retinoblastoma, neuroblastoma, Wilms tumour and medulloblastoma. In those entries the risk-factor effect sizes carry no evidence grade, which is a real asymmetry against the entries where the summary was available.

**Several SEER pages could not be retrieved** — childhood cancers, bones and joints — and there is no page at all for basal or squamous cell skin carcinoma or for nasopharyngeal carcinoma separately. SEER also publishes no stage-specific table for brain and central nervous system tumours, acute myeloid leukaemia, chronic lymphocytic leukaemia, chronic myeloid leukaemia, multiple myeloma or testicular cancer, so the risk-stratified figures in those entries are literature-derived.

**Key randomised trials could not be retrieved in primary form** and are cited qualitatively or not at all: the Osmanabad trials of visual inspection and human papillomavirus screening in India; PLCO and UKCTOCS for ovarian screening; the Kerala oral visual inspection trial; the Hong Kong plasma Epstein-Barr virus DNA screening study; the ERSPC sixteen-year follow-up, with the thirteen-year figures given instead; and the Swedish human papillomavirus cohort, with the summary of it given instead. NordICC, previously carried without any numbers, is now closed: 18 per cent incidence reduction, risk ratio 0.82, interval 0.70 to 0.93, 0.98 against 1.20 per cent at ten years, with its per-protocol and adjusted figures from a secondary source without intervals.

**Drug prices are of two incompatible kinds and are not like-for-like.** The figures for pembrolizumab, imatinib and tamoxifen are United States cash prices from a price guide whose data stamps are October 2026 and which does not date its prices; they are not international reference prices. The figures for antiretrovirals, tenofovir, generic antivirals and the intrauterine system are global procurement figures. The UNICEF catalogue figures are indicative prices read off the catalogue on 19 October 2026, and the catalogue returns different indicative prices for the same material number on different pages, so they are printed as indicative and dated and never as a price. The standing international reference — the MSH International Medical Products Price Guide — is retired: its last edition is 2017 and its site ceased to be accessible after 30 June 2024, so it cannot close this book's price debt. Prices for CAR-T, trastuzumab, blinatumomab, dinutuximab, brentuximab vedotin, the BTK inhibitors and venetoclax could not be retrieved, and the figures given for those are literature-derived and labelled.

**Confidence intervals are missing in two places in the autopsy evidence**: the breast meta-analysis does not report them in its abstract, and the intermediate age-group figures for the prostate meta-analysis are not in its abstract either.

**de Martel and colleagues gave case counts for four infectious agents only**, so Epstein-Barr virus, human herpesvirus 8, HTLV-1 and *Schistosoma haematobium* counts could not be retrieved, which affects the Hodgkin lymphoma, nasopharyngeal carcinoma, Kaposi sarcoma, non-Hodgkin lymphoma and bladder cancer entries.

**Late-effect and survivorship figures are literature-derived throughout** — second cancers, cardiac toxicity, cognitive loss after craniospinal irradiation, infertility. For Hodgkin lymphoma, testicular cancer, medulloblastoma, retinoblastoma and childhood cancer generally those figures are central to management, and their absence from primary verification is substantive.

**Where sources disagree, both figures are printed.** The genuine disagreements recorded in this chapter: mammography, at 19 per cent overdiagnosis with a relative risk of 0.80 against 30 per cent with a non-significant 0.90 in the adequately randomised trials; prostate-specific antigen screening, at rate ratios of 0.79, 1.04 and 0.99 across three trials, and overdiagnosis of 21 per cent against 50 per cent; low-dose CT lung screening overdiagnosis, at a NELSON ceiling of 8.9 per cent against higher NLST-derived estimates; melanoma overdiagnosis, at roughly 15 to 60 per cent; red and processed meat, where PDQ finds no reliable evidence and IARC classifies Group 1 and Group 2A with an 18 per cent increase per 50 grams a day; glyphosate and non-Hodgkin lymphoma, where IARC says Group 2A and the European and United States regulators disagree; perineal talc and ovarian cancer, where case-control meta-analyses give 1.24 to 1.33 with no dose-response and the prospective cohorts give null results; occult leiomyosarcoma in fibroid surgery, at one in 350 against one in 1,000 to one in 2,000; mobile phones and brain tumours, where IARC's Group 2B of 2011 stands against flat registry incidence and a null 2024 review; hot beverages and oesophageal cancer, where IARC says Group 2A and PDQ is silent; sunscreen, where PDQ finds the evidence inadequate with poor validity and public health guidance recommends it universally; the preventable fraction of all cancer, at 30 to 50 per cent unsourced, 38 per cent, and 37.8 per cent with a published derivation; the infection-attributable fraction, at 13 per cent for 2018 against 10 and 10.2 per cent for 2022, with 30 per cent for low- and lower-middle-income countries; and keratinocyte skin cancer mortality, where an inference from PDQ's ratio gives 10,000 to 15,000 globally against GBD 2023's 63,900. Two WHO pages also contradict themselves in figures this chapter uses: the cancer fact sheet on the infection-attributable share, and the malaria fact sheet on the under-five share of African Region deaths, at 75 per cent in its key facts and 76 then 75 per cent in two adjacent paragraphs of its body. Both are printed in the entries concerned.

---

*End of chapter.*

# Chapter 12 — Blood, Immunity, and the Endocrine, Nutritional and Metabolic Diseases

## ICD-11 chapters 03, 04 and 05

Forty-nine conditions. Twelve of the blood and blood-forming organs, fourteen of the immune system, twenty-three of the endocrine, nutritional and metabolic group.

---

## Introduction

The third question this book asks of every condition — what can be done where there is no industry, no cold chain and no money — usually returns a partial answer. A cheap drug that helps. A free measure that prevents some of the harm. A test that costs little and changes the management. In this chapter it returns a different kind of answer ten times over. For ten of these forty-nine conditions the simple means is the whole of the treatment, not an adjunct to it. In seven of the ten it is also the cure. In three it is not: haemochromatosis, polycythaemia vera and phenylketonuria are CONTROLLABLE in their own entries, and in each the simple means holds the state without removing it.

Seven of the ten are nutritional deficiencies, and in each the deficiency ends when the nutrient arrives. Five are deficiencies of a single nutrient, one is of two (vitamin B12 and folate), and one is of food itself (protein-energy malnutrition). **Vitamin A deficiency**: the Cochrane review of supplementation in children aged 6 to 59 months pools 19 randomised trials and 1,202,382 children and finds all-cause mortality at a relative risk of 0.88 (95% CI 0.83–0.93), graded high certainty, with night blindness at 0.32 (0.21–0.50) (Imdad et al., 2022). The capsule costs cents and the delivered cost is of the order of one to two dollars per child per year. **Iodine deficiency**: potassium iodate added at the salt works costs a few cents a tonne, household coverage of iodised salt now stands near 89 per cent (Iodine Global Network Annual Report 2025), and endemic cretinism has been prevented across most of the world, while the brain damage already done is RELIEF ONLY. **Rickets**: a vitamin D drop given daily to a breastfed infant costs a few dollars a year, and Finland's fortification of fluid milks and fat spreads raised mean population 25-hydroxyvitamin D by roughly 20 nmol/L and cut the proportion below 50 nmol/L from roughly 55 to roughly 9 per cent between the 2000 and 2011 national health surveys. **Zinc deficiency**: a 10-to-14-day course of dispersible zinc costs well under two dollars†, and zinc shortens a diarrhoeal episode by 25 per cent and reduces stool volume by 30 per cent (WHO diarrhoeal disease fact sheet, 7 March 2024).

**Iron deficiency** is the largest of them by burden. Anaemia of all causes reached 1.92 billion cases in 2021, 24.3 per cent of the world population (GBD 2021 anaemia analysis, *The Lancet Haematology*, 2023), and dietary iron deficiency is the ninth-ranked cause of years lived with disability in the world at 39.3 million YLDs (95% UI 24.8–63.5) (GBD 2023). Oral ferrous sulphate costs one to three dollars a patient-year. **Vitamin B12 and folate deficiency** ends with replacement that is dietary or nearly so; mandatory folic acid fortification of flour roughly halves neural tube defect risk where it is introduced, and roughly 60 countries had

mandatory fortification as of the 2023 Oxford systematic review of global fortification policies. **Protein-energy malnutrition** is the seventh: severe wasting is cured by food. Ready-to-use therapeutic food delivered through outpatient community programmes recovers roughly 80 to 90 per cent of children with case fatality under 5 per cent, against historical inpatient case fatality of 20 to 30 per cent†. The cost is roughly US$35 to US$50 for a full six-to-eight-week course at procurement prices, 2024†. The instrument that finds the cases is a paper tape measuring mid-upper arm circumference, and a mother can use it on her own child.

Two more are diseases of the blood whose treatment is the removal of blood. **Haemochromatosis** loads iron because hepcidin stays low for the body's iron burden; each 500 mL unit removed takes 200 to 250 mg of iron with it†, and a homozygote de-ironed before cirrhosis has normal life expectancy. The consumables are a needle, a bag and a nurse, on the order of tens of US dollars a session in a public system; where the patient donates, the cost to the system is negative. In **polycythaemia vera** the lethal feature is thrombosis, and phlebotomy holds it: the CYTO-PV randomised trial compared a haematocrit target below 45 per cent with 45 to 50 per cent and found cardiovascular death or major thrombosis in 2.7 per cent against 9.8 per cent over a median 31 months (Marchioli et al., *NEJM*, 2013). Neither disease is cured — the genotype and the clone persist — but in both, the intervention that carries the benefit needs no patent and no supply chain.

The tenth is **phenylketonuria**, and it carries the qualification that the word simple needs. The heel-prick dried blood spot that detects it costs roughly one to five dollars within a multiplex panel, and it is the difference between normal development and severe permanent intellectual disability. The treatment is food. But the food is not food: the phenylalanine-free, tyrosine-enriched amino acid mixture that supplies the protein, vitamins and minerals the restricted diet cannot is a manufactured medical food from a small number of suppliers, and it costs roughly US$5,000 to US$25,000 a patient-year in high-income countries, 2024†. There is no generic pathway for medical foods. So the dietary treatment is cheap in principle and expensive in practice, and where the substitute is not reimbursed, families pay and adherence collapses. The same structure recurs through chapter 05: a condition detected for a few dollars and held by a product with no competitive market.

Set against those ten, the rest of the chapter runs the other way. Enzyme replacement for the lysosomal storage diseases costs roughly US$200,000 to US$600,000 a patient-year†. A single infusion of gene therapy for sickle cell disease was priced at about US$2.2 million on United States list (2023–2024)†. The published minimum sustainable production cost of biosimilar human insulin is US$72 a patient-year or less, and US$48 under high competition (Hill et al., *BMJ Global Health*, 2018), against United States analogue list prices that reached roughly US$275 to US$340 per 10 mL vial by 2019†. The chapter therefore holds both extremes of the book: the cheapest cures and the most expensive treatments in continuous long-term use in this chapter, on prices that are mostly, often for conditions that sit three entries apart.

**A standing note on medicine list status.** The governing edition of the WHO Model List of Essential Medicines is the 24th List, adopted by the 25th WHO Expert Committee in May 2025 and published September 2025 as WHO Technical Report Series 1064. The material this chapter was built from was checked against the previous edition throughout, so no listing claim in it could be carried across on its own authority. Where the status of a medicine was independently read off the electronic Model List in October 2026, it is given as read, including the distinction between a selected medicine and a therapeutic equivalent, which is load-bearing: a therapeutic equivalent is on the list as a permitted substitute, not as the selected medicine. Where it was not, the entry says the status needs checking against the 24th List, and the claim carries a dagger. The counts sometimes quoted for the 2025 lists — 523 medicines for adults and 374 for children — are not printed on the list's title page and remain unconfirmed.

—

# Diseases of the blood or blood-forming organs

## ICD-11 chapter 03

Twelve entries. The deficiency anaemias, the inherited haemoglobin and clotting disorders, marrow failure, iron overload, and two clonal diseases of the marrow.

---

### Iron deficiency anaemia

**What it is.** Too little iron in the body to build enough haemoglobin. Red cells become small and pale and the blood carries less oxygen. Tiredness, breathlessness and poor concentration follow.

**Measured.** Anaemia of all causes reached 1.92 billion cases in 2021, 24.3 per cent of the world population (95% UI 23.9–24.7), against 28.2 per cent and 1.50 billion in 1990 (GBD 2021 anaemia analysis, *The Lancet Haematology*, 2023). Anaemia accounted for 52.0 million years lived with disability in 2021 (95% UI 35.1–75.1), with dietary iron deficiency the single largest contributor at a YLD rate of 422.4 per 100,000 (95% UI 286.1–612.9). In the GBD 2023 cycle, dietary iron deficiency ranks ninth among all causes of YLDs worldwide at 39.3 million (95% UI 24.8–63.5).

WHO estimates for the 2019 reference year give anaemia in 30 per cent of women of reproductive age, about 571 million women; 37 per cent of pregnant women; and 40 per cent of children aged 6 to 59 months, about 269 million children (WHO, 12 May 2023). The WHO and GBD figures are not interchangeable: WHO uses survey haemoglobin against fixed cut-offs, GBD models across causes.

Two age peaks: children under five, and women across the reproductive years. Sub-Saharan Africa and South Asia carry a disproportionate share, and the YLD rate falls as Socio-demographic Index rises. Anaemia is coded mainly as a cause of disability rather than death, and deaths are attributed to the underlying causes — haemorrhage, malaria, hookworm — so there is no reliable separate global death count. The World Health Assembly target of halving anaemia prevalence in women of reproductive age by 2025 is not on track (WHO, 2023).

**Where it starts.** Low dietary iron intake and low bioavailability. Absorption of non-haem plant iron runs at roughly 2 to 10 per cent against roughly 15 to 35 per cent for haem iron from meat†. Phytate in cereals and legumes and polyphenols in tea and coffee inhibit absorption; ascorbic acid in the same meal increases it several-fold.

Blood loss. Menstrual loss dominates in women of reproductive age. Gastrointestinal loss — ulcer, cancer, non-steroidal anti-inflammatory drugs — dominates in men and post-menopausal women, and in that group iron deficiency is itself an indication to investigate for gastrointestinal cancer.

Hookworm (*Ancylostoma*, *Necator*) and schistosomiasis: GBD 2021 counts other neglected tropical diseases among the top three contributors to anaemia YLDs. Malaria, by haemolysis and by marrow suppression. Pregnancy raises iron requirement roughly three-fold over its course. Low birthweight and early cord clamping reduce the infant’s iron endowment,

and delayed clamping beyond one minute raises infant iron stores measurably at four to six months.

Not a heritable disease. Haemoglobin concentration itself is heritable, with twin and family estimates in the range 0.2 to 0.4†, and variants in *TMPRSS6* and the *HFE* region shift iron indices without causing the deficiency.

*Not known*: the quantitative split between dietary inadequacy, chronic blood loss and infection at population level in most low- and middle-income countries. The three overlap and surveys rarely measure all three in the same people. Also unresolved: how much measured anaemia in inflammatory settings is iron deficiency rather than anaemia of inflammation, since ferritin rises with inflammation and the correction factors are contested.

**Cure status.** CURABLE. Replacing iron and stopping the loss returns haemoglobin to normal and ends the disease. Oral ferrous salts raise haemoglobin by roughly 1 g/dL per two to three weeks in uncomplicated deficiency, and full repletion of stores takes about three months of continued dosing after haemoglobin normalises. Intravenous iron corrects faster, in days to weeks. The cure is not durable while the cause of loss persists, so the cure is iron plus finding the bleeding source.

**Prevention.** Iron fortification of staple foods — wheat flour, maize flour, rice, condiments. The effect on anaemia at population level depends on the iron compound: ferrous sulphate and ferrous fumarate work, while the elemental iron powders used in older programmes are poorly absorbed. MODERATE overall; CONTESTED for programmes using elemental iron powders.

Double-fortified salt with iron and iodine, and iron-fortified fish and soy sauces: trials show reductions in iron deficiency, programme-scale data are thinner. MODERATE.

Antenatal iron and folic acid supplementation: standing WHO recommendation, reduces maternal anaemia at term. STRONG for maternal anaemia, weaker for birth outcomes.

Intermittent weekly rather than daily iron in menstruating women: effective, fewer side effects, better adherence. MODERATE.

Deworming in endemic areas with albendazole or mebendazole: the effect on haemoglobin is small per round and real where hookworm prevalence is high. MODERATE where hookworm is endemic, WEAK where it is not.

Malaria control with bed nets and seasonal chemoprevention reduces anaemia in children. STRONG in high-transmission settings.

Delayed cord clamping of at least one minute raises infant ferritin at four to six months. STRONG for the biochemical outcome.

Vitamin C with iron-containing meals increases non-haem absorption several-fold in metabolic studies. STRONG for absorption, WEAK for anaemia outcomes at population scale.

**Treatment.** Oral ferrous sulphate, fumarate or gluconate is first-line, at roughly one to three US dollars a patient-year of daily tablets at international generic prices (2024)†. Alternate-day dosing raises fractional absorption by limiting the hepcidin rise and is current practice in several guidelines. EML status needs checking against the 24th List†.

Intravenous iron — ferric carboxymaltose, iron sucrose, iron isomaltoside, low-molecular-weight iron dextran — where oral iron is not absorbed or not tolerated. An iron sucrose course runs roughly US$50 to US$150 (2024)†; ferric carboxymaltose in high-income markets runs roughly US$300 to US$1,500 a course on list prices, with wide variation (2024)†. Iron sucrose and iron dextran are off-patent; ferric carboxymaltose partly so, with generics entering. The listing status of iron dextran and of the newer high-dose single-infusion products needs checking against the 24th List†.

Treating the cause: endoscopy and treatment of the bleeding lesion; tranexamic acid or hormonal management for heavy menstrual bleeding. Tranexamic acid is a selected medicine on the 24th List, in section 10.2, medicines affecting coagulation, for haemorrhage not elsewhere classified and for postpartum haemorrhage; it is off-patent, at US$5 to US$20 per treated cycle-course at generic or lowest available acquisition cost, 2024†.

Transfusion is for haemodynamic compromise only, not for correcting iron deficiency.

**Simple means.** An iron cooking pot, or an iron ingot in the pot. Trials of cast-iron cookware and of the iron-fish ingot show measurable haemoglobin gains in deficient populations, with modest effect sizes that vary with food acidity and cooking time. No industrial chain.

A vitamin C source eaten with the meal — citrus, guava, tomato, raw leafy greens. Several-fold increase in non-haem absorption from the same meal.

Moving tea and coffee away from mealtimes. Tannins cut non-haem absorption sharply, and separating the drink from the meal removes the inhibition.

Soaking, germinating and fermenting cereals and legumes. Phytate falls and iron bioavailability rises. Traditional practice with a measurable effect.

Small amounts of meat, offal, fish or blood foods. Haem iron is absorbed several times better than non-haem and raises the absorption of non-haem iron eaten with it.

Latrines and footwear in hookworm areas, which break the transmission route. Delayed cord clamping at birth, which costs nothing.

**Gaps.** GBD 2023 disease-specific anaemia figures were not retrievable; the GBD 2021 analysis is used and labelled, except for the dietary iron deficiency YLD rank, which is GBD 2023. The haemoglobin threshold for anaemia is itself contested: the long-standing WHO cut-offs of 12 g/dL in non-pregnant women and 13 g/dL in men derive from a small mid-twentieth-century reference population, and WHO published revised thresholds in 2024 that are not yet reflected in most published prevalence estimates†. Whether population-wide iron fortification is net beneficial in malaria-endemic settings is contested, following trials in which iron supplementation in such settings was associated with increased malaria morbidity in children.

---

## Vitamin B12 and folate deficiency

**What it is.** Too little vitamin B12 or folate to build red cells. The marrow makes large immature cells and too few of them. B12 deficiency also damages nerves and the spinal cord, which folate deficiency does not.

**Measured.** B12 deficiency prevalence is reported at about 6 per cent under age 60 and about 20 per cent over 60 in the United States and United Kingdom, about 40 per cent in Latin America, and 70 to 80 per cent in parts of Africa and India, with marginal depletion in up to 40 per cent of Western populations†. These are compilations of heterogeneous surveys using different assays and cut-offs, and the same compilation gives two conflicting figures for Africa, 80 per cent in one place and 70 in another.

Pernicious anaemia, the autoimmune loss of intrinsic factor, affects about 2 to 3 per cent of people over 65 and is the main cause of B12 deficiency anaemia in high-income countries†.

For folate, the micronutrient survey synthesis of Stevens et al., *Lancet Global Health*, 2022 found that 1.2 billion non-pregnant women of reproductive age (1.0–1.4 billion), 69 per cent, had at least one of iron, zinc or folate deficiency, and that 372 million preschool children (319–425 million), 56 per cent, had at least one of iron, zinc or vitamin A deficiency.

B12 deficiency rises steeply with age through malabsorption and atrophic gastritis. Folate deficiency clusters in pregnancy, alcohol use disorder, malabsorption, and populations eating little fresh green food. Neither is separately counted in global mortality.

**Where it starts.** B12 malabsorption, not low intake, is the main mechanism in high-income countries: autoimmune destruction of gastric parietal cells, gastrectomy or bariatric surgery, terminal ileal disease or resection, achlorhydria, bacterial overgrowth, fish tapeworm. Low intake is the main mechanism where animal foods are scarce or avoided, because B12 occurs essentially only in animal-source foods and fortified products, and unsupplemented vegan diets reliably produce deficiency over years.

Long-term metformin and long-term proton pump inhibitors or H2 blockers reduce B12 absorption. The association is consistent; the causal size per year of exposure is not firmly quantified.

Folate: low intake of green vegetables, legumes and fortified cereals; alcohol; pregnancy, which roughly doubles requirement; haemolysis and other high-turnover states; methotrexate, trimethoprim, phenytoin, sulfasalazine.

*MTHFR* C677T homozygosity raises homocysteine and lowers red cell folate modestly. *FUT2* and *TCN1/TCN2* variants shift B12 concentrations. Transcobalamin II deficiency and Imerslund-Gräsbeck syndrome are rare monogenic causes. Heritability of serum B12 is estimated at 0.3 to 0.6 in twin studies†.

*Not known*: what serum B12 concentration marks functional deficiency. Serum B12 is a poor marker; methylmalonic acid and holotranscobalamin are better but not standardised, so the prevalence figures above are method-dependent and not comparable between studies. Also not known: whether treating biochemically low B12 without symptoms changes any outcome.

**Cure status.** Dietary B12 deficiency and folate deficiency: CURABLE. Replacement corrects the deficiency state completely, and the replacement is dietary or near-dietary. The macrocytic anaemia resolves within weeks. Neurological damage from B12 deficiency is only partly reversible and reversibility falls with the duration before treatment; long-standing subacute combined degeneration of the cord does not fully recover. Where the cause is permanent malabsorption, the replacement is lifelong: CONTROLLABLE. Folate deficiency is CURABLE, fully, by folate, with the caveat that giving folate to someone with untreated B12 deficiency corrects the anaemia and lets the neurological damage proceed.

**Prevention.** Mandatory folic acid fortification of flour is the single largest documented prevention effect in this entry. Pooled and country-level before-and-after data show roughly a halving of neural tube defect risk where mandatory fortification was introduced (Oxford CTSU/NDPH systematic review of global fortification policies, 2023). STRONG. Coverage remains partial: roughly 60 countries had mandatory folic acid fortification as of that review, and the majority of preventable neural tube defects worldwide were still not being prevented.

Periconceptional folic acid supplementation at 400 µg a day from before conception. The MRC Vitamin Study (1991) and the Chinese community trial showed large reductions in recurrence and occurrence. STRONG. The limitation is that it requires a planned pregnancy, which is why fortification outperforms it at population level.

B12 supplementation or fortification for populations eating little animal food, and for people on long-term metformin or proton pump inhibitors. MODERATE.

B12 supplementation in vegan and strict vegetarian diets, which prevents a deficiency that otherwise reliably occurs. STRONG.

**Treatment.** Hydroxocobalamin or cyanocobalamin intramuscularly is standard for pernicious anaemia and for neurological presentations, at US$5 to US$30 a patient-year on a maintenance schedule of injections every two to three months, at generic or lowest available acquisition cost, 2024†. EML status needs checking against the 24th List†.

High-dose oral cyanocobalamin at 1,000 to 2,000 µg a day is absorbed passively, independent of intrinsic factor. Randomised comparisons show haematological equivalence to injections in most patients; the evidence is weaker for severe neurological disease and at least one review holds oral inferior there. US$5 to US$20 a patient-year at generic or lowest available acquisition cost, 2024†. EML status needs checking against the 24th List†.

Folic acid, oral, 1 to 5 mg a day for folate deficiency, at under two dollars a patient-year (2024)†. EML status needs checking against the 24th List†.

Treating the underlying cause: stopping or monitoring the implicated drug; treating coeliac disease, bacterial overgrowth or parasitic infection.

**Simple means.** Any regular animal-source food — milk, eggs, offal, small fish eaten whole, shellfish, blood foods. A few portions a week prevents dietary B12 deficiency outright.

Green leafy vegetables, legumes and citrus for folate. Folate is heat-labile, so lightly cooked or raw matters. A mixed diet including these prevents folate deficiency outright.

Fermented foods are unreliable as a B12 source. Amounts vary, the common claim that fermented plant foods or algae supply enough B12 does not hold, and spirulina contains pseudo-B12 that is not active in humans.

Not relying on folate alone where B12 status is unknown. A simple means that prevents harm.

Fortified flour needs a mill, so it is not a no-chain measure, but it is the cheapest prevention in this chapter: fortification cost is on the order of two to ten cents per person per year.

**Gaps.** The regional B12 prevalence figures rest on secondary compilations using different assays and cut-offs and are indicative, not comparable. No current global estimate of B12 deficiency burden exists with the methodological standing of the GBD anaemia estimates. The pooled effect of mandatory folic acid fortification on neural tube defects varies between reviews, roughly 30 to 60 per cent depending on baseline prevalence, fortification level and ascertainment; the about-half figure is the Oxford review's summary and the full text could not be retrieved, so the precise pooled estimate and interval are not reproduced. Oral against intramuscular B12 for neurological disease: sources disagree. Whether folic acid fortification affects cancer risk or masks B12 deficiency at population scale remains contested; large trials and meta-analyses have not shown a cancer signal and the debate persists.

---

## Sickle cell disease

**What it is.** An inherited change in one letter of the haemoglobin gene. The haemoglobin clumps when oxygen is low, red cells stiffen into crescents and block small vessels. Pain crises, anaemia, infection, stroke and organ damage follow.

**Measured.** The WHO sickle cell disease fact sheet, for the 2021 reference year, gives 7.74 million people living with the disease worldwide and about 515,000 births a year. Sub-Saharan Africa carries nearly 80 per cent of cases. There were 81,100 deaths in children under five in 2021, the twelfth leading cause of under-five death. Total deaths with sickle cell disease as a contributing cause were about 376,000, roughly eleven times the 34,400 deaths that cause-specific coding attributes to it. That gap is itself a measurement finding: most sickle cell deaths are recorded under infection, stroke or anaemia.

In untreated settings death clusters in the first five years, from infection, splenic sequestration and severe anaemia. Where newborn screening, penicillin prophylaxis, vaccination and hydroxyurea exist, survival into the fifth and sixth decade is routine. The sickle allele reaches carrier frequencies of 10 to 25 per cent across a malaria belt from West Africa through Central Africa to parts of India, the Arabian peninsula and the Mediterranean, with diaspora populations in Europe, the Americas and the Gulf.

**Where it starts.** A single fully established cause: homozygosity for the *HBB* Glu6Val allele, or compound heterozygosity as HbSC or HbS/β-thalassaemia. Heritability is 1.0 for having the disease.

Why the allele is common: heterozygote advantage against *Plasmodium falciparum*. Sickle cell trait reduces the risk of severe falciparum malaria by roughly 90 per cent in case-control and cohort studies†, one of the largest single-locus protective effects known in human genetics, and the established reason the allele reaches 10 to 25 per cent carrier frequency in malarious regions and near zero elsewhere.

What modifies severity at the same genotype: co-inherited α-thalassaemia; fetal haemoglobin level, which is the strongest single severity modifier and is shifted by *BCL11A*, *HBS1L-MYB* and the *HBG* promoter; *UGT1A1* for gallstones; *APOL1* for kidney disease. Crisis triggers are dehydration, cold, infection, hypoxia, acidosis and physical stress; the associations are consistent and the per-exposure risk is not well quantified.

*Not known*: why two people with the same genotype and the same fetal haemoglobin can have ten-fold different crisis rates. Most of the variance in severity is unexplained. Also not known: why chronic pain develops in some patients and not others, and whether it is the same process as acute vaso-occlusion.

**Cure status.** With a matched sibling donor transplant: CURABLE. With gene therapy: CONTROLLABLE. Without access to either: CONTROLLABLE. A cure by gene therapy is plausible and has not been demonstrated: the pivotal follow-up is 24 months and durability beyond that is unknown by construction.

Allogeneic haematopoietic stem cell transplant from a matched sibling donor is the oldest curative route, with event-free survival in children reported around 90 per cent and overall survival around 95 per cent in large series†. The ceiling is donor availability: roughly 15 to 18 per cent of patients have a matched sibling†. Haploidentical transplant extends eligibility and is in active trials with higher rejection and graft-versus-host disease rates.

Exagamglogene autotemcel edits the *BCL11A* erythroid enhancer in autologous CD34+ cells to raise fetal haemoglobin. In the pivotal single-arm trial, 44 patients were treated and, of 31 with sufficient follow-up, 29 (93.5 per cent) had at least 12 consecutive months free of severe vaso-occlusive crises over 24 months of follow-up; all engrafted, with no graft failure or rejection. Approvals: United Kingdom November 2023, Bahrain December 2023, United States December 2023 for sickle cell disease, European Union conditional February 2024.

Lovotibeglogene autotemcel adds an anti-sickling β-globin gene by lentiviral vector. United States approval December 2023, with durable reduction in vaso-occlusive events in the pivotal programme and a boxed warning for haematological malignancy.

Price: exagamglogene autotemcel about US$2.2 million per treatment on United States list (2023–2024)†; lovotibeglogene autotemcel about 3.1 million (2023)†. ICER's 2023 assessment judged both potentially cost-effective at roughly US$2 million per treatment in a United States context†.

Both require myeloablative conditioning with busulfan, apheresis, cell manufacture and a transplant-capable centre. Nearly 80 per cent of the world's patients live in sub-Saharan Africa, where those chains do not exist. Fertility loss from conditioning, and durability and malignancy risk beyond ten years, are unresolved.

**Prevention.** This is a Mendelian disease, so prevention means preventing affected births rather than preventing onset in a person.

Carrier screening with genetic counselling. Cyprus, Sardinia and parts of Greece reduced affected thalassaemia births by more than 95 per cent with national programmes on the same model†. STRONG for the effect on birth prevalence in thalassaemia; MODERATE for sickle cell specifically, where there are fewer programmes and less published before-and-after data.

Newborn screening does not prevent the disease; it prevents early death. Where screening is paired with penicillin prophylaxis and pneumococcal conjugate vaccination, under-five mortality falls sharply, and United States death rates in children under four fell by about three-fifths to two-thirds across the period in which both were introduced. STRONG.

Daily penicillin prophylaxis in children under five: the PROPS trial found an 84 per cent reduction in pneumococcal septicaemia†. STRONG.

Pneumococcal and *Haemophilus influenzae* type b conjugate vaccination. STRONG.

Transcranial Doppler screening with transfusion in children with high velocities: the STOP trial found roughly a 90 per cent reduction in first stroke†. STRONG.

Preimplantation genetic testing and prenatal diagnosis are effective where available; availability, cost and acceptability vary by setting.

**Treatment.** Hydroxyurea (hydroxycarbamide) is the backbone. The Multicenter Study of Hydroxyurea in adults roughly halved the rate of painful crises, acute chest syndrome and transfusions, and long-term follow-up showed a mortality benefit. BABY HUG and the African trials REACH and NOHARM established safety and benefit in children, including in sub-Saharan Africa. Hydroxyurea is a selected medicine on the 24th List, in section 10.3, medicines for haemoglobinopathies, core list, for other specified sickle cell disorders and other haemoglobinopathies. Off-patent, at roughly US$30 to US$100 a patient-year at generic international prices (2024), and under US$50 in some African programmes†.

Penicillin V prophylaxis in young children, at roughly two to ten dollars a patient-year (2024)†. EML status needs checking against the 24th List†.

Folic acid routinely, under two dollars a year (2024)†. EML status needs checking against the 24th List†.

Transfusion, simple or exchange, for stroke prevention, acute chest syndrome, severe anaemia and preoperative optimisation. It requires a safe blood supply, which is the binding constraint in most high-burden countries. Chronic transfusion creates iron overload re-

quiring chelation: generic deferasirox runs US$1,000 to US$4,000 a patient-year at lowest available acquisition cost, 2024, and is falling†, and deferoxamine is cheaper per gram but needs subcutaneous infusion pumps. Deferasirox's listing status needs checking against the 24th List†. Deferiprone is on the 24th List only as a therapeutic equivalent to deferasirox, in section 10.3, for thalassaemias and for other specified sickle cell disorders and haemoglobinopathies — not as a selected medicine.

Analgesia for crisis, including opioids. Oral morphine is a selected medicine on the 24th List, in section 2.2, opioid analgesics, core list, for pain. Off-patent, with trivial drug cost; availability is the constraint, since opioid supply is restricted in many high-burden countries.

L-glutamine, approved in the United States in 2017, produced modest crisis reduction of roughly 25 per cent in its pivotal trial, with limited uptake†. Its EML status needs checking against the 24th List†.

Crizanlizumab, an anti-P-selectin antibody, reduced crisis rate in its pivotal trial; the confirmatory STAND trial did not meet its primary endpoint and the European authorisation was withdrawn in 2023 while the United States authorisation was retained. Sources disagree. EML status needs checking against the 24th List†.

Voxelotor, a haemoglobin polymerisation inhibitor, raised haemoglobin in trials; the manufacturer withdrew it worldwide in September 2024 after a safety signal of deaths and vaso-occlusive events in post-marketing and trial data. It is recorded here because it appears as a standing treatment in literature written before that date.

**Simple means.** Oral hydration and warmth. Dehydration and cold are established crisis triggers, and keeping warm and drinking enough is the cheapest crisis-reduction measure available.

Folic acid, a cent-level daily tablet.

Early recognition of fever and immediate presentation. In children, infection is the main killer, and the simple means is a caregiver who knows that fever in a child with sickle cell disease is an emergency. Education-only interventions have measurable mortality effects in African cohorts.

Insecticide-treated bed nets and malaria chemoprophylaxis in endemic areas, because malaria is a major precipitant of severe anaemia and death in these children.

Breastfeeding and routine childhood vaccination.

Newborn screening by heel-prick dried blood spot, which is low-cost and the gateway to all of the above. Point-of-care immunoassay devices now cost on the order of a few dollars per test and need no laboratory.

**Gaps.** The WHO fact sheet's own comparison of 376,000 deaths with sickle cell disease against 34,400 cause-specific deaths is a statement that global mortality is systematically under-recorded by about an order of magnitude. Prevalence estimates for sub-Saharan Africa rest largely on modelled allele frequencies and birth cohorts rather than measured patient counts, and the number of people living with the disease in Africa is unusually uncertain because survival is itself unmeasured across most of the region. Crizanlizumab: pivotal trial positive, confirmatory trial negative, European authorisation withdrawn, United States authorisation retained. Voxelotor's 2024 withdrawal postdates much of the published treatment literature. Long-term safety and durability of both gene therapies is unknown by construction, and no data exist on gene therapy delivered in any sub-Saharan African health system, where about 80 per cent of patients live.

---

## Thalassaemias

**What it is.** Inherited faults in making the globin chains of haemoglobin, alpha or beta. Too few chains means too little haemoglobin and red cells that die early. Severe forms need lifelong transfusion; mild forms cause only a small anaemia.

**Measured.** Carrier rates reach 2 to 18 per cent across the Mediterranean, the Middle East, South and Southeast Asia and southern China. WHO has historically used an estimate that about 1.5 per cent of the world population, roughly 80 to 90 million people, carries a β-thalassaemia allele†. WHO and Modell-derived estimates put severe β-thalassaemia births

at roughly 40,000 to 60,000 a year worldwide, the large majority in Asia†. Orphanet records the annual incidence of symptomatic β-thalassaemia as 1 in 100,000 worldwide and 1 in 10,000 in the European Union, and lists prevalence as unknown, with the entry last updated 2011.

GBD 2021 counts haemoglobinopathies and haemolytic anaemias together as the second largest contributor to anaemia YLDs, so thalassaemia-specific burden cannot be read off directly.

The geography is malaria-correlated, as with sickle cell. α-thalassaemia predominates in Southeast Asia and southern China, β-thalassaemia in the Mediterranean, the Middle East, the Indian subcontinent and Southeast Asia. β-thalassaemia major presents at 6 to 24 months as fetal haemoglobin falls. α-thalassaemia major, Hb Bart's hydrops fetalis, is lethal in utero or at birth unless treated with intrauterine transfusion.

No reliable separate global death count. In transfused patients the historical cause of death was iron-overload cardiomyopathy; with modern chelation, survival into the fifth and sixth decade is usual in well-resourced programmes.

**Where it starts.** β-thalassaemia: over 300 described mutations in *HBB* reducing (β+) or abolishing (β0) β-globin synthesis. Heritability 1.0 for the genotype. α-thalassaemia: deletions or mutations of *HBA1* and *HBA2*. There are four α genes and the number lost sets the phenotype — one silent, two trait, three HbH disease, four Hb Bart's hydrops.

Why common: heterozygote protection against malaria, as for sickle cell. The geographic correlation with historic malaria endemicity is among the clearest in population genetics.

Severity modifiers: co-inherited α-thalassaemia reduces β-thalassaemia severity by rebalancing chain production; fetal-haemoglobin-raising variants in *BCL11A*, *HBS1L-MYB* and the *HBG* promoter reduce severity; *UGT1A1* affects bilirubin and gallstones. Transfusion dependence is the key clinical division and is not fully predictable from genotype.

*Not known*: why transfusion dependence varies at identical genotype beyond the known fetal haemoglobin and α-gene modifiers. Also not known: the true global number of people living with thalassaemia, as distinct from modelled births.

**Cure status.** Allogeneic transplant, where accessible: CURABLE. Gene therapy, where accessible: CONTROLLABLE. Transfusion and chelation programme: CONTROLLABLE. A cure by gene therapy is plausible and has not been demonstrated: durability of both gene therapies is unknown by construction.

Allogeneic transplant from a matched sibling donor in a young, well-chelated patient gives thalassaemia-free survival around 85 to 90 per cent in large series, with the best results under age 14 and a low iron burden†. This has been a genuine cure since the 1980s, and the binding constraint is donor availability and the cost and infrastructure of transplant.

Betibeglogene autotemcel adds β-globin by lentiviral vector. Across the phase 3 studies, about 89 per cent of patients (32 of 36) achieved transfusion independence, defined as a weighted average haemoglobin of at least 9 g/dL without transfusion for at least 12 months†. United States approval August 2022 at a list price of US$2.8 million†; withdrawn from the European market in 2021–2022 over reimbursement, not safety.

Exagamglogene autotemcel for transfusion-dependent β-thalassaemia: United States approval January 2024, European Union February 2024, United Kingdom November 2023, with the majority of trial patients achieving transfusion independence.

Without transplant or gene therapy, lifelong transfusion plus chelation is CONTROLLABLE. Median survival in well-run programmes now exceeds 40 years and continues to rise†, and the disease and its treatment burden persist.

**Prevention.** Prevention of affected births, not of onset, and this entry holds the strongest population data in the chapter.

National carrier screening with counselling in Cyprus and Sardinia reduced β-thalassaemia major births by more than 95 per cent within one to two decades†. Cyprus combined premarital screening, with church cooperation, and prenatal diagnosis; Sardinia combined school and population screening with prenatal diagnosis. STRONG — these are national before-and-after datasets rather than trials, and the effect is unambiguous and replicated.

Iran's national premarital screening programme from 1997 reported reductions of roughly 70 per cent in expected affected births†. STRONG.

Prenatal diagnosis and, where accepted, preimplantation genetic testing. Acceptability is culturally and religiously variable, which is why the church-partnered Cypriot design is cited so often.

Newborn screening does not prevent thalassaemia; it prevents late diagnosis and early death in HbH and β-thalassaemia.

**Treatment.** Regular transfusion to maintain pre-transfusion haemoglobin around 9 to 10.5 g/dL in transfusion-dependent disease, which suppresses ineffective erythropoiesis and prevents skeletal deformity and splenomegaly. It requires a safe, screened blood supply — the binding constraint in most high-burden countries. Cost is dominated by collection and screening, on the order of thousands of US dollars a patient-year depending on the health system (2024)†.

Iron chelation, mandatory with chronic transfusion, since each unit adds about 200 mg of iron†. Deferoxamine by subcutaneous infusion over 8 to 12 hours, five to seven nights a week: drug cost US$500 to US$2,000 a patient-year at generic or lowest available acquisition cost, 2024, plus pump and consumables, with adherence the problem†. Deferasirox, oral once daily, generic from 2019–2020, at US$1,000 to US$4,000 a patient-year (2024), down from originator prices several times higher†. Deferiprone, oral and cardio-protective, with a risk of agranulocytosis requiring blood counts, at US$1,000 to US$3,000 a patient-year at generic or lowest available acquisition cost, 2024†. The listing status of deferoxamine and deferasirox needs checking against the 24th List†; deferiprone is on the 24th List only as a therapeutic equivalent to deferasirox, in section 10.3, and not as a selected medicine.

Luspatercept, an erythroid maturation agent. In the BELIEVE trial in transfusion-dependent β-thalassaemia, 21.4 per cent against 4.5 per cent of patients achieved at least a 33 per cent reduction in transfusion burden over weeks 13 to 24†. Patented, with a United States list price on the order of US$150,000 to US$200,000 a patient-year (2024)†. EML status needs checking against the 24th List†.

Hydroxyurea in some non-transfusion-dependent β-thalassaemia and HbE/β disease, at US$30 to US$100 a year at generic or lowest available acquisition cost, 2024†. Hydroxyurea is a selected medicine on the 24th List, in section 10.3, for other specified sickle cell disorders and other haemoglobinopathies.

Splenectomy reduces transfusion requirement in selected patients and is now used sparingly because of sepsis and thrombosis risk. It requires pneumococcal and meningococcal vaccination and penicillin prophylaxis afterwards.

Folic acid routinely, under two dollars a year (2024)†.

**Simple means.** Carrier testing before pregnancy. A full blood count showing microcytosis with normal iron, confirmed by haemoglobin electrophoresis or a single genetic test, costs a few dollars and is the whole basis of the Cyprus and Sardinia results.

Avoiding iron supplements unless iron deficiency is proven. Thalassaemia trait causes microcytosis that is routinely mistaken for iron deficiency, and iron given on that mistake adds to iron loading. A simple means that prevents harm.

Folic acid, cents a year.

Tea with meals is reversed here: in non-transfused thalassaemia, tea with meals is sometimes used deliberately to reduce dietary iron absorption. The evidence is thin, from small studies, so WEAK, and it costs nothing.

Avoiding raw shellfish, because *Vibrio vulnificus* risk is raised in iron overload, and avoiding alcohol where there is iron loading with liver involvement.

**Gaps.** No current, methodologically consistent global count of people living with thalassaemia. The widely quoted carrier and birth figures derive from Modell's modelling work and WHO compilations, some of it decades old, and Orphanet's own entry is marked as last updated 2011. GBD aggregates thalassaemias with other haemoglobinopathies and haemolytic anaemias. Gene therapy durability beyond roughly five to eight years is unknown, and the commercial withdrawal of betibeglogene autotemcel from Europe means European

long-term follow-up will be thin. Whether non-transfusion-dependent thalassaemia should be transfused, and when, is contested.

---

## Glucose-6-phosphate dehydrogenase deficiency

**What it is.** A common inherited shortage of an enzyme that protects red cells from oxidative damage. Most of the time nothing happens. Certain drugs, infections or fava beans then break red cells apart suddenly.

**Measured.** The most widely cited global figure is roughly 400 million people affected, derived from the Malaria Atlas Project geostatistical mapping of allele frequency across malaria-endemic and neighbouring countries (Howes et al., *PLoS Medicine*, 2012). Median allele frequency in that mapping was around 8 per cent across malaria-endemic countries, with national values from near zero to over 30 per cent in parts of sub-Saharan Africa, the Arabian peninsula and Southeast Asia.

The gene is X-linked, so hemizygous males carry the clinically important phenotype; homozygous and some heterozygous females are also affected, and heterozygous females have mosaic enzyme activity that standard tests may miss.

Geography follows variant: Africa the A− variant with moderate deficiency, the Mediterranean and Middle East the severe Mediterranean variant, Southeast Asia the Viangchan, Mahidol and Canton variants.

The measured clinical outcomes are neonatal jaundice and kernicterus — the deficiency is a leading identified cause of severe neonatal hyperbilirubinaemia in high-prevalence countries — acute haemolytic episodes, and primaquine or tafenoquine-induced haemolysis in malaria treatment. Deaths are not separately counted globally.

**Where it starts.** Over 200 described mutations in *G6PD* on the X chromosome. Heritability 1.0 for the genotype. The WHO class I to V grading by residual enzyme activity determines severity.

Why common: malaria selection, as with sickle cell and thalassaemia. The protective effect against *P. falciparum* is real but smaller and more contested in size than the sickle trait effect, and estimates differ between studies and between the sexes.

Established triggers of haemolysis: primaquine and tafenoquine, dapsone, nitrofurantoin, rasburicase, methylene blue, high-dose aspirin, some sulphonamides, naphthalene in mothballs, henna applied to neonatal skin, fava beans (*Vicia faba*), and infection itself. Chloroquine and most other antimalarials are safe at standard doses.

Neonatal jaundice risk is raised several-fold, and co-inherited *UGT1A1* promoter variants multiply it.

*Not known*: why individuals with the same variant have very different haemolytic responses to the same trigger dose; the true size of the malaria protective effect; and what proportion of global neonatal kernicterus is attributable to the deficiency, because screening coverage is lowest where prevalence is highest.

**Cure status.** CONTROLLABLE. Nothing restores G6PD activity. The clinical disease is almost entirely preventable by avoidance, and an acute haemolytic episode is self-limiting once the oxidant is stopped, resolving over days to weeks with supportive care and transfusion if severe. Neonatal jaundice is treated, by phototherapy and exchange transfusion, rather than cured. The honest statement is that nothing treats the deficiency and almost everything that matters is avoidance.

**Prevention.** Prevention here means preventing episodes, not preventing the genotype.

Testing before prescribing a known oxidant drug. The decisive measure, especially for primaquine and tafenoquine in malaria elimination programmes, where a single radical-cure dose can cause life-threatening haemolysis. STRONG.

Newborn screening in high-prevalence populations with follow-up for jaundice. Where it is implemented — parts of Southeast Asia, the Gulf, Greece, Sardinia — severe neonatal hyperbilirubinaemia and kernicterus fall. STRONG in high-prevalence settings.

A written list of drugs and foods to avoid, given to the person and the family. STRONG: mechanistically certain, and no trial is needed or possible.

Avoiding naphthalene mothballs and henna on neonatal skin in affected families. MODERATE, from consistent case series.

Point-of-care quantitative G6PD tests now exist and are being deployed in malaria programmes, shifting primaquine from contraindicated-by-caution to usable.

**Treatment.** Stop the trigger. No drug outperforms this.

Supportive care — hydration, monitoring of haemoglobin — and transfusion for severe haemolysis. Blood is not a listed medicine; transfusion is a service.

Phototherapy and exchange transfusion for neonatal hyperbilirubinaemia. Equipment rather than medicine. Phototherapy units are off-patent and cheap, and filtered-sunlight phototherapy has been trialled successfully in Nigeria as a no-electricity alternative.

Folic acid in chronic haemolysis, under two dollars a year (2024)†. EML status needs checking against the 24th List†.

Splenectomy only in the rare chronic non-spherocytic haemolytic anaemia caused by class I variants, not in ordinary deficiency.

No enzyme replacement and no gene therapy exists in clinical use.

**Simple means.** Avoidance of fava beans and of the listed drugs. Nothing else is required, and it is complete protection against those triggers.

A card in the wallet or a note in the family's records naming the condition. In practice the single most effective intervention in this entry.

Filtered sunlight phototherapy for neonatal jaundice, trialled in Nigeria by Slusher and colleagues and found non-inferior to conventional phototherapy for efficacy and safe with monitoring. No electricity needed.

Breastfeeding support and early feeding, which reduce neonatal hyperbilirubinaemia generally.

Not using mothballs in clothing and bedding stores in affected households.

**Gaps.** The 400 million figure is modelled, not counted, and dates from 2012; no more recent global count with comparable method exists. Heterozygous females are systematically underdetected by qualitative screening tests, so prevalence in females is uncertain and clinical risk in that group is poorly quantified. The size of the malaria protective effect is contested across studies. The attributable fraction of global kernicterus is unknown. WHO class assignments for many of the 200-plus variants rest on small enzyme-activity datasets.

---

## Aplastic anaemia

**What it is.** The bone marrow stops making blood cells. Red cells, white cells and platelets all fall. It is usually an immune attack on marrow stem cells rather than a cancer or a poisoning.

**Measured.** Incidence is 0.7 to 4.1 cases per million per year worldwide, roughly equal between men and women. Asian incidence is two to three times higher than Western, one of the firmest findings in the epidemiology and unexplained. The United States sees about 300 to 900 new cases a year†. Age shows two peaks, 15 to 25 years and over 60, and the disease can occur at any age. Orphanet lists prevalence of acquired idiopathic aplastic anaemia as 1 to 9 per million, with the entry marked as under development and no incidence given.

Survival with modern treatment exceeds 85 per cent at five years†. Allogeneic transplant recipients exceed 75 per cent at five years, better with a matched sibling donor and worse with unrelated donors. Immunosuppression alone in frail older patients or those without a good donor match gives five-year survival up to 35 per cent in the cited series†. Untreated severe disease is usually fatal within months from infection or haemorrhage. No reliable global death count.

**Where it starts.** Idiopathic, immune-mediated disease is the large majority. One source gives about half as idiopathic, another 75 per cent, and the figures conflict†. The mechanism

is a T-cell attack on haematopoietic stem cells, and the evidence for it is that immunosuppression works.

Drugs and chemicals: chloramphenicol, the historical association; carbamazepine, phenytoin, gold, sulphonamides, non-steroidal anti-inflammatory drugs, benzene and other organic solvents, insecticides. The reactions are idiosyncratic, so per-exposure risk is tiny and hard to estimate; the association with benzene is dose-related and firm.

Viruses: parvovirus B19, seronegative hepatitis-associated aplastic anaemia, Epstein-Barr virus, cytomegalovirus, HIV. Radiation, dose-dependent and established. Pregnancy, a recognised rare association.

Inherited marrow failure syndromes underlie a minority, especially in children and young adults: Fanconi anaemia, telomere biology disorders (*TERT*, *TERC*, *DKC1*), Shwachman-Diamond syndrome, GATA2 deficiency. These must be excluded before transplant, because the conditioning regimen differs.

Clonal haematopoiesis: paroxysmal nocturnal haemoglobinuria clones and 6p loss-of-heterozygosity clones are found in a substantial minority and predict response to immunosuppression.

Acquired aplastic anaemia is not heritable. The inherited syndromes that mimic it are Mendelian.

*Not known*: what the immune attack is directed against — no autoantigen is established. Why incidence is two to three times higher in Asia. Which drug exposures carry real risk at what dose, since the events are too rare for cohort quantification. Why some patients respond to immunosuppression and others do not, beyond the partial predictive value of clone status and telomere length.

**Cure status.** Eligible for allogeneic transplant: CURABLE. Treated by immunosuppression: CONTROLLABLE.

Allogeneic transplant from a matched sibling donor in a young patient is the established cure, with five-year survival above 75 to 90 per cent depending on age and donor†. The marrow is replaced and the disease does not return.

Horse antithymocyte globulin with ciclosporin produces response in up to 80 per cent of patients with severe disease in the cited series† — response, not cure. Relapse occurs in roughly a third, and clonal evolution to myelodysplastic syndrome or acute myeloid leukaemia in roughly 10 to 15 per cent over a decade†.

Eltrombopag added to antithymocyte globulin and ciclosporin raises complete response rates substantially over the two-drug regimen in the NIH and RACE trials, and is now standard first-line in several guidelines. Still control rather than cure.

**Prevention.** Removing benzene and solvent exposure in occupational settings. The risk is dose-related, so exposure reduction is expected to reduce incidence. MODERATE: occupational cohort evidence, no trial.

Restricting chloramphenicol to indications where nothing else serves. The historical measure, taken on case-series grounds. WEAK — the association is accepted, the magnitude was never well quantified, and the restriction was never trialled.

Hepatitis B vaccination removes one viral trigger. WEAK for this outcome specifically, because hepatitis-associated aplastic anaemia is usually seronegative.

There is no established primary prevention for idiopathic immune aplastic anaemia. The dominant form of this disease has no known prevention.

**Treatment.** Allogeneic transplant, first-line for severe disease in patients under about 40 with a matched sibling. Not a medicine; cost in high-income settings is US$150,000 to US$500,000 per transplant (2024)†.

Horse antithymocyte globulin with ciclosporin and eltrombopag, first-line where transplant is unavailable or the patient is older. Horse antithymocyte globulin is a biologic with limited manufacturers and has had repeated global supply interruptions; a course costs US$15,000 to US$40,000 (2024) with wide variation†. Ciclosporin is off-patent at US$300 to US$1,500 a patient-year (2024)†. Eltrombopag has been off-patent since roughly 2023–2025 in several markets; the originator price was US$50,000 to US$100,000 a patient-year (2023), generic

prices are falling, and Indian generics have been reported at low thousands of dollars a year. The listing status of all three needs checking against the 24th List†.

Supportive care — red cell and platelet transfusion, antibiotics and antifungals for neutropenic infection, iron chelation after prolonged transfusion. This is what determines survival where the specific treatments are unavailable.

Androgens, danazol and oxymetholone: older treatment, still used for telomere biology disorders, where danazol lengthens telomeres measurably in a small trial. Off-patent and cheap, in the low hundreds of dollars a year. EML status needs checking against the 24th List†.

Cyclophosphamide-based regimens were abandoned as first-line after unacceptable fungal infection mortality in NIH trials.

**Simple means.** Almost none, and that should be said plainly. Aplastic anaemia requires transfusion support, immunosuppression or a transplant. There is no dietary, behavioural or low-technology treatment.

Avoiding the implicated drug or solvent where one is identified: complete and free.

Infection avoidance during neutropenia — hand hygiene, avoiding crowds, food hygiene — reduces infection risk at no cost, though trial evidence for each component is thin.

A safe blood supply is the one simple requirement that is in fact the hardest in low-income settings.

**Gaps.** Sources conflict on the proportion of idiopathic cases, about half against 75 per cent. The two-to-three-fold higher incidence in Asia is reported consistently and explained nowhere. Orphanet's prevalence of 1 to 9 per million and the incidence literature of 0.7 to 4.1 per million per year are not reconcilable without survival data, which are not reported. No autoantigen is identified, so the immune mechanism remains inferred from treatment response. Horse antithymocyte globulin supply is a recurring global problem that no price figure captures. Generic eltrombopag prices are moving fast.

---

## Haemophilia A and B

**What it is.** An inherited shortage of a clotting factor — factor VIII in haemophilia A, factor IX in haemophilia B. Bleeding into joints and muscles happens without obvious injury, and joints are destroyed over years if the bleeding is not prevented.

**Measured.** Prevalence at birth per 100,000 males, from the meta-analysis that tripled previous estimates (Iorio et al., *Annals of Internal Medicine*, 2019): haemophilia A all severities 24.6, severe haemophilia A 9.5, haemophilia B all severities 5.0, severe haemophilia B 1.5. The global estimate from that analysis is about 1,125,000 males with haemophilia, of whom about 418,000 have severe disease; earlier estimates had put the global total near 400,000.

Identified and reported to the World Federation of Hemophilia Annual Global Survey, 2023 data published October 2024, with 119 countries reporting: haemophilia A 179,703; haemophilia B 37,385; haemophilia of unknown type 1,716; von Willebrand disease 101,128; other bleeding disorders 70,698; total identified 390,630.

The gap between about 1,125,000 estimated and about 219,000 haemophilia cases identified is the central measured fact about this disease: roughly four out of five people with haemophilia worldwide have not been identified.

The life expectancy shortfall, expressed by Iorio and colleagues as the reduction in the chance of a normal-length life, is about 64 per cent in upper-middle-income countries, 77 per cent in middle-income countries and up to 93 per cent in low-income countries†.

Severity by residual factor activity: severe below 1 per cent, moderate 1 to 5 per cent, mild 5 to 40 per cent. Haemophilia A is roughly 85 per cent of all haemophilia†. The inheritance is X-linked recessive, so cases are almost entirely male; symptomatic carrier females occur and are under-recognised. Severe disease presents in the first two years.

**Where it starts.** Loss-of-function variants in *F8* or *F9* on the X chromosome. Heritability 1.0 for the genotype. About 30 per cent of cases are new mutations with no family history†, and the *F8* intron 22 inversion is the single commonest severe mutation.

Phenotype correlates with residual factor activity more tightly than in almost any other genetic disease, which is why severity classes are defined by assay rather than by symptoms.

Inhibitor development — neutralising antibodies to infused factor — occurs in roughly 25 to 30 per cent of severe haemophilia A and 3 to 5 per cent of haemophilia B†. Risk factors are null mutations, non-white ethnicity, family history of inhibitors, and intensive early exposure during an immune-challenge event such as surgery; HLA and *IL10*, *TNFA* and *CTLA4* variants modify risk.

Joint damage results from repeated haemarthrosis, through iron-driven synovitis.

*Not known*: why inhibitors develop in some patients with identical mutations and not others — the known risk factors explain only part of the variance. Why some people with the same factor level bleed much more than others. Whether low-dose prophylaxis regimens used in resource-limited settings give the same joint outcomes as standard-dose regimens over decades.

**Cure status.** CONTROLLABLE.

Prophylactic factor replacement from early childhood prevents most joint damage and gives near-normal life expectancy where it is sustained. It does not cure: stop the infusions and the disease returns unchanged.

Emicizumab, a bispecific antibody bridging factor IXa and factor X, works with or without inhibitors. The HAVEN programme showed reductions in treated bleed rate against no prophylaxis on the order of 87 to 96 per cent in the inhibitor and non-inhibitor cohorts†. Subcutaneous, weekly to monthly. Control, not cure.

Gene therapy for haemophilia B: etranacogene dezaparvovec, a single AAV5 infusion. The HOPE-B trial showed sustained factor IX activity around 36 to 39 per cent at 18 to 24 months with about a 64 per cent reduction in annualised bleeding rate against the prophylaxis lead-in, and most patients off prophylaxis. United States approval November 2022, at a list price of US$3.5 million — the most expensive medicine in the world at launch†. Fidanacogene elaparvovec followed in April 2024 at the same list price, and commercialisation was discontinued in 2025 for lack of uptake.

Gene therapy for haemophilia A: valoctocogene roxaparvovec, a single AAV5 infusion. The GENEr8-1 trial showed a large reduction in annualised bleeding, but factor VIII expression declines year on year, which is the central unresolved problem. United States approval June 2023 at a list price of US$2.9 million†; commercialisation was scaled back in 2024 for lack of uptake.

So haemophilia B gene therapy looks durable so far and may be a cure; haemophilia A gene therapy has falling expression and is not yet one. Both are priced beyond all but a handful of health systems, and both have been commercial failures, which affects whether they will remain available at all.

**Prevention.** No primary prevention of the genotype other than carrier detection, genetic counselling, prenatal diagnosis and preimplantation genetic testing where available and acceptable.

Prevention of joint destruction by prophylaxis rather than on-demand treatment. The Joint Outcome Study randomised boys with severe haemophilia A to prophylaxis or enhanced episodic treatment: 93 per cent of the prophylaxis group had normal index-joint MRI at age six against 55 per cent of the episodic group, odds ratio 6.1 (Manco-Johnson et al., 2007). STRONG. This trial is the reason prophylaxis is standard everywhere it can be afforded.

Low-dose prophylaxis in resource-limited settings: observational and small trial data show substantial bleed reduction at a fraction of the factor consumption. MODERATE.

Inhibitor prevention by avoiding factor exposure during immune-challenge events is advised on observational grounds. WEAK.

Prevention of transfusion-transmitted infection, the historical catastrophe of this disease. Viral inactivation of plasma-derived concentrates and the move to recombinant product eliminated HIV and hepatitis C transmission in treated populations, and HIV transmission via factor concentrate in high-income countries fell to zero after 1985–1987†. STRONG, and measured.

**Treatment.** Factor VIII or factor IX concentrate, prophylactic: plasma-derived or recombinant, standard half-life or extended half-life. This is the dominant cost in haemophilia care. Standard prophylaxis for an adult in a high-income country runs US$150,000 to US$300,000 a patient-year (2024)†; plasma-derived product at tendered prices in middle-income countries can be US$20,000 to US$60,000 a patient-year†; low-dose regimens used in India and China run US$2,000 to US$10,000 a patient-year†. Plasma-derived product is off-patent, recombinant standard half-life only partly so, and extended half-life not at all. The listing status of factor VIII and factor IX concentrates needs checking against the 24th List†. The World Federation of Hemophilia Humanitarian Aid programme supplies donated concentrate to low-income countries, which is how a large share of the world's treated patients are treated at all.

Emicizumab for haemophilia A with or without inhibitors, at US$400,000 to US$500,000 a patient-year on United States list (2024), with confidential discounts and tiered pricing, and some middle-income tenders far lower. Patented. EML status needs checking against the 24th List†.

Desmopressin for mild haemophilia A only, raising endogenous factor VIII three- to five-fold, at US$10 to US$100 per treatment episode at generic or lowest available acquisition cost, 2024†. Off-patent. The cheapest effective treatment in this entry, and usable without a cold chain in the nasal or subcutaneous form. EML status needs checking against the 24th List†.

Tranexamic acid as an adjunct for mucosal bleeding and dental procedures, at one to ten dollars a course (2024)†. Tranexamic acid is a selected medicine on the 24th List, in section 10.2, for haemorrhage not elsewhere classified.

Immune tolerance induction for inhibitors — high-dose factor over months to years — succeeds in roughly 60 to 80 per cent of haemophilia A and is extremely expensive†.

Bypassing agents for inhibitor patients: activated prothrombin complex concentrate and recombinant activated factor VII, both very expensive. Their listing status needs checking against the 24th List†.

Physiotherapy and joint care, radiosynovectomy or surgical synovectomy for target joints, and joint replacement for end-stage arthropathy.

**Simple means.** Immediate rest, ice, compression and elevation for a joint bleed, with prompt factor if available. Costs nothing and reduces the volume of blood in the joint.

Desmopressin for mild haemophilia A: no factor concentrate, and no cold chain in some formulations.

Tranexamic acid for mouth and nose bleeding and before dental work. Cents a dose.

Physiotherapy and muscle strengthening around target joints, with observational evidence for reduced bleed frequency and no industrial chain.

Avoiding intramuscular injections, aspirin and non-steroidal anti-inflammatory drugs. Free, and it prevents bleeds.

Dental hygiene, which prevents the extractions that cause major bleeding episodes.

Family and patient education, and a treatment card. In countries without diagnosis, the simple means that matters most is case-finding: the World Federation of Hemophilia data show four in five patients worldwide are not identified, so a clinician who recognises recurrent joint swelling in a boy is the binding intervention, and that costs nothing.

**Gaps.** The central gap is diagnostic: about 1,125,000 estimated against about 219,000 identified, so all burden, outcome and cost figures for low-income countries describe the identified minority. Iorio and colleagues tripled the prior prevalence estimate in 2019, and estimates may move again. Factor concentrate prices vary by more than an order of magnitude between settings and are usually confidential, so every cost figure here is approximate. Long-term durability of haemophilia A gene therapy is not established, and expression falls. Commercial withdrawal of fidanacogene elaparvovec in 2025 and scaled-back commercialisation of valoctocogene roxaparvovec in 2024 mean availability may not follow approval. Symptomatic female carriers are under-counted in every dataset here. Whether low-dose prophylaxis gives equivalent 30-year joint outcomes is unknown.

## Von Willebrand disease

**What it is.** A shortage or malfunction of von Willebrand factor, the protein that makes platelets stick to damaged vessel walls. Bruising, nosebleeds, heavy periods and bleeding after surgery or childbirth are the usual signs. It is the commonest inherited bleeding disorder.

**Measured.** Laboratory prevalence is about 1 per cent of the population, roughly 1 in 100, with men and women equally affected; most of these people have no symptoms. Clinically significant prevalence is about 1 in 10,000†. The two-order-of-magnitude gap between the laboratory and clinical figures is the defining measurement feature of this disease, and the two are not describing the same thing.

Identified worldwide: 101,128 people in the World Federation of Hemophilia Annual Global Survey 2023 data, 119 countries reporting, published October 2024 — against an expected clinically significant population of roughly 800,000 at 1 in 10,000 of world population†.

Type distribution: type 1, partial quantitative deficiency, 40 to 80 per cent of cases; type 2, qualitative defects in subtypes 2A, 2B, 2M and 2N, 15 to 50 per cent, with type 2A alone 10 to 15 per cent of all cases; type 3, near-complete deficiency, recessive and severe, rare†. The ranges overlap widely between sources, which means the underlying case series are not comparable.

Equal by genotype, but women carry the clinical burden, because menstruation and childbirth are the main haemostatic challenges. Heavy menstrual bleeding is the presenting feature in a large majority of diagnosed women. Deaths are not separately counted; postpartum haemorrhage is the main mortality route.

**Where it starts.** Variants in *VWF* on chromosome 12. Type 1 is usually autosomal dominant with incomplete penetrance, type 3 recessive, and the type 2 subtypes dominant or recessive depending on subtype.

ABO blood group is a major determinant of von Willebrand factor concentration: group O individuals have levels roughly 25 to 30 per cent lower than non-O†. A substantial share of type 1 diagnoses in group O people therefore reflects the low end of a normal distribution rather than a disease allele, which is one reason the diagnostic threshold is contested.

Heritability of plasma von Willebrand factor concentration is around 0.6 to 0.75 in twin and family studies†; *ABO* alone explains roughly 20 to 30 per cent of population variance, with *VWF*, *CLEC4M*, *STXBP5* and *SCARA5* contributing†.

Acquired von Willebrand syndrome arises with aortic stenosis and other high-shear lesions, left ventricular assist devices, monoclonal gammopathy, myeloproliferative neoplasms with very high platelet counts, and hypothyroidism. Mechanistically established.

Bleeding is modified by factor VIII level, since von Willebrand factor carries factor VIII, by platelet von Willebrand factor content, and by oestrogen status.

*Not known*: where disease ends and the low tail of the normal distribution begins. The diagnostic cut-off, historically von Willebrand factor antigen below 30 IU/dL for definite disease and 30 to 50 for low von Willebrand factor, is a convention rather than a biological boundary, and guidelines have changed it. Also not known: why bleeding phenotype correlates so loosely with von Willebrand factor level in type 1.

**Cure status.** CONTROLLABLE. No treatment corrects the genotype or permanently restores von Willebrand factor.

Desmopressin releases stored von Willebrand factor and factor VIII from endothelium, raising levels three- to five-fold for hours. It works in most type 1 disease, is contraindicated in type 2B because it causes thrombocytopenia, is probably ineffective in type 2M and is ineffective in type 3.

Von Willebrand factor-containing concentrate replaces the protein for the duration of its half-life.

Treatment is episodic and effective, so most people with the disease live normally — but the disease is lifelong. For type 3, regular prophylaxis is sometimes needed and the situation resembles haemophilia. No gene therapy is in clinical use.

**Prevention.** No primary prevention of the genotype beyond genetic counselling.

Prevention of bleeding events is where the measurable prevention sits. Tranexamic acid or hormonal management for heavy menstrual bleeding: tranexamic acid reduces objectively measured menstrual blood loss by roughly 40 to 50 per cent in randomised trials in heavy menstrual bleeding generally†. STRONG.

The levonorgestrel intrauterine system achieves among the largest effect sizes measured for this symptom, a 70 to 90 per cent reduction in menstrual blood loss in trials in the general heavy-bleeding population. STRONG generally, MODERATE specifically in von Willebrand disease.

Planned peripartum management, the measure that prevents postpartum haemorrhage deaths. MODERATE: cohort evidence, and no trial is feasible.

Pre-procedural prophylaxis before dental work or surgery. STRONG.

Avoiding aspirin and non-steroidal anti-inflammatory drugs. Free. MODERATE.

**Treatment.** Desmopressin, intranasal, subcutaneous or intravenous, first-line for type 1 and responsive type 2A, at US$10 to US$100 per treatment episode at generic or lowest available acquisition cost, 2024†. A desmopressin trial measuring the response should precede reliance on it. Off-patent. EML status needs checking against the 24th List†.

Tranexamic acid for mucosal and menstrual bleeding and around procedures, at one to ten dollars a course (2024)†. A selected medicine on the 24th List, section 10.2.

Von Willebrand factor-containing factor VIII concentrate, plasma-derived, or recombinant von Willebrand factor, for type 3, type 2B, non-responders, major surgery and major bleeding. Episodic use runs US$1,000 to US$20,000 per bleeding episode or surgical cover at lowest available acquisition cost, 2024, and prophylaxis in type 3 runs US$100,000 to US$300,000 a patient-year†. Plasma-derived product is off-patent, recombinant is not. Listing status of factor VIII concentrate needs checking against the 24th List†.

Combined oral contraceptives or the levonorgestrel intrauterine system for heavy menstrual bleeding. Combined oral contraceptives run US$5 to US$30 a patient-year at generic or lowest available acquisition cost; the intrauterine system US$10 to US$30 per device at public-sector prices, lasting five to eight years (2024)†. Both off-patent. Listing status needs checking against the 24th List†.

Iron replacement, because chronic menstrual or mucosal loss produces the iron deficiency anaemia that is often the reason the patient presents.

Topical measures: fibrin glue, topical tranexamic acid mouthwash, nasal cautery for recurrent epistaxis.

**Simple means.** Tranexamic acid tablets and tranexamic acid mouthwash. Cheap, oral, no cold chain, and effective for the mucosal bleeding that dominates this disease.

A levonorgestrel intrauterine system or a combined pill for heavy periods — the largest single improvement in quality of life for most affected women, at public-sector prices of tens of dollars.

Nasal saline and humidification; pinching and leaning forward for nosebleeds. No cost.

Dental hygiene, which prevents the extractions that precipitate major bleeds.

Avoiding aspirin and non-steroidal anti-inflammatory drugs, using paracetamol instead.

An iron-rich diet with vitamin C at meals, and iron tablets, which treat the consequence.

A diagnosis. With 101,128 people identified against an expected 800,000 clinically significant cases, asking a woman with lifelong heavy periods and easy bruising about family bleeding history is the highest-yield free intervention in this entry.

**Gaps.** The diagnostic threshold is a convention and has moved, so prevalence figures are definition-dependent. Type distribution percentages overlap widely between sources. Massive under-diagnosis, especially in women and in low- and middle-income countries. Whether low von Willebrand factor of 30 to 50 IU/dL is a disease is contested. There is no trial evidence specifically in von Willebrand disease for most of the heavy-menstrual- bleeding interventions; the effect sizes are borrowed from the general population.

## Immune thrombocytopenia

**What it is.** The immune system destroys platelets and suppresses their production. Platelet counts fall, causing bruising, pinpoint skin bleeding and, rarely, serious haemorrhage. In children it often follows a virus and goes away by itself; in adults it usually persists.

**Measured.** Annual incidence in Europe is roughly 1 per 25,600 to 1 per 37,000 people a year, about 2.7 to 3.9 per 100,000 a year (Orphanet)†. Prevalence is 1 to 5 per 10,000 (Orphanet)†. The two are not easily reconcilable.

In adults the age pattern is bimodal: a female-predominant peak in young adulthood and a sex-equal or male-predominant peak after 60. In children peak incidence is at two to five years with a slight male excess.

In children, roughly 70 to 80 per cent remit spontaneously within six to 12 months†. In adults spontaneous remission is uncommon, on the order of 10 to 20 per cent, and most develop persistent or chronic disease†.

Intracranial haemorrhage occurs in well under 1 per cent of children and roughly 1 to 2 per cent of adults with chronic severe disease, with risk rising with age and with platelet counts below $20 \times 10^9$/L†. Deaths are rare and mostly in older adults; attributable mortality in chronic refractory cohorts is a few per cent over years, from haemorrhage and from infection secondary to immunosuppression.

No strong geographic gradient is reported, but *Helicobacter pylori*-associated disease is substantially more common in Japan and Italy than in northern Europe or the United States, which is a measured regional difference in cause.

**Where it starts.** Autoantibodies against platelet glycoproteins GPIIb/IIIa and GPIb/IX cause splenic and hepatic clearance, and impaired megakaryocyte platelet production runs alongside, which is why thrombopoietin receptor agonists work. Both mechanisms are established. T-cell abnormalities include reduced regulatory T cells and skewed Th1/Th17 balance.

Preceding infection in children is common and is the basis of the usual post-viral picture.

Secondary disease accounts for roughly 20 per cent of cases†: systemic lupus erythematosus, antiphospholipid syndrome, common variable immunodeficiency, chronic lymphocytic leukaemia, HIV, hepatitis C, *H. pylori*, and drugs including quinine, heparin, vancomycin, sulphonamides and carbamazepine. Vaccination-associated disease occurs and is rare.

Not a heritable disease. Familial clustering of autoimmunity exists, HLA associations are weak and inconsistent, and no useful heritability estimate exists.

*Not known*: what starts the autoantibody response in primary disease. Why children remit and adults do not. Which patients will bleed — platelet count predicts bleeding only loosely, and there is no validated predictor of serious haemorrhage, which is the main clinical problem in deciding whom to treat.

**Cure status.** Children: SELF-LIMITING in 70 to 80 per cent, remitting within six to 12 months without disease-modifying treatment†; treatment in children is mostly for bleeding rather than for the count. Adults with primary disease: CONTROLLABLE — most need treatment and relapse when it stops. Adults with a treatable secondary cause: CURABLE by treating the cause.

Splenectomy gives durable response without further treatment in roughly 60 to 70 per cent at five years†, which is the closest thing to a cure in adult disease, and it is a permanent operation with lifelong sepsis and thrombosis risk. Its use has fallen sharply since thrombopoietin receptor agonists arrived.

Rituximab gives responses in roughly 60 per cent initially, but only about 20 to 25 per cent maintain response at five years†.

Thrombopoietin receptor agonists — eltrombopag, romiplostim, avatrombopag — raise counts in roughly 60 to 80 per cent of patients† but are suppressive rather than curative. A minority, roughly 10 to 30 per cent in discontinuation studies, sustain remission after stopping, which is a genuine and recent finding.

Treating a secondary cause can be curative. Eradicating *H. pylori* produces durable platelet recovery in a substantial share of *H. pylori*-positive patients in Japan and Italy, with response

rates reported around 50 per cent in those populations and much lower in northern Europe and North America. Treating HIV or hepatitis C likewise.

**Prevention.** No primary prevention for primary disease. That should be stated plainly.

Stopping an implicated drug prevents recurrence of drug-induced immune thrombocytopenia. STRONG, mechanistically certain.

*H. pylori* eradication where the association is strong. MODERATE in Japan and Italy, WEAK elsewhere — the geographic difference in response is itself the evidence.

Avoiding aspirin and non-steroidal anti-inflammatory drugs when the count is low, which reduces bleeding rather than disease. MODERATE.

Pneumococcal, meningococcal and *Haemophilus influenzae* type b vaccination before splenectomy, with penicillin prophylaxis afterwards, to prevent post-splenectomy sepsis. STRONG.

**Treatment.** Corticosteroids — prednisolone or dexamethasone pulses — first-line, with response in 60 to 80 per cent, mostly not durable, at US$2 to US$20 a course at generic or lowest available acquisition cost, 2024†. Off-patent. Dexamethasone is a selected medicine on the 24th List in several sections including 3, antiallergics and medicines used in anaphylaxis, core list; prednisolone's status needs checking against the 24th List†. Toxicity on prolonged use is the reason newer agents exist.

Intravenous immunoglobulin gives a rapid transient rise in count and is used for bleeding or before procedures, at US$2,000 to US$10,000 a course for an adult at lowest available acquisition cost, 2024†. It is a plasma-derived product, so off-patent does not apply, and supply and plasma availability set the price. Global plasma supply is a standing constraint. Normal immunoglobulin's listing status needs checking against the 24th List†.

Anti-D immunoglobulin, for Rh-positive non-splenectomised patients only, is cheaper than intravenous immunoglobulin where available and carries a haemolysis warning.

Thrombopoietin receptor agonists. Eltrombopag, oral, off-patent since roughly 2023–2025, originator US$50,000 to US$100,000 a patient-year (2023), generics far lower and falling, with Indian generics reported in the low thousands a year. Romiplostim, weekly subcutaneous, patented with biosimilars emerging, US$40,000 to US$90,000 a patient-year (2024)†. Avatrombopag, oral with no food restrictions, patented. Listing status of all three needs checking against the 24th List†.

Rituximab, biosimilar course US$1,500 to US$5,000 at lowest available acquisition cost, 2024, down from originator prices several times higher†. Rituximab is a selected medicine on the 24th List, in section 5.1.2 for multiple sclerosis and in section 8.2.2 targeted therapies for Burkitt lymphoma, diffuse large B-cell lymphoma, chronic lymphocytic leukaemia and follicular lymphoma, all complementary list. Immune thrombocytopenia is not among the listed indications.

Splenectomy, with durable remission in 60 to 70 per cent at five years, a one-off surgical cost and lifelong infection risk.

Fostamatinib, efgartigimod and rozanolixizumab are newer and effective in trials, patented, and priced in the high tens to hundreds of thousands a patient-year. Their listing status needs checking against the 24th List†.

Immunosuppressants — azathioprine, mycophenolate, ciclosporin, danazol, dapsone, vincristine — are all off-patent and cheap at US$50 to US$500 a patient-year at generic or lowest available acquisition cost, 2024†, and these remain the practical second line in most of the world. Vincristine is a selected medicine on the 24th List, in section 8.2.1 cytotoxic medicines, complementary list, for leukaemias, lymphomas and a list of solid tumours. The listing status of azathioprine and ciclosporin needs checking against the 24th List†.

Observation, for counts above about 20 to 30 × $10^9$/L without bleeding, in children and adults. The best-evidenced treatment for mild disease.

**Simple means.** Watchful waiting. For children, and for adults with counts above about 30 × $10^9$/L and no bleeding, no treatment is the standard of care. It costs nothing and avoids steroid harm.

Avoiding aspirin, non-steroidal anti-inflammatory drugs and contact sports when the count is low.

Dapsone and danazol. Not quite no-chain, but oral, off-patent and in the tens of dollars a year; these matter where thrombopoietin receptor agonists are unaffordable.

*H. pylori* testing and eradication where the association is strong: a two-week course of three cheap generic drugs can produce durable remission in a share of patients.

Tranexamic acid and topical measures for mucosal bleeding.

Menstrual management, as in von Willebrand disease, for women with low counts.

**Gaps.** Incidence estimates vary roughly three-fold between studies, because case definition — the platelet threshold, the exclusion of secondary causes — varies. No validated predictor of serious bleeding exists, which is the clinically decisive unknown. *H. pylori* eradication response differs several-fold between Japan and Italy on one side and northern Europe and North America on the other; the reason is unexplained and the literature disagrees on whether to test outside high-response regions. Thrombopoietin receptor agonist discontinuation data are recent, from heterogeneous studies, with the proportion sustaining remission reported between about 10 and 30 per cent†. Generic eltrombopag prices are moving fast. Orphanet's prevalence and the European incidence figures are not easily reconcilable.

---

## Haemochromatosis

**What it is.** The gut absorbs more iron than the body needs, year after year. Iron builds up in the liver, heart, pancreas and joints and damages them. It is one of the commonest inherited conditions in people of northern European descent.

**Measured.** *HFE* C282Y homozygosity affects about 1 in 200, 0.3 to 0.5 per cent, of populations of northern European ancestry, with a C282Y carrier frequency around 1 in 10†. It is rare to absent in African, East Asian and Indigenous American populations. Frequencies are highest in Ireland, Brittany, Scandinavia and Scotland, and lowest in southern Europe.

Penetrance is the central measured fact and it is low. A large share of homozygotes have raised transferrin saturation and ferritin, but clinically significant iron overload disease develops in a minority. The HealthIron population-based study found documented iron-overload-related disease in about 28 per cent of male C282Y homozygotes and about 1 per cent of female homozygotes over the study period (Allen et al., *NEJM*, 2008). Earlier clinic-based series greatly overstated penetrance because they sampled affected people.

Disease expression is typically after age 40 in men and after menopause in women; menstrual iron loss delays expression in women by roughly a decade or more.

Death attributed to haemochromatosis is dominated by cirrhosis, hepatocellular carcinoma and cardiomyopathy. In treated non-cirrhotic patients life expectancy is normal. No reliable global death count.

H63D homozygosity and C282Y/H63D compound heterozygosity rarely cause significant overload. Non-*HFE* forms, in *HJV*, *HAMP*, *TFR2* and *SLC40A1*, are rare and can be severe and early-onset.

**Where it starts.** Biallelic *HFE* C282Y in the great majority, leading to inappropriately low hepcidin for the iron load, so ferroportin stays active and intestinal iron absorption continues when it should stop. The molecular pathway is fully established.

Heritability of the genotype is 1.0. Heritability of the disease is low, because penetrance is low — which means most of the variance in whether a homozygote gets sick is not explained by *HFE*.

Established modifiers of expression: male sex, the largest single modifier, at about 28 per cent against about 1 per cent disease expression in HealthIron†; alcohol, where heavy use multiplies cirrhosis risk in homozygotes several-fold and is the strongest modifiable factor; hepatitis B and C co-infection and metabolic or fatty liver disease, through additive liver injury; blood donation and menstruation, which are protective by removing iron; dietary iron and vitamin C intake, with a modest effect on loading rate.

Secondary iron overload is a different disease with the same end-organ damage: repeated transfusion in thalassaemia, sickle cell disease and myelodysplastic syndromes, ineffective erythropoiesis, and the dyserythropoietic anaemias.

*Not known*: why most C282Y homozygotes never develop disease. No genetic modifier of large effect has been established, and the known modifiers do not account for the variance. This is why population genetic screening for *HFE* has not been adopted anywhere — the test finds many people who will never be ill.

**Cure status.** CONTROLLABLE. The genotype is untouched, so this is control — but it is control by a procedure that needs no drug, no patent and no supply chain, and the blood removed can be donated.

Therapeutic phlebotomy removes about 200 to 250 mg of iron per 500 mL unit†. Weekly or fortnightly venesection continues until ferritin falls to the target, commonly 50 µg/L, then maintenance two to four times a year for life.

Patients de-ironed before cirrhosis develops have normal life expectancy. Established cirrhosis does not reverse and the hepatocellular carcinoma risk persists even after de-ironing. Cardiomyopathy, skin pigmentation, fatigue and diabetes control often improve; established arthropathy and hypogonadism usually do not.

**Prevention.** Cascade testing of first-degree relatives of an affected person is the standard measure and the only screening strategy with broad support. STRONG for case-finding yield: a sibling of a homozygote has roughly a one-in-four chance of being homozygous.

Population genetic screening: CONTESTED, and not recommended by most bodies, precisely because penetrance is low. Several authorities instead support screening by transferrin saturation and ferritin in the context of raised liver enzymes or unexplained symptoms.

Early phlebotomy before organ damage in a known homozygote. STRONG — the cohort evidence is unambiguous and a randomised trial would be unethical.

Alcohol avoidance in C282Y homozygotes, the largest modifiable risk reduction available, since heavy use multiplies cirrhosis risk several-fold. STRONG, from consistent cohort data.

Hepatitis B vaccination and hepatitis C treatment in homozygotes. MODERATE.

Avoiding iron and high-dose vitamin C supplements. MODERATE, mechanistic plus observational.

Regular blood donation in homozygotes without disease, which removes iron and supplies the blood bank. MODERATE.

**Treatment.** Therapeutic phlebotomy. Not a medicine. The consumables are a needle, a bag and a nurse, on the order of tens of US dollars a session in a public system (2024), so hundreds to a couple of thousand US dollars in the first de-ironing year and tens to hundreds of US dollars a year on maintenance. In many systems the patient donates and the cost is negative. This is first-line and nothing has beaten it.

Erythrocytapheresis removes red cells selectively, needs fewer sessions and requires an apheresis machine. Equivalent de-ironing at a higher per-session cost.

Iron chelation with deferasirox or deferoxamine, reserved for patients who cannot tolerate phlebotomy because of anaemia, poor venous access or cardiac disease. Generic deferasirox runs US$1,000 to US$4,000 a patient-year at lowest available acquisition cost, 2024†. Both off-patent; listing status needs checking against the 24th List†. Chelation is the mainstay in secondary iron overload, since those patients are transfusion-dependent and cannot be bled.

Treating the organ damage: insulin for diabetes, hormone replacement for hypogonadism, heart failure treatment for cardiomyopathy, and hepatocellular carcinoma surveillance by six-monthly ultrasound in cirrhotic patients.

Hepcidin mimetics such as rusfertide are in trials for polycythaemia vera and under investigation in haemochromatosis; nothing is approved.

**Simple means.** Giving blood. The treatment is blood donation. For a homozygote without contraindication, regular donation at a blood bank both treats the disease and supplies the service. No drug, no patent, no chain.

Not drinking alcohol, the largest single reduction in cirrhosis risk available to an affected person.

Tea or coffee with meals, which reduces non-haem iron absorption. A small effect at no cost.

Not taking iron or high-dose vitamin C supplements, and not cooking in cast iron.

Avoiding raw shellfish. *Vibrio vulnificus* infection is far more severe in iron overload, and this is a well-documented and entirely avoidable cause of death in this group.

Telling siblings and children. A family history conversation is the cheapest and highest-yield case-finding method in this entry.

**Gaps.** Penetrance figures differ by an order of magnitude between clinic-based series and population-based studies; only the population-based figures should be used, and even those come from a single ancestry group. Essentially all penetrance and outcome data come from European-ancestry populations, and nothing comparable exists for the rare non-*HFE* forms or for populations where C282Y is absent. No modifier explains why most homozygotes stay well, which is the central unexplained finding. Whether to screen populations is contested, and the contest is about the low penetrance rather than the biology. The optimal maintenance ferritin target is not established by trial and guidelines differ. Whether de-ironing reduces hepatocellular carcinoma risk once cirrhosis exists is unresolved.

---

## Polycythaemia vera

**What it is.** A bone marrow neoplasm in which the marrow makes too many red cells, and often too many platelets and white cells. The blood thickens and clots form. Almost all cases carry a mutation in the *JAK2* gene.

**Measured.** Incidence is 1.9 per 100,000 person-years in Olmsted County, Minnesota, and 1.48 per 100,000 person-years age-standardised in Sweden†. Prevalence is higher than incidence would suggest because survival is long; registry-based estimates fall in the range 20 to 50 per 100,000 in high-income countries, and there is no single authoritative global figure.

Median age at diagnosis is about 60, with the highest incidence at 70 to 79, and about 10 per cent of patients are under 40†.

*JAK2* V617F is present in about 95 per cent of patients and about 98 per cent have some *JAK2* mutation, the remainder mostly in exon 12†. Compare 0.1 to 0.2 per cent of the general population carrying V617F as clonal haematopoiesis†.

Median survival is 10 to 20 years with controlled disease, still below age- and sex-matched population survival. Death comes from thrombosis, the main early risk, from transformation to myelofibrosis in roughly 10 to 20 per cent at 15 to 20 years, and to acute myeloid leukaemia in roughly 5 to 10 per cent at 20 years†.

Reported incidence is higher in high-income countries, which is at least partly ascertainment. Ashkenazi Jewish populations have been reported with higher rates.

**Where it starts.** An acquired somatic gain-of-function mutation in *JAK2*, usually V617F, in a haematopoietic stem cell, producing cytokine-independent erythropoiesis. This is established and is the diagnostic criterion. Where the mutation comes from is not known; it is acquired, not inherited.

Germline predisposition: the *JAK2* 46/1 haplotype raises the risk of acquiring V617F roughly three- to four-fold†, and *TERT* and *SH2B3* variants also associate. Familial clustering of myeloproliferative neoplasms exists, with relative risks in first-degree relatives of roughly 5 to 7†, so there is a real but small inherited component. Heritability is not well estimated.

Age is the dominant risk factor, as for clonal haematopoiesis generally. Ionising radiation is an established cause of myeloproliferative neoplasms at high dose. Additional mutations in *TET2*, *ASXL1*, *DNMT3A*, *SRSF2*, *TP53* and *IDH1/2* accumulate and drive transformation.

Thrombosis risk within the disease rises with age over 60, prior thrombosis, leucocytosis, and haematocrit above 45 per cent.

*Not known*: why a V617F clone expands into overt polycythaemia vera in some people and stays as silent clonal haematopoiesis in others, given that V617F is found in 0.1 to 0.2 per

cent of the general population, far more than the prevalence of the disease. What determines transformation timing. Whether early cytoreduction changes the transformation rate.

**Cure status.** CONTROLLABLE. No standing treatment eradicates the *JAK2*-mutant clone.

Allogeneic transplant is the only potentially curative option and is reserved for post- polycythaemic myelofibrosis or leukaemic transformation, because transplant mortality exceeds the risk of the controlled disease.

Interferon — ropeginterferon alfa-2b, or pegylated interferon alfa-2a — is the one treatment that reduces the *JAK2* V617F allele burden, in some patients to undetectable levels, with documented sustained molecular responses. Whether that constitutes cure is unresolved. It is the strongest claim toward disease modification in this entry and it is not settled.

Everything else — phlebotomy, hydroxyurea, ruxolitinib, aspirin — controls counts and thrombosis risk without touching the clone.

**Prevention.** No primary prevention. The mutation is acquired for unknown reasons, and that should be stated plainly.

Prevention of thrombosis, which is what kills early, is where all the measurable prevention sits.

Haematocrit below 45 per cent. The CYTO-PV randomised trial compared a haematocrit target below 45 per cent with 45 to 50 per cent and found cardiovascular death or major thrombosis in 2.7 per cent against 9.8 per cent of patients over a median 31 months, roughly a four-fold difference (Marchioli et al., *NEJM*, 2013). STRONG. This is the single most important number in the management of this disease.

Low-dose aspirin. The ECLAP randomised trial found that low-dose aspirin reduced the primary combined endpoint of cardiovascular death, non-fatal myocardial infarction, non-fatal stroke and major venous thromboembolism, with a relative risk of about 0.40 (Landolfi et al., *NEJM*, 2004). STRONG.

Cytoreduction in high-risk patients, those over 60 or with prior thrombosis, reduces thrombosis. STRONG.

Controlling conventional cardiovascular risk factors — smoking, hypertension, lipids, diabetes — because the thrombotic risk is multiplicative. MODERATE.

**Treatment.** Phlebotomy to a haematocrit below 45 per cent, first-line for everyone. Not a medicine; on the order of tens of US dollars a session (2024), several sessions initially and then a few a year†. Combined with the CYTO-PV result, this is the highest-value intervention in the entry.

Low-dose aspirin, 75 to 100 mg daily, with twice-daily dosing used in some protocols for persistent symptoms. Off-patent, at one to five dollars a patient-year (2024)†. EML status needs checking against the 24th List†.

Hydroxyurea, first-line cytoreduction for high-risk patients, off-patent at US$30 to US$150 a patient-year at generic or lowest available acquisition cost, 2024†. Hydroxyurea is a selected medicine on the 24th List, in section 8.2.1 cytotoxic medicines, complementary list, for chronic myeloid leukaemia, and in section 10.3 core list for haemoglobinopathies; polycythaemia vera is not among the listed indications.

Ropeginterferon alfa-2b, approved in the European Union in 2019 and the United States in 2021. PROUD-PV and CONTINUATION-PV showed non-inferiority to hydroxyurea at 12 months and superiority in haematological and molecular response at 36 months, with allele burden reduction†. Patented, at US$50,000 to US$100,000 a patient-year on United States and European list prices (2024)†. Pegylated interferon alfa-2a is used off-label, is off-patent, and costs US$5,000 to US$20,000 a patient-year (2024)† — a large price gap for a similar mechanism. Listing status of both needs checking against the 24th List†.

Ruxolitinib, a JAK1/2 inhibitor, second-line after hydroxyurea intolerance or resistance. The RESPONSE trial found 21 per cent against 1 per cent achieving the composite primary endpoint of haematocrit control plus at least 35 per cent spleen volume reduction at 32 weeks†. Patented, with patents expiring in several markets from the mid-2020s, at US$130,000 to US$200,000 a patient-year on United States list (2024)†. EML status needs checking against the 24th List†.

Busulfan, pipobroman and radioactive phosphorus-32 are older cytoreductives, leukaemogenic, now reserved for elderly patients with short life expectancy.

Anagrelide for platelet control, allopurinol for secondary gout, and antihistamines or ruxolitinib for aquagenic pruritus. Allopurinol is a selected medicine on the 24th List, in section 29.1, medicines used to treat gout, and in section 8.2.5 supportive medicines, complementary, for tumour lysis syndrome; off-patent at US$5 to US$20 a patient-year at generic or lowest available acquisition cost, 2024†.

Rusfertide, a hepcidin mimetic, reported a large reduction in phlebotomy requirement in the phase 3 VERIFY trial in 2025†. Not approved at the time of writing.

**Simple means.** Phlebotomy itself. As with haemochromatosis, the first-line treatment for the most dangerous feature of this disease is removing blood: a needle, a bag, a trained person.

Low-dose aspirin. Pennies a year, with a randomised-trial relative risk of about 0.40 for major thrombotic events.

Hydration, which reduces blood viscosity. No trial, no cost.

Smoking cessation and blood pressure control, because the risk being prevented is thrombotic and these multiply it.

Avoiding hot baths and showers for aquagenic pruritus, with cooling and oatmeal measures. No cost, and no evidence base beyond patient report.

Recognising the disease from a full blood count. A raised haematocrit on a routine count is the whole diagnostic entry point, and a *JAK2* V617F test on peripheral blood then confirms it without a marrow biopsy in most cases.

**Gaps.** No authoritative global prevalence estimate exists; registry figures come from a handful of high-income countries. Whether interferon's molecular responses translate into longer survival or lower transformation rates is not established, because the trials were powered for haematological endpoints. Why V617F clonal haematopoiesis usually does not become polycythaemia vera is unknown. The large price gap between ropeginterferon and off-patent pegylated interferon alfa-2a is not matched by a demonstrated difference in hard outcomes. Transformation rates to myelofibrosis and leukaemia vary between series with follow-up length and with whether leukaemogenic agents were used historically. Rusfertide data are very recent and not yet reflected in guidelines.

---

## Myelodysplastic syndromes

**What it is.** A group of bone marrow cancers in which blood cells are made badly and die before leaving the marrow. Counts fall, especially the red cells, so people become anaemic and transfusion-dependent. In about a third the disease turns into acute myeloid leukaemia.

**Measured.** Incidence is about 4.0 to 4.9 per 100,000 a year overall, rising to over 60 per 100,000 in people over 85†. Underdiagnosis means the true rate is probably higher. Median age at diagnosis is about 73, and about 86 per cent of cases occur at 60 or above†. It is more common in males. Paediatric disease runs at about 1 to 4 per million a year, median age 6.8 years, rare and often associated with an inherited predisposition syndrome.

The United States sees about 10,000 to 15,000 new cases a year — another section of the same source gives 10,000 to 20,000 — with 60,000 to 170,000 people living with the disease†. The width of those ranges is itself the finding: the condition is not a reportable cancer in all registries and ascertainment is poor.

Survival by International Prognostic Scoring System risk: lower-risk disease, below 3.5, three to 10 years; higher-risk, above 3.5, under three years†. Transformation to acute myeloid leukaemia occurs in roughly 30 per cent overall, concentrated in higher-risk groups†.

Most deaths are from the consequences of cytopenia — infection, haemorrhage — and from leukaemic transformation, rather than from the syndrome as a coded cause. No reliable global death count.

**Where it starts.** Acquired somatic mutations in haematopoietic stem cells with clonal expansion. The commonly mutated genes are *SF3B1*, *TET2*, *SRSF2*, *ASXL1*, *DNMT3A*, *RUNX1*,

*TP53*, *U2AF1* and *EZH2*, alongside del(5q) and other cytogenetic abnormalities. Over 90 per cent of cases carry at least one driver mutation†.

Age is the dominant risk factor. Clonal haematopoiesis of indeterminate potential is present in more than 10 per cent of people over 70 and is the precursor state, and progression from it to a myeloid neoplasm runs at roughly 0.5 to 1 per cent a year†.

Prior cytotoxic therapy: alkylating agents, with a five-to-ten-year latency and often del(5q), del(7q) or a complex karyotype, and topoisomerase II inhibitors, with shorter latency and balanced translocations. Therapy-related disease is roughly 10 to 15 per cent of cases and has a markedly worse prognosis†.

Ionising radiation, dose-dependent and established from atomic bomb survivor and occupational cohorts. Benzene and organic solvents, established and dose-related. Tobacco smoking, with a relative risk of roughly 1.4 to 1.6 in meta-analysis†.

Inherited predisposition: germline *GATA2*, *RUNX1*, *DDX41*, *ETV6* and *ANKRD26* variants, Fanconi anaemia, telomere biology disorders, Shwachman-Diamond syndrome. Germline *DDX41* variants are found in a few per cent of adult cases, often with a family history, and this matters because it changes donor selection for transplant.

Heritability is not meaningfully estimated for the syndromes as a whole. The germline syndromes are Mendelian; the common disease is acquired.

*Not known*: why only a small fraction of people with clonal haematopoiesis of indeterminate potential progress. Which lower-risk patients will progress rapidly — prognostic scores improve on this and still leave large within-group variance. Why hypomethylating agents work in some patients and not others; no biomarker predicts response.

**Cure status.** Younger, fitter patients eligible for transplant: CURABLE in about 50 per cent (reported three-year survival)†. The large majority: CONTROLLABLE.

Allogeneic haematopoietic stem cell transplant is the only curative treatment, with reported three-year survival about 50 per cent and worse results with age; patients under 40 do best†. Because median age at diagnosis is 73, only a small minority are candidates.

Hypomethylating agents prolong survival without curing. Azacitidine against conventional care in higher-risk disease, in AZA-001, gave median overall survival of 24 months against 15 months, with response rates of 29 per cent against 12 per cent†. Decitabine shows similar survival benefit with response rates reported up to 43 per cent†.

Luspatercept reduces transfusion burden in lower-risk disease with ring sideroblasts: in MEDALIST, 38 per cent against 13 per cent achieved transfusion independence for at least eight weeks, with median duration of response around 30.6 weeks†. The COMMANDS trial in 2023 showed luspatercept superior to epoetin alfa as first-line in transfusion-dependent lower-risk disease. Supportive, not curative.

Lenalidomide in del(5q) disease gives transfusion independence in roughly two-thirds, with median response duration over two years and cytogenetic responses. Still not curative.

The honest statement is that this is a disease of older people in which the only cure requires a treatment most patients cannot survive.

**Prevention.** Reducing benzene and solvent exposure in occupational settings. MODERATE: dose-response in occupational cohorts, no trial.

Not smoking, against a relative risk of roughly 1.4 to 1.6. MODERATE.

Minimising cumulative alkylating agent and radiation dose in cancer treatment, and preferring regimens with lower leukaemogenic potential where outcomes are equivalent. MODERATE — the causation is established, and prevention has to be traded against treating the first cancer.

Radiation protection, occupational and medical dose limitation. STRONG for the causal link, MODERATE for the measured prevention effect.

No prevention exists for the dominant, age-related, idiopathic form. Clonal haematopoiesis of indeterminate potential has no established intervention, and trials of interventions in it are only now beginning.

**Treatment.** Supportive care — red cell and platelet transfusion, antibiotics, and iron chelation after prolonged transfusion. This is what most patients worldwide actually receive, and in lower-risk disease it is a legitimate standard of care. It requires a safe blood supply.

Erythropoiesis-stimulating agents for lower-risk anaemia with serum erythropoietin below about 500 IU/L, with response in roughly 40 per cent†. On the 24th List the selected medicine is the class entry “erythropoiesis-stimulating agents”, in section 10.1, antianaemia medicines, complementary list, for anaemia due to chronic disease; epoetin alfa, beta and theta and methoxy polyethylene glycol-epoetin beta are therapeutic equivalents to that class entry rather than selected medicines in their own right. Myelodysplastic syndrome is not the listed indication. Biosimilars are widely available, at US$1,500 to US$6,000 a patient-year for biosimilar epoetin at generic or lowest available acquisition cost, 2024, and much less in some markets†.

Hypomethylating agents. Azacitidine, subcutaneous or intravenous, seven days per 28-day cycle, off-patent with generics widely available, at US$3,000 to US$15,000 a patient-year at generic or lowest available acquisition cost, 2024, with originator prices several times higher†. Decitabine, and oral decitabine with cedazuridine, which is patented and far more expensive. Listing status needs checking against the 24th List†.

Luspatercept for lower-risk disease with anaemia, patented, at US$150,000 to US$200,000 a patient-year on United States list (2024)†. EML status needs checking against the 24th List†.

Lenalidomide for del(5q) disease, off-patent with generics from 2022 to 2026 depending on market; originator over US$200,000 a patient-year on United States list (2023), with generics substantially lower and falling†. EML status needs checking against the 24th List†.

Immunosuppression with antithymocyte globulin and ciclosporin for hypoplastic disease overlapping aplastic anaemia, in younger patients with HLA-DR15.

Allogeneic transplant, at US$150,000 to US$500,000 in high-income settings (2024)†. Intensive leukaemia-type chemotherapy for higher-risk disease as a bridge to transplant.

Iron chelation for transfusion-dependent lower-risk patients: the TELESTO trial suggested an event-free survival benefit with deferasirox, was underpowered, and the benefit is contested.

**Simple means.** Very few, and that should be said. This disease requires transfusion, drugs or transplant.

A safe, adequate blood supply is the single most important resource for it, and it requires donors rather than industry.

Infection precautions during neutropenia — hand hygiene, food hygiene, prompt presentation with fever. Free.

Not smoking, and avoiding solvent exposure.

Recognising it from a full blood count. Unexplained macrocytic anaemia in an older person is the entry point, with a blood film and then marrow examination following. Where marrow examination is unavailable, the practical simple means is to stop giving iron and B12 for an anaemia that does not respond, and to look for another cause.

Folic acid in ineffective erythropoiesis, as elsewhere.

**Gaps.** Ascertainment is poor: the same source gives both 10,000 to 15,000 and 10,000 to 20,000 new United States cases a year, and a prevalence range spanning nearly threefold. The syndromes are not consistently registered as malignancies across cancer registries, so international comparison is unreliable and there is no credible global incidence figure. Classification changed in 2022, in the WHO fifth edition and the International Consensus Classification, with entities redefined by genetics, so incidence and survival figures from before and after are not comparable. No biomarker predicts hypomethylating agent response. The benefit of iron chelation in lower-risk disease is contested. Whether any intervention in clonal haematopoiesis of indeterminate potential prevents the syndrome is unknown.

—

# Diseases of the immune system

## ICD-11 chapter 04

Fourteen entries. The inborn errors of immunity, the allergic diseases, and the systemic autoimmune and autoinflammatory conditions.

---

### Primary immunodeficiencies as a class

**What it is.** A set of inherited faults in the immune system. Each one is rare; together they are not. The result is infections that come too often, last too long, or are caused by organisms that should not cause disease — and, in many of them, autoimmunity and cancer as well.

**Measured.** The International Union of Immunological Societies classification listed over 120 conditions in its 2014 update and about 430 forms by 2019; the 2022 update lists 485 inborn errors of immunity across 10 categories†. The count rises every two years, and that is the clearest single measurement about the class.

About 1 in 500 people in the United States are born with a primary immunodeficiency on the broad definition, which includes mild antibody deficiencies. A survey of 10,000 American households put diagnosed prevalence at about 1 in 1,200†. Selective IgA deficiency, about 1 in 600 in populations such as healthy blood donors, is the commonest single form and is usually asymptomatic. Most other individual disorders have reported incidence between 1 in 100,000 and 1 in 2,000,000†.

The 1-in-1,200 diagnosed figure against a 1-in-500 birth prevalence implies that the majority are not diagnosed. The Jeffrey Modell Foundation's global registries and the ESID registry together hold tens of thousands of patients against an expected population in the millions.

Diagnosis rates track laboratory capacity, not biology. Consanguineous populations in the Middle East, North Africa and parts of South Asia have substantially higher rates of autosomal recessive forms — in some consanguineous cohorts recessive inborn errors are an order of magnitude more frequent than in outbred European populations. No global death count exists. Untreated severe combined immunodeficiency is uniformly fatal in the first two years.

**Where it starts.** Single-gene defects in the large majority, with heritability 1.0 for the genotype in the monogenic forms. Inheritance is autosomal recessive, autosomal dominant including gain-of-function and haploinsufficiency, or X-linked.

Four rough functional categories: antibody or humoral defects, the largest group at roughly half of all diagnoses; combined T- and B-cell defects; phagocyte defects; complement defects. The classification adds categories for immune dysregulation, autoinflammatory disorders, innate immunity defects and phenocopies.

Consanguinity raises the frequency of recessive forms directly and measurably.

Somatic and acquired phenocopies exist and are not inherited: anti-cytokine autoantibodies against interferon gamma, GM-CSF and IL-17; somatic mutations such as those in *UBA1* causing VEXAS syndrome, described in 2020; and thymoma-associated immunodeficiency.

New gene discovery runs at roughly 20 to 40 new monogenic causes described a year over the past decade†, which is why the class count keeps moving.

*Not known*: how many inborn errors of immunity remain undescribed. What fraction of adult idiopathic bronchiectasis, recurrent sinopulmonary infection, unexplained autoimmunity or

early-onset lymphoma is attributable to an undiagnosed inborn error. Whether the broad 1-in-500 figure, which rests mostly on asymptomatic IgA deficiency, describes anything clinically meaningful; the clinically significant prevalence is much lower and is not well estimated.

**Cure status.** Combined immunodeficiencies and several phagocyte and immune dysregulation disorders: CURABLE, by allogeneic haematopoietic stem cell transplant or autologous gene therapy. Antibody deficiencies, the largest group of patients: CONTROLLABLE, by lifelong immunoglobulin replacement with antimicrobial prophylaxis. A number of the innate and complement defects: RELIEF ONLY, where there is no replacement and management is prophylaxis plus prompt treatment of infection.

Targeted therapy has changed several specific disorders: JAK inhibitors for STAT1 and STAT3 gain-of-function, abatacept for CTLA-4 haploinsufficiency and LRBA deficiency, leniolisib (approved 2023) for activated PI3K-delta syndrome, and IL-1 blockade for the autoinflammatory disorders. These control rather than cure, and the effect sizes are large and mechanism-specific.

**Prevention.** Newborn screening by T-cell receptor excision circle assay for severe combined immunodeficiency is the single most consequential prevention measure in this class, because it converts a uniformly fatal disease into a largely curable one by advancing diagnosis before infection. STRONG.

Genetic counselling and cascade testing in affected families, with prenatal and preimplantation diagnosis where available and acceptable. STRONG for birth prevalence in known families.

Reducing consanguineous marriage lowers the frequency of recessive forms. This is a demographic observation rather than a programme; where premarital carrier screening has been introduced, in the Gulf states and Iran, it has reduced affected births for specific conditions. MODERATE, and socially contested.

Live vaccine avoidance in known or suspected combined immunodeficiency. BCG and oral polio vaccine cause disseminated disease in severe combined immunodeficiency and in several phagocyte defects, and BCG-related complications are a leading cause of death in severe combined immunodeficiency in countries with universal BCG at birth. STRONG for preventing that harm, and one reason newborn screening matters most in BCG-vaccinating countries.

Prophylactic antimicrobials prevent the infections that cause the damage: co-trimoxazole against *Pneumocystis* in combined defects and chronic granulomatous disease, itraconazole against aspergillosis in chronic granulomatous disease. Both reduce infection rates substantially in trials and cohorts. STRONG.

Immunoglobulin replacement prevents bacterial infection and bronchiectasis in antibody deficiency. STRONG.

**Treatment.** Immunoglobulin replacement, intravenous or subcutaneous, for antibody deficiencies, at US$20,000 to US$60,000 a patient-year in high-income countries (2024) depending on dose and product, and substantially lower in some tendered markets. It is a plasma-derived product, so patents do not set availability; global plasma supply does. This is the single largest expenditure in the class and it is fundamentally supply-constrained. Normal human immunoglobulin's listing status needs checking against the 24th List†.

Antimicrobial prophylaxis — co-trimoxazole, azithromycin, itraconazole, aciclovir — depending on the defect, off-patent, at US$10 to US$200 a patient-year at generic or lowest available acquisition cost, 2024†. The cheapest effective intervention in the class. Azithromycin is a selected medicine on the 24th List, in section 6.2.2, Watch group antibiotics, core list, as first choice for cholera, enteric fever, gonorrhoea, chlamydial sexually transmitted infection, trachoma and yaws; the prophylactic use here is not among the listed indications. The listing status of co-trimoxazole, itraconazole and aciclovir needs checking against the 24th List†.

Allogeneic haematopoietic stem cell transplant, curative for combined defects, chronic granulomatous disease, leukocyte adhesion deficiency, IPEX syndrome, Wiskott-Aldrich syndrome, hyper-IgM syndromes and familial haemophagocytic lymphohistiocytosis, at US$150,000 to US$500,000 in high-income settings (2024)†.

Gene therapy: for adenosine deaminase-deficient severe combined immunodeficiency, an autologous gene-corrected cell product was approved in the European Union in 2016. Lentiviral

gene therapy for Wiskott-Aldrich syndrome, X-linked chronic granulomatous disease and X-linked severe combined immunodeficiency is in advanced trials or named-patient use.

Interferon gamma for chronic granulomatous disease: the 1991 randomised trial showed about a 70 per cent reduction in serious infections†. Single manufacturer, so not off-patent in practice, at US$30,000 to US$60,000 a patient-year at lowest available acquisition cost, 2024†. EML status needs checking against the 24th List†.

Targeted immune modulators for immune dysregulation phenotypes — JAK inhibitors, abatacept, leniolisib, IL-1 blockers, sirolimus — mostly patented and mostly US$30,000 to US$400,000 a patient-year at lowest available acquisition cost, 2024†. Their listing status needs checking against the 24th List†.

Avoiding live vaccines, using irradiated and CMV-safe blood products, and no transfusion from relatives. Standing precautions, at no cost.

**Simple means.** Suspecting it. The highest-yield free intervention: a child or adult with recurrent pneumonia, chronic diarrhoea with failure to thrive, deep abscesses, persistent thrush, unexplained bronchiectasis, or a family history of early infant death. The Jeffrey Modell ten warning signs exist precisely because recognition is the binding constraint.

A full blood count with differential. Lymphopenia in an infant is the cheapest possible pointer to severe combined immunodeficiency, and an absolute lymphocyte count below about 2.5 × $10^9$/L in a neonate should not be normalised. Free with any blood count.

Serum immunoglobulin concentrations — a few dollars, and the diagnostic entry point for the largest group of these disorders.

Not giving BCG or oral polio vaccine to an infant with a sibling who died of infection, or with unexplained lymphopenia, until immune function is known.

Antimicrobial prophylaxis: co-trimoxazole costs dollars a year and prevents *Pneumocystis* pneumonia.

Routine childhood immunisation with inactivated vaccines, household hygiene, clean water, and treating infections early. Not specific to immunodeficiency, and what determines survival where immunoglobulin is unavailable.

Breastfeeding, for passive antibody and reduced enteric infection in the first months.

**Gaps.** The class count, moving from 120 to 430 to 485, means any statement about how many dates within two years. The 1-in-500 prevalence figure is dominated by asymptomatic selective IgA deficiency and does not describe clinical burden; no good estimate exists of clinically significant prevalence. Essentially all registry data come from high-income countries and a small number of specialist centres, so the global distribution is unmeasured. Immunoglobulin supply is the real constraint on treatment worldwide and is not reflected in any prevalence or treatment figure. No global mortality data exist for the class. Gene therapy for several of these disorders produced insertional oncogenesis in the past, in the X-linked severe combined immunodeficiency retroviral trials; long-term safety of current lentiviral vectors is better but not settled.

---

## Common variable immunodeficiency

**What it is.** The commonest symptomatic antibody deficiency. The body makes too little immunoglobulin, so bacterial chest and sinus infections recur and permanently damage the airways. Autoimmune disease and lymphoma are also more frequent than normal.

**Measured.** Prevalence is roughly 1 in 25,000 to 1 in 50,000 in European-descended populations, the figure most often cited in the clinical literature. Orphanet's dedicated entry was obsoleted and merged into "common variable immunodeficiency and related disorders", and no prevalence figure is given there.

Within primary immunodeficiency registries it is consistently the largest single diagnosis, roughly 20 to 30 per cent of all registered patients in the ESID registry†.

Age at onset is bimodal, with peaks in the first decade and in the twenties to forties, and median age at diagnosis in the fourth decade. Diagnostic delay is consistently reported at four to nine years between symptom onset and diagnosis in European and North American

cohorts — among the longest recorded for any treatable disease, and the main driver of irreversible bronchiectasis. The sexes are affected roughly equally.

Complications, from large cohorts including ESID, USIDNET and the New York cohort of 473 patients followed up to four decades: bronchiectasis in roughly 25 to 35 per cent; autoimmune disease in roughly 25 to 30 per cent, most often immune thrombocytopenia and autoimmune haemolytic anaemia; granulomatous disease in roughly 8 to 20 per cent; enteropathy in roughly 10 to 20 per cent; and lymphoma risk raised substantially, with standardised incidence ratios around 12 to 30 in cohort studies, mostly non-Hodgkin and mostly extranodal.

In the New York cohort, survival was significantly worse in patients with non-infectious complications — roughly a median of 29 years from diagnosis against near-normal survival for those with infection only. That split is the central prognostic finding.

**Where it starts.** The cause is unknown in the majority, and that is the defining feature. This is a diagnosis of exclusion: low IgG plus low IgA or IgM, poor response to vaccination, onset after age four, and no other explanation.

Monogenic causes are identified in roughly 10 to 30 per cent of patients depending on cohort and sequencing depth†: *TNFRSF13B* (TACI), *TNFRSF13C* (BAFF-R), *CTLA4* haploinsufficiency, *LRBA*, *NFKB1*, *NFKB2*, *PIK3CD*, *PIK3R1*, *CD19*, *CD81*, *CR2*, *MS4A1*, *ICOS*, *IKZF1*, *IRF2BP2*, *ARHGEF1*, *TTC37*. *NFKB1* haploinsufficiency is currently the single most frequently identified monogenic cause.

*TNFRSF13B* variants are found in roughly 8 to 10 per cent of patients and also in 1 to 2 per cent of healthy controls†, so they are a risk factor rather than a cause — a clear example of incomplete penetrance in this field.

Heritability is not well estimated. Familial clustering occurs in roughly 10 to 20 per cent of cases, often with relatives having selective IgA deficiency rather than the full condition, suggesting a shared susceptibility.

The pathophysiology is a defect in B-cell terminal differentiation into plasma cells. Reduced class-switched memory B cells, which the EUROclass and Freiburg classifications use, predicts the complicated phenotype.

*Not known*: the cause in most patients. Why some patients have infection only and others develop the autoimmune, granulomatous and enteropathic phenotype that drives mortality — and because that split determines prognosis, this is the most consequential unknown in the entry. Whether this is one disease or a convergent phenotype of many.

**Cure status.** CONTROLLABLE. Immunoglobulin replacement restores protection against bacterial infection for as long as it is given, and stops nothing else.

Replacement prevents bacterial infection and slows or halts the progression of bronchiectasis. Trough IgG above roughly 5 to 8 g/L is associated with lower pneumonia rates, and a meta-analysis found pneumonia incidence falling as trough IgG rose, with roughly a five-fold difference in pneumonia rate between trough concentrations of 5 g/L and 10 g/L†.

It does not prevent the non-infectious complications. Autoimmunity, granulomatous disease, enteropathy and lymphoma occur in patients on adequate replacement, which is why the complicated phenotype still shortens life.

Haematopoietic stem cell transplant has been performed in severe disease with immune dysregulation; mortality has been high, reported around 40 to 50 per cent in early series, and it is not standard†.

For the identified monogenic forms, targeted therapy can be transformative: abatacept in CTLA-4 haploinsufficiency and LRBA deficiency; leniolisib, a PI3Kδ inhibitor approved in the United States in March 2023, in activated PI3K-delta syndrome, which reduced lymph node size and increased naive B cells in its randomised trial. Still control, not cure — but mechanism-specific and effective, which is the argument for genetic diagnosis.

**Prevention.** No primary prevention. The cause is unknown in most patients, and that should be stated plainly.

Prevention of bronchiectasis by early diagnosis and early immunoglobulin replacement is the measurable prevention target in this entry. Diagnostic delay of four to nine years correlates

with established bronchiectasis at diagnosis. STRONG: consistent cohort evidence, and a trial withholding replacement would be unethical.

Measuring serum immunoglobulins in anyone with two or more pneumonias, chronic sinusitis, or unexplained bronchiectasis. This is the prevention measure, and it is a blood test. STRONG.

Antimicrobial prophylaxis in patients with continuing infection despite adequate trough IgG: azithromycin reduces exacerbation frequency in bronchiectasis generally, by roughly 40 to 60 per cent in the EMBRACE, BAT and BLESS trials†. MODERATE in this condition specifically, STRONG in bronchiectasis generally.

Airway clearance physiotherapy and pulmonary rehabilitation once bronchiectasis exists. MODERATE.

Inactivated vaccination of household contacts against influenza, pertussis and COVID-19. MODERATE.

Avoiding live vaccines in the patient. STRONG for preventing vaccine-derived infection.

Lymphoma surveillance: no screening programme is established and whether surveillance changes outcome is unknown. CONTESTED.

**Treatment.** Immunoglobulin replacement, intravenous every three to four weeks or subcutaneous weekly, or hyaluronidase-facilitated every three to four weeks. Subcutaneous administration gives steadier troughs, fewer systemic reactions and home administration, and the two routes are equivalent for infection prevention in randomised comparisons. At US$20,000 to US$60,000 a patient-year (2024) in high-income countries at standard dosing of 0.4 to 0.6 g/kg a month, and lower in tendered markets†. Dose is weight-based, so cost rises with body weight. It is plasma-derived and supply-constrained, so patent status does not apply. Listing status needs checking against the 24th List†.

Antibiotics for exacerbations, and prophylactic azithromycin in selected patients, at US$10 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†. Amoxicillin and azithromycin are both selected medicines on the 24th List: amoxicillin in section 6.2.1, Access group antibiotics, core list, as first choice for mild to moderate community-acquired pneumonia, chronic obstructive pulmonary disease exacerbation, otitis media, pharyngitis, sinusitis, neonatal sepsis, child sepsis, severe acute malnutrition and dental abscess; azithromycin in section 6.2.2, Watch group antibiotics, core list. The listing status of co-amoxiclav and doxycycline needs checking against the 24th List†.

Airway clearance and pulmonary rehabilitation. No medicine; the equipment is a positive-expiratory-pressure device or nothing at all.

Treatment of the autoimmune complications — corticosteroids, rituximab at a biosimilar course of US$1,500 to US$5,000 at lowest available acquisition cost, 2024†, and budesonide or immunosuppression for enteropathy. These are the same cheap off-patent agents listed under immune thrombocytopenia. Rituximab is a selected medicine on the 24th List, in sections 5.1.2 and 8.2.2, for multiple sclerosis and four haematological malignancies; this indication is not among them.

Targeted therapy where a monogenic cause is identified — abatacept, sirolimus, leniolisib, JAK inhibitors — patented, at US$30,000 to US$400,000 a patient-year at lowest available acquisition cost, 2024†. Listing status needs checking against the 24th List†.

Genetic testing, now standard of care because it changes management in the 10 to 30 per cent with an identified cause. A gene panel or exome costs hundreds to thousands of US dollars (2024) and is a one-off†.

Avoiding corticosteroid-first management of granulomatous disease without excluding infection.

**Simple means.** A serum immunoglobulin test. A few dollars, and it is the entire diagnostic gateway. In a disease whose main harm comes from four to nine years of diagnostic delay, the simple means is ordering the test in anyone with recurrent pneumonia or unexplained bronchiectasis.

Airway clearance by breathing technique and postural drainage. No equipment required, and established in bronchiectasis management.

Prophylactic co-trimoxazole or azithromycin, at tens of dollars a year.

Not smoking, and no household smoke exposure, which accelerates bronchiectasis.

Dental and sinus care, and prompt treatment of any infection.

Inactivated influenza vaccination of the household, and hand hygiene.

Avoiding live vaccines in the patient — free, and it prevents a specific serious harm.

The core treatment, immunoglobulin, has no simple-means substitute. It requires thousands of plasma donations per patient-year, and that constraint has no workaround.

**Gaps.** Orphanet's entry was obsoleted and the replacement carries no prevalence figure, so the commonly quoted 1-in-25,000 to 1-in-50,000 range rests on older clinical literature and registry denominators rather than a population survey. This is a diagnosis of exclusion with criteria that have changed, in ESID 2014 and ICON 2016, so prevalence and cohort composition are definition-dependent. The proportion with an identified monogenic cause rises with sequencing depth and differs three-fold between cohorts, meaning the category is shrinking as genetics advances. No trial establishes the optimal trough IgG target; the dose-response evidence is observational meta-analysis. Why the complicated phenotype develops is unknown, and it is what determines survival. No evidence shows that lymphoma surveillance improves outcome. Essentially all cohort data are from high-income countries.

---

## Severe combined immunodeficiency

**What it is.** A group of inherited defects that leave a baby with no working T cells, and often no working B or NK cells either. Infections that other infants shrug off are fatal. Without treatment it kills in the first one to two years of life.

**Measured.** Incidence from newborn screening, the only unbiased measurement: the United States multi-state T-cell receptor excision circle screening programme, covering 3,030,083 newborns across 11 programmes, found severe combined immunodeficiency in 1 in 58,000 births (95% CI 1 in 46,000 to 1 in 80,000) (Kwan et al., *JAMA*, 2014). That was roughly twice the pre-screening clinical estimate of about 1 in 100,000, because infants who died before diagnosis had never been counted. Later and larger United States datasets give incidence in the range 1 in 50,000 to 1 in 65,000†.

Incidence is higher in consanguineous populations, reported at 1 in 2,500 to 1 in 10,000 in some Middle Eastern and North African cohorts, and at roughly 1 in 2,000 in Navajo and Apache populations carrying a *DCLRE1C* founder mutation†.

Genotype distribution in Western cohorts: X-linked *IL2RG* about 40 to 50 per cent, adenosine deaminase deficiency about 10 to 20 per cent, *RAG1/RAG2* about 10 per cent, *IL7R* about 10 per cent, with *JAK3*, *DCLRE1C*, *CD3* subunits and others making up the remainder†. Male predominance, because *IL2RG* is X-linked.

Survival depends almost entirely on age at transplant. Transplanted under 3.5 months of age, overall survival is roughly 92 to 94 per cent; transplanted later with active infection, roughly 50 to 66 per cent (Primary Immune Deficiency Treatment Consortium multicentre analyses; Pai et al., *NEJM*, 2014, and subsequent reports). Untreated, mortality is essentially 100 per cent by age two.

No global death count. In countries without newborn screening most affected infants die undiagnosed, which is why the pre-screening incidence estimate was half the true figure.

**Where it starts.** Monogenic defects in T-cell development or function, with over 20 established causal genes and heritability 1.0 for the genotype. X-linked recessive: *IL2RG*, the common gamma chain and the single commonest form. Autosomal recessive: *ADA*, *RAG1*, *RAG2*, *DCLRE1C* (Artemis), *IL7R*, *JAK3*, *CD3D/E/Z*, *PTPRC*, *LIG4*, *NHEJ1*, *AK2* (reticular dysgenesis), *PNP*, *CORO1A*, *ZAP70*, *DOCK2*, *RAC2*.

Consanguinity directly raises the frequency of the autosomal recessive forms, by an order of magnitude in highly consanguineous populations. Founder mutations occur in genetically isolated populations: *DCLRE1C* in Navajo and Apache communities, *RAG1* and *ZAP70* in Mennonite communities.

What makes it lethal: absence of T-cell immunity means no control of *Pneumocystis jirovecii*, cytomegalovirus, adenovirus, rotavirus, BCG, *Candida* and live vaccine organisms, and maternal T-cell engraftment can cause graft-versus-host disease.

The one modifiable determinant of outcome is age at treatment, which is a health-system variable rather than a biological one.

*Not known*: the proportion of cases worldwide accounted for by genes not yet described — new causes continue to be identified. Why some genotypes, such as hypomorphic *RAG1* variants, give leaky disease or Omenn syndrome rather than classical disease. The long-term immune reconstitution and malignancy outcomes of gene therapy beyond 20 years, which is too recent to measure.

**Cure status.** CURABLE. This is one of the clearest curable entries in the chapter, and it has been since the first successful transplant in 1968.

Allogeneic haematopoietic stem cell transplant: Primary Immune Deficiency Treatment Consortium data give overall survival roughly 92 to 94 per cent when transplanted before 3.5 months of age, falling to roughly 50 to 66 per cent when transplanted later with active infection†. Matched sibling donors give the best results, but with modern haploidentical and matched unrelated approaches donor availability is no longer the limiting factor. Age at transplant is.

Gene therapy for adenosine deaminase deficiency, using autologous CD34+ cells transduced with an *ADA* gene. The retroviral product approved in the European Union in 2016 achieved 100 per cent survival in its registrational cohort at a median follow-up of several years, with the large majority free of enzyme replacement, priced at €594,000 per treatment (2016) under an outcomes-based arrangement†; it is commercially near-dormant. Lentiviral adenosine deaminase gene therapy reported overall survival of 100 per cent and event-free survival around 95 per cent in pooled United States and United Kingdom cohorts at two to three years, with no insertional oncogenesis to date.

Gene therapy for X-linked disease. The first-generation retroviral trials of 1999 to 2006 cured the immunodeficiency but caused T-cell leukaemia in 5 of 20 patients through insertional activation of *LMO2*† — the defining safety event of the gene therapy field. Self-inactivating lentiviral vectors have since produced immune reconstitution in infants and in previously transplanted older children, in the St Jude and UCSF trials reported in *NEJM* in 2019 and later, with no leukaemia reported to date†. Not yet licensed.

Enzyme replacement for adenosine deaminase deficiency, with pegademase bovine and later elapegademase, bridges to definitive treatment and sustains some patients for years, but immune reconstitution is incomplete and declines. Control, not cure.

Thymus transplantation for complete DiGeorge syndrome or athymia — not severe combined immunodeficiency proper but the same clinical problem — using allogeneic processed thymus tissue approved in the United States in 2021, with survival roughly 70 to 75 per cent at one year and subsequent T-cell development†.

**Prevention.** Newborn screening by T-cell receptor excision circle assay on the dried blood spot. The decisive intervention. It does not prevent the disease; it prevents death from it by identifying affected infants before infection. Measured effects: it doubled the measured incidence by finding infants who previously died undiagnosed; and it shifted transplant age below 3.5 months for the majority, which is the difference between roughly 92 and roughly 50 to 66 per cent survival†. Now implemented in all 50 United States states, completed 2018, and in a growing number of countries including Israel, Taiwan, Norway, Sweden, Iceland, Switzerland, Spain, parts of Germany, the Netherlands, Catalonia, New Zealand, parts of Canada, and England as a pilot. The assay adds on the order of five to seven dollars per newborn screened in United States estimates for 2014 to 2020†, and cost-effectiveness analyses in the United States and Europe find it cost-saving or highly cost-effective. STRONG. This is the best-evidenced prevention measure in chapter 04.

Avoiding BCG, rotavirus and other live vaccines before immune status is known in a screen-positive or at-risk infant. In countries with universal BCG at birth, disseminated BCG is a leading cause of death. STRONG.

Avoiding non-irradiated, non-CMV-safe blood products and transfusion from relatives. STRONG.

Carrier testing and genetic counselling in affected families, prenatal diagnosis, and preimplantation genetic testing. STRONG for birth prevalence in known families.

Premarital or preconception carrier screening in highly consanguineous populations, where it has reduced affected births for other recessive conditions. MODERATE, and socially contested.

Co-trimoxazole prophylaxis and immunoglobulin from diagnosis to transplant. STRONG.

**Treatment.** Allogeneic transplant, as early as possible, at US$150,000 to US$500,000 in high-income settings (2024)†. Not a medicine. The conditioning regimen varies by genotype and donor, and some *IL2RG* and *JAK3* patients engraft without conditioning from a matched sibling.

Gene therapy: licensed in the European Union for adenosine deaminase deficiency at €594,000 (2016)†; X-linked and *RAG1* products in trials.

Enzyme replacement with elapegademase, approved in the United States in 2018, patented, at US$300,000 to US$500,000 a patient-year (2024), used as a bridge†. EML status needs checking against the 24th List†.

Immunoglobulin replacement from diagnosis until B-cell function is established after transplant, which in some genotypes is never, at US$20,000 to US$60,000 a patient-year at lowest available acquisition cost, 2024†. Listing status needs checking against the 24th List†.

Co-trimoxazole for *Pneumocystis*, fluconazole or itraconazole for fungal prophylaxis, aciclovir, and pre-emptive cytomegalovirus and adenovirus monitoring with ganciclovir, valganciclovir or cidofovir. All off-patent, at US$50 to US$500 a patient-year at generic or lowest available acquisition cost, 2024†. Their listing status needs checking against the 24th List†.

Protective isolation until transplant. Irradiated, leucodepleted, CMV-negative blood products only. Nutritional support, because these infants present with failure to thrive and chronic diarrhoea.

**Simple means.** A full blood count with differential in a sick infant. Lymphopenia — an absolute lymphocyte count below roughly $2.5 \times 10^9$/L in a neonate, or below 2.0 in an older infant — is present in the great majority of cases and costs nothing extra on a blood count already being taken. Where there is no screening programme this is the only practical case-finding tool.

Not giving BCG, oral polio or rotavirus vaccine to an infant with unexplained lymphopenia, persistent thrush, chronic diarrhoea with failure to thrive, or a sibling who died in infancy. Free, and it prevents a specific fatal outcome.

Co-trimoxazole prophylaxis, at dollars a year, which prevents *Pneumocystis* pneumonia, the classic presenting killer.

Asking about previous infant deaths and about parental relatedness. In consanguineous populations this is the highest-yield question available and it costs nothing.

Breastfeeding, with the caveat that cytomegalovirus in breast milk is a recognised hazard here, so this is one of the few entries in the chapter where breastfeeding carries a specific risk and needs a clinical decision.

Protective isolation at home: hand hygiene, no visitors with infections, no crowds.

The cure requires a transplant centre. There is no simple-means cure. The simple means here are those that keep the infant alive until a transplant is possible, and those that prevent the iatrogenic deaths from live vaccines and unirradiated blood.

**Gaps.** The trade and international non-proprietary names of the adenosine deaminase gene therapy products have changed through development, and are distinct from the separate lentiviral products for metachromatic leukodystrophy and beta-thalassaemia; the product names should be checked against current regulatory listings before publication. Incidence outside countries with newborn screening is unknown, and because the pre-screening estimate was out by a factor of two, current figures for non-screening countries should be assumed to be underestimates by a similar margin. Long-term outcomes of lentiviral gene therapy beyond 20 years are unknown by construction. The insertional leukaemia experience in the X-linked retroviral trials means safety reassurance for current vectors rests on relatively short follow-up in small cohorts. Optimal conditioning intensity by genotype is not

settled; the trade-off is between engraftment, B-cell reconstitution and late toxicity including infertility. Almost no data exist from sub-Saharan Africa or South Asia, where consanguinity rates in some populations predict high incidence.

---

## Hereditary angioedema

**What it is.** An inherited shortage, or malfunction, of C1 inhibitor. Without it, bradykinin accumulates and causes sudden swelling of the skin, gut wall or throat. Antihistamines and adrenaline do not work on it, and laryngeal attacks can suffocate.

**Measured.** Prevalence is about 1 in 50,000, the long-standing and most widely used figure, with published estimates ranging from 1 in 10,000 to 1 in 150,000†. There is no population-based survey; all estimates derive from referral-centre case counts over defined populations.

Type I, with low C1-inhibitor antigen and function, is about 85 per cent; type II, with normal antigen and low function, about 15 per cent; and hereditary angioedema with normal C1 inhibitor, formerly type III, including *F12*, *PLG*, *ANGPT1*, *KNG1*, *MYOF* and *HS3ST6* variants and unknown causes, is a small and growing residual category.

The median age at first attack is in late childhood to adolescence, with roughly 50 per cent by age 10 and 90 per cent by age 20†. Untreated attack frequency is highly variable: a median of roughly one attack every one to two weeks in severely affected patients, with long attack-free intervals in others.

Historical series report mortality from laryngeal attacks of roughly 25 to 30 per cent in untreated patients†. That figure comes from pre-treatment-era cohorts and is the reason the condition is treated aggressively. With modern on-demand treatment and prophylaxis, death from it is rare.

Diagnostic delay is consistently reported at roughly 10 to 13 years from first attack to diagnosis in European and United States cohorts — among the longest in medicine, and the main avoidable harm. No major ethnic predilection is reported, and apparent differences track diagnostic capacity; Iceland, Denmark and Italy have the best-characterised national cohorts.

**Where it starts.** For types I and II, loss-of-function variants in *SERPING1*, autosomal dominant, with heritability 1.0 for the genotype. Roughly 20 to 25 per cent are de novo mutations with no family history†.

The mechanism is fully established: C1 inhibitor normally restrains plasma kallikrein and factor XIIa. Without it, kallikrein cleaves high-molecular-weight kininogen to release bradykinin, which binds the bradykinin B2 receptor and causes vascular leak. Every effective modern drug targets a step in this pathway, which is unusually clean evidence for a mechanism.

For disease with normal C1 inhibitor, *F12* gain-of-function (p.Thr328Lys) is the best established, with *PLG*, *ANGPT1*, *KNG1*, *MYOF* and *HS3ST6* following. In many families no gene is found.

Attack triggers established by patient-report cohorts: mechanical trauma, especially dental work and intubation; emotional stress; infection; menstruation; and oestrogen — combined oral contraceptives and hormone replacement reliably worsen the disease.

ACE inhibitors are contraindicated. ACE degrades bradykinin, so inhibiting it worsens the disease markedly. This is a drug interaction with a clean mechanism and a large effect.

Penetrance is high, and attack severity within a family varies widely at identical genotype.

*Not known*: why attack frequency and severity vary so much within families carrying the same *SERPING1* variant. What determines which anatomical site an attack affects. The cause in the substantial share of normal-C1-inhibitor families where no gene is identified. Whether long-term prophylaxis started in childhood changes the natural history.

**Cure status.** CONTROLLABLE. No cure exists; nothing restores *SERPING1* function.

On-demand treatment aborts attacks reliably. Icatibant, C1-inhibitor concentrate and ecallantide all shorten attacks substantially against placebo in randomised trials, with time to onset of symptom relief typically reduced from many hours to under one to two hours.

Long-term prophylaxis now achieves near-complete attack prevention in a large share of patients, which is a recent and large change. Lanadelumab, an anti-plasma-kallikrein monoclonal antibody, reduced attack rate by 87 per cent against placebo at the 300 mg every-two-weeks dose in the HELP trial, with 44 per cent of patients attack-free throughout the 26-week treatment period†. Berotralstat, an oral plasma kallikrein inhibitor, reduced attack rate by roughly 30 to 44 per cent against placebo in APeX-2 — a smaller effect than lanadelumab, and oral and once-daily†. Subcutaneous C1 inhibitor reduced attack rate by roughly 95 per cent at the higher dose in the per-protocol analysis of COMPACT, with a large share attack-free. Donidalorsen, an antisense agent against prekallikrein approved in the United States in August 2024, and garadacimab, an anti-factor-XIIa monoclonal approved in the European Union and United States in 2025, both reported attack rate reductions of roughly 85 to 90 per cent in phase 3 with high attack-free proportions†. Sebetralstat, an oral on-demand plasma kallikrein inhibitor approved in 2025, is the first oral on-demand treatment and removes the injection requirement for acute attacks.

So the disease persists for life, and in treated patients with access, attacks can be reduced to near zero. The constraint is price and access, not efficacy.

**Prevention.** No prevention of the genotype beyond genetic counselling, cascade testing of relatives, and prenatal or preimplantation diagnosis.

Cascade testing of first-degree relatives. Autosomal dominant with high penetrance, so the yield is roughly 50 per cent per first-degree relative. This is the measure that shortens the 10-to-13-year diagnostic delay in the next generation. STRONG.

Avoiding oestrogen-containing contraceptives and hormone replacement. STRONG: a consistent, large, mechanistically explained effect.

Avoiding ACE inhibitors. STRONG, mechanistic plus case evidence; angiotensin receptor blockers are preferred where an antihypertensive is needed.

Short-term prophylaxis with C1-inhibitor concentrate before dental work, surgery and intubation, which prevents the perioperative laryngeal attacks that caused much of the historical mortality. STRONG.

Long-term prophylaxis in patients with frequent attacks, with the trial figures above. STRONG.

A medical alert card or bracelet, which prevents the fatal misdiagnosis of a laryngeal attack as anaphylaxis, where adrenaline, steroids and antihistamines do not work and time is lost. STRONG in practical terms, with no trial.

**Treatment.** On-demand, first-line: plasma-derived or recombinant C1 inhibitor concentrate, at US$3,000 to US$10,000 per attack treated on United States and European list prices (2024)†. Plasma-derived product is supply-limited rather than patent-limited. EML status needs checking against the 24th List†.

Icatibant, a bradykinin B2 receptor antagonist, subcutaneous and self-administered, off-patent with generics since roughly 2019 to 2021. Originator US$8,000 to US$11,000 a dose on United States list (2023); generic US$1,500 to US$4,000 a dose (2024)†. The price fall on generic entry is one of the clearest in the chapter. EML status needs checking against the 24th List†.

Sebetralstat, oral on-demand, approved 2025, patented, with price not established in most markets at the time of writing.

Ecallantide, United States only, with a risk of anaphylaxis requiring healthcare administration.

Fresh frozen plasma contains C1 inhibitor and is the fallback where nothing else exists, used successfully for decades, with the caveat that it also contains the substrates and can occasionally worsen an attack. It is universally available where there is a blood bank.

Long-term prophylaxis: subcutaneous C1 inhibitor at US$400,000 to US$600,000 a patient-year on United States list (2024); lanadelumab at 500,000 to 700,000; oral daily berotralstat at 500,000 to 600,000; donidalorsen and garadacimab of a similar order†. None is off-patent, and the listing status of each needs checking against the 24th List†.

Attenuated androgens — danazol, stanozolol, oxandrolone — reduce attack frequency substantially, with older trials and long cohorts reporting roughly 60 to 90 per cent reductions†. Off-patent, at US$200 to US$1,500 a patient-year at generic or lowest available acquisition cost, 2024†. Side effects — virilisation, dyslipidaemia, hepatic adenoma, growth suppression in children — are why high-income guidelines moved away from them. In most of the world they remain the only affordable prophylaxis, and they work. This price gap, roughly 300-fold, is the central economic fact of this condition. Listing status needs checking against the 24th List†.

Tranexamic acid, with weak evidence, used where androgens are contraindicated, particularly in children and in disease with normal C1 inhibitor, at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†. Tranexamic acid is a selected medicine on the 24th List, section 10.2, for haemorrhage not elsewhere classified; hereditary angioedema is not among the listed indications.

What does not work: antihistamines, corticosteroids and adrenaline. Stating this is itself a treatment point, because the attacks are bradykinin-mediated rather than histamine-mediated, and treating them as anaphylaxis wastes the time in which a laryngeal attack kills.

Airway management: early intubation or surgical airway in laryngeal attacks.

**Simple means.** A medical alert card naming the diagnosis and stating that adrenaline and antihistamines do not work. Costs nothing, and prevents the commonest fatal error in managing this disease.

Avoiding oestrogen contraceptives and ACE inhibitors. Free, and among the largest modifiable effects available.

Tranexamic acid tablets, at tens of dollars a year, oral and with no cold chain; weak evidence but real use.

Danazol or stanozolol, at hundreds of dollars a year, oral, off-patent and substantially effective. Not a no-chain intervention, and it is the difference between prophylaxis and none in most countries.

Fresh frozen plasma for an acute attack where no specific agent exists. It needs a blood bank, not a pharmaceutical supply chain.

Telling the family. Autosomal dominant, 50 per cent per first-degree relative, and a 10-to-13-year diagnostic delay. A family conversation is the highest-yield free intervention here.

Pre-procedure planning for dental work: telling the dentist, and arranging short-term prophylaxis or at least on-site airway capability.

Knowing the prodrome — erythema marginatum, tingling — so that treatment is taken early, when it works best.

**Gaps.** No population-based prevalence study exists; the 1-in-50,000 figure is conventional and the published range spans fifteen-fold. The 25-to-30-per-cent untreated laryngeal mortality figure comes from pre-treatment-era case series with ascertainment biased toward severe families; it is probably an overestimate of population risk and is nonetheless the number used to justify treatment. Prophylaxis prices in high-income markets are two to three orders of magnitude above the off-patent androgen alternative, with no head-to-head trial of modern prophylaxis against danazol, so the two cannot be compared on efficacy at equal cost. Disease with normal C1 inhibitor has no diagnostic test in most families, no agreed criteria, and contested response to the same treatments. Almost no published data exist from low-income countries; the condition is presumed undiagnosed rather than absent. Whether early long-term prophylaxis in childhood alters natural history is unknown.

---

## Allergic rhinitis

Allergic rhinitis is an allergic reaction of the lining of the nose to inhaled pollen, dust mite, animal dander or mould. It brings sneezing, blockage, a running nose and itching, seasonally or year-round. ICD-11 codes it in chapter 12, among the diseases of the respiratory system, as CA08.0, and the full entry is there: “Allergic rhinitis”, in the chapter on circulatory and respiratory diseases. It carries all eight sections.

A reader in the immune chapter is sent there because the condition is an IgE-mediated allergy, and a reader looking for allergy will look among the immune diseases first. ICD-11 classes it by the organ it affects. The respiratory entry also sets it beside asthma, which it often accompanies.

---

## Food allergy

**What it is.** An immune reaction to a food protein, usually IgE-mediated, producing hives, vomiting, swelling, wheeze or collapse within minutes to two hours of eating. Milk, egg, peanut, tree nut, wheat, soy, fish, shellfish and sesame account for most of it.

**Measured.** Self-reported prevalence greatly exceeds confirmed prevalence, and this is the central measurement fact. Self-report runs at 10 to 20 per cent of the population; challenge-proven food allergy is roughly 1 to 5 per cent of adults and 5 to 8 per cent of children in high-income countries†.

HealthNuts, the largest population-based infant study using oral food challenge, found challenge-proven IgE-mediated food allergy in 10 per cent of 12-month-olds in Melbourne — raw egg 8.9 per cent, peanut 3.0 per cent, sesame 0.8 per cent†. This is among the highest measured anywhere, and Australia is a genuine high-prevalence outlier. United States surveys by Gupta and colleagues for 2018 to 2019 found about 7.6 per cent of children and 10.8 per cent of adults affected by stringent symptom criteria, though not challenge-confirmed. EuroPrevall, the standardised European multi-centre study with challenge, found challenge-confirmed prevalence of specific food allergies generally under 1 to 2 per cent per food, with large between-country differences.

Incidence peaks in the first two years. Milk and egg allergy resolve in the majority — roughly 50 to 80 per cent of milk allergy by school age, and similar for egg — while peanut, tree nut, fish and shellfish allergy mostly persist, with peanut allergy resolving in roughly 20 per cent of children†.

The trend is rising. Peanut allergy prevalence in United Kingdom and United States children roughly tripled between the mid-1990s and the mid-2000s, and hospital admissions for food-induced anaphylaxis rose several-fold in the United Kingdom, United States and Australia over two to three decades.

Measured prevalence is highest in Australia, the United Kingdom, the United States and northern Europe, and lower across much of Asia and Africa, though measurement there is sparse. Food patterns differ: buckwheat in Japan, chickpea in India, sesame in the Middle East.

Food-induced anaphylaxis fatality is rare, at population fatality rates of roughly one to three per million person-years among people with food allergy, and food allergy is a less common cause of anaphylaxis death than drugs or venom in most national series. The disparity between the fear and the measured mortality is itself a finding.

**Where it starts.** IgE sensitisation to a food protein, then mast cell and basophil activation on ingestion. Non-IgE mechanisms — food protein-induced enterocolitis syndrome, eosinophilic oesophagitis, coeliac disease — are separate entities.

The dual-allergen-exposure hypothesis holds that sensitisation occurs through an impaired skin barrier while oral exposure induces tolerance, and the trial that confirmed its practical consequence is LEAP. In LEAP (Learning Early About Peanut Allergy, Du Toit et al., *NEJM*, 2015), 640 infants aged four to 11 months at high risk, with severe eczema or egg allergy, were randomised to peanut consumption or avoidance to age five. Peanut allergy at age five was reduced by about 81 per cent in the consumption group in the intention-to-treat primary analysis — in the skin-prick-negative stratum 13.7 per cent against 1.9 per cent, and in the sensitised stratum 35.3 per cent against 10.6 per cent. In LEAP-On, after one year of avoidance, 18.6 per cent of the former avoidance group were allergic against 4.8 per cent of the former consumption group, so tolerance persisted after peanut was withdrawn. The EAT trial in general-population infants found no significant effect in intention-to-treat and a significant effect per-protocol, with adherence to early introduction of multiple allergens the limiting factor. PETIT, in Japan, found that early introduction of heated egg reduced egg allergy from 37.7 per cent to 8.3 per cent†.

Eczema is the strongest risk factor. Severe infantile eczema raises food allergy risk several-fold, and the earlier and more severe the eczema, the higher the risk.

Other established risk factors: male sex in childhood, family history of atopy, vitamin D insufficiency (contested), caesarean delivery (modest), Asian or Black ancestry in Western countries, where risk is higher than in white children in United States and Australian data and the reason is unexplained, and migration from low- to high-prevalence countries, where risk rises in the children of migrants.

Twin studies for peanut allergy give heritability estimates around 0.8†, and *FLG* loss-of-function variants, which cause skin barrier defects, are associated with peanut allergy, which supports the skin-sensitisation route.

*Not known*: why food allergy prevalence rose so sharply. Why milk and egg allergy resolve and peanut and shellfish allergy do not. Why Australia measures the highest prevalence in the world. What determines anaphylaxis severity — no clinical or laboratory marker reliably predicts who will have a severe reaction, which is why all food allergy is managed as if it could be severe, and this is the largest unsolved problem in the field.

**Cure status.** Milk and egg allergy in children: SELF-LIMITING, with the majority resolving by school age without any intervention; supervised reintroduction of baked milk and baked egg accelerates resolution in some children. Peanut, tree nut, fish and shellfish allergy: CONTROLLABLE by avoidance, with roughly 20 per cent of peanut allergy resolving spontaneously.

Oral immunotherapy achieves desensitisation, not cure. In PALISADE, the trial of peanut allergen powder approved in the United States and European Union in 2020, 67.2 per cent of treated participants tolerated 600 mg of peanut protein at exit challenge against 4.0 per cent on placebo†. That is desensitisation while on daily treatment; stop the daily dose and protection is lost in most patients. Sustained unresponsiveness, persisting after stopping, is achieved in a minority, roughly 20 to 35 per cent in trials that tested it after a period of avoidance†. Adverse events are common: gastrointestinal symptoms in most, eosinophilic oesophagitis in roughly 3 to 5 per cent, and systemic allergic reactions more frequent on oral immunotherapy than on avoidance — a meta-analysis found oral immunotherapy roughly tripled the risk of anaphylaxis compared with avoidance while achieving desensitisation. That trade-off is real and is why uptake is contested. Epicutaneous and sublingual immunotherapy have smaller effects and are better tolerated.

Omalizumab, approved in the United States in February 2024 for reducing allergic reactions to accidental exposure in multi-food allergy: in the OUtMATCH trial, 67 per cent of treated participants could consume 600 mg of peanut protein against 7 per cent on placebo, with similar effects for other foods†. This is protection while on treatment, not cure.

Avoidance plus an adrenaline autoinjector is the standard of care worldwide, and nothing yet cures food allergy.

**Prevention.** This is the strongest prevention entry in chapter 04 after newborn screening for severe combined immunodeficiency, and the evidence reversed previous advice.

Early introduction of allergenic foods in infancy, from around four to six months, alongside continued breastfeeding. LEAP: about an 81 per cent reduction in peanut allergy in high-risk infants†. PETIT: egg allergy from 37.7 per cent to 8.3 per cent†. STRONG for peanut in high-risk infants, MODERATE for egg, MODERATE for the general population, where EAT was negative in intention-to-treat and positive per-protocol. This reversed the guidance of the 1990s and 2000s, which recommended delaying allergenic foods; Australian and United States guidelines changed in 2016 and 2017 following LEAP. After Australia's 2016 infant feeding guideline change, population studies reported a measurable fall in peanut allergy prevalence in subsequent infant cohorts, roughly a 16 per cent relative reduction in challenge-confirmed peanut allergy in Melbourne infants between the 2007–2011 and 2018–2019 cohorts† — one of the few documented before-and-after population effects of an allergy prevention policy.

Eczema treatment and skin barrier care in infancy: mechanistically compelling given the dual-allergen hypothesis, but the trials of emollient from birth to prevent eczema and food allergy, BEEP and PreventADALL, were negative for eczema prevention, and BEEP found

more food allergy in the emollient group. CONTESTED. This is a clear case where mechanism and trial disagree and the trials should be believed.

Exclusive breastfeeding: CONTESTED for food allergy prevention; no consistent effect.

Maternal dietary avoidance during pregnancy or lactation: WEAK to no effect. Cochrane reviews find no benefit and it is no longer recommended.

Hydrolysed infant formula to prevent allergy: CONTESTED to negative. The evidence base was found to be weak and partly compromised, and a 2016 *BMJ* systematic review and subsequent guideline changes withdrew the recommendation.

Vitamin D supplementation: CONTESTED.

Prevention of death: adrenaline autoinjector availability, written anaphylaxis plans, school and restaurant policy, and allergen labelling law. MODERATE, from before-and-after policy data; no trials are possible.

**Treatment.** Adrenaline (epinephrine) intramuscularly, by autoinjector or ampoule and syringe, is first-line and the only treatment that alters the course of anaphylaxis. The molecule is off-patent — but autoinjector devices are not: device patents kept autoinjector prices at US$300 to US$700 per two-pack in the United States (2024), while an ampoule of adrenaline costs well under one dollar (2024) and a prefilled syringe only slightly more†. This gap between drug and device is the central economic fact of food allergy care. Intranasal adrenaline was approved in the United States in 2024. Epinephrine's listing status needs checking against the 24th List†.

Avoidance of the specific food, with label reading and cross-contamination awareness. The standard of care. No cost beyond the dietary constraint and the dietitian time.

Antihistamines, for skin symptoms only. They do not treat anaphylaxis, and giving them instead of adrenaline is a recognised cause of death. Off-patent, cents a dose. Listing status needs checking against the 24th List†.

Oral immunotherapy: the licensed peanut product for ages one to 17, and non-standardised food-protein oral immunotherapy in specialist centres. Patented, at about US$10,000 to US$15,000 a patient-year on United States list (2024)†. EML status needs checking against the 24th List†.

Omalizumab for multi-food allergy, at US$30,000 to US$60,000 a patient-year at lowest available acquisition cost, 2024†. **Omalizumab is not on the 24th List at all, for any indication: a live query of the electronic Model List returns zero recommendations, zero medicines and zero therapeutic equivalents**. Biosimilars are entering.

Supervised baked milk or baked egg introduction in children who tolerate it, which accelerates resolution, expands the diet and costs nothing but clinic time.

Dietitian input, to prevent the nutritional deficiency and growth faltering that multiple food exclusion causes in children. Under-provided everywhere.

A written anaphylaxis emergency plan, with training of the family, school and workplace.

**Simple means.** Early introduction of allergenic foods in infancy. Smooth peanut butter thinned with water or milk, or well-cooked egg, from around four to six months, continued regularly. This is food, not medicine; it costs nothing; and the measured effect in high-risk infants is about an 81 per cent reduction in peanut allergy. It is the clearest case in the chapter of a simple means being the prevention.

Continuing to eat the food regularly once introduced. LEAP-On showed tolerance was lost in a fifth of children after a year of avoidance, so regular ingestion is the maintenance.

Adrenaline in an ampoule with a syringe, where autoinjectors are unaffordable. The drug costs under a dollar. Training a parent to draw up and inject is feasible and is done in several countries. Not ideal — delay and dose error are real risks — and it is the difference between having adrenaline and not having it.

Label reading, and cooking from whole ingredients. The single most effective daily measure.

Lying flat with legs raised in anaphylaxis with hypotension, and not standing the person up, which is associated with fatal outcomes. Free, and it matters.

Telling people: a written plan, a bracelet, informing school and restaurant staff.

Breastfeeding alongside the introduction of solids. No evidence that it prevents food allergy, and good evidence for other outcomes.

**Gaps.** Self-reported prevalence exceeds challenge-proven prevalence by a factor of two to ten, so any figure must state which it is, and most published national figures are self-reported. Almost all population data with oral food challenge come from Australia, Europe and North America; prevalence in Africa, South Asia and most of Latin America is essentially unmeasured. Why prevalence rose, and why Australia is the outlier, are unexplained. BEEP and PreventADALL contradict the skin-barrier prevention hypothesis, and BEEP found more food allergy with emollient; mechanism and trial disagree. Hydrolysed formula recommendations were withdrawn after the underlying evidence base was found to be weak, and some national guidelines still carry the old advice. Oral immunotherapy increases anaphylaxis risk while achieving desensitisation, and whether that trade is worth it is contested, with patient and clinician views differing. No marker predicts reaction severity, which is the field's central unsolved problem. The EAT trial was negative in intention-to-treat and positive per-protocol, and sources cite whichever suits.

---

## Anaphylaxis

**What it is.** A sudden, whole-body allergic reaction. Airways swell and narrow, blood pressure drops, and the person can die within minutes. Adrenaline into the muscle reverses it; nothing else reliably does.

**Measured.** Incidence is roughly 50 to 112 episodes per 100,000 person-years in systematic reviews of European and North American data, and lifetime prevalence of at least one episode roughly 0.3 to 5.1 per cent, with the commonly cited figure around 1.6 to 2 per cent†.

Hospital admissions rose several-fold over two to three decades in the United Kingdom, United States, Australia and Canada; in England, admissions rose roughly five- to sevenfold between the early 1990s and the late 2010s while case fatality fell†. The admissions rise is partly real and partly increased recognition and coding.

Case fatality is roughly 0.3 to 2 per cent of hospital-presenting episodes, and population mortality roughly 0.5 to 1 death per million population per year in high-income national series.

The cause distribution differs by age, and this is well measured. In children food is the dominant trigger, roughly 60 to 85 per cent of paediatric cases†. In adults drugs and insect venom dominate: in United Kingdom national fatality data, drugs — antibiotics, neuromuscular blockers, radiocontrast — and venom together account for the majority of anaphylaxis deaths, with food a minority.

Perioperative anaphylaxis occurs in roughly 1 in 10,000 to 1 in 20,000 anaesthetics, with neuromuscular blocking agents, antibiotics and chlorhexidine the leading causes; the United Kingdom Royal College of Anaesthetists national audit NAP6, in 2018, found mortality of about 4 per cent in perioperative anaphylaxis†.

Measured risk factors for a fatal outcome: delayed adrenaline administration; upright or sitting posture during the reaction; concomitant asthma, especially poorly controlled; adolescence and early adulthood; and peanut or tree nut as the trigger. Deaths run to a few hundred a year in large high-income countries, with no global count.

**Where it starts.** IgE-mediated mast cell and basophil degranulation in the majority, releasing histamine, tryptase, leukotrienes and platelet-activating factor, causing vasodilation, increased permeability, bronchospasm and myocardial depression. Non-IgE mechanisms: complement activation, direct mast cell activation via MRGPRX2 by vancomycin, fluoroquinolones and neuromuscular blockers, and NSAID-mediated reactions.

Established triggers: foods (peanut, tree nuts, milk, egg, shellfish, fish, sesame, wheat); drugs (beta-lactam antibiotics, NSAIDs, neuromuscular blockers, radiocontrast, chemotherapeutics, biologics); Hymenoptera venom from bee, wasp and ant; latex; chlorhexidine; and alpha-gal sensitisation after tick bite, which causes delayed anaphylaxis to mammalian meat and was described only in 2009 and is now recognised worldwide.

Measured cofactors that amplify a reaction: exercise, alcohol, NSAIDs, acute infection, menstruation and emotional stress. Food-dependent exercise-induced anaphylaxis, classically to omega-5-gliadin in wheat, requires both the food and the cofactor.

Mastocytosis and elevated baseline serum tryptase, including hereditary alpha-tryptasemia from extra copies of *TPSAB1* present in roughly 4 to 6 per cent of the general population, raise the risk of severe anaphylaxis, particularly to venom.

Heritability is not well estimated for anaphylaxis as an event. The underlying atopy is heritable, and hereditary alpha-tryptasemia is a Mendelian copy-number trait.

*Not known*: why a person reacts mildly on one exposure and fatally on the next to the same dose of the same allergen. No test predicts severity. Specific IgE concentration and skin test size correlate with the probability of reacting but not with the severity of the reaction. This is the central unknown, and it is the reason every allergic person is told to carry adrenaline. Also not known: whether the rise in admissions represents a true rise in incidence.

**Cure status.** The episode: SELF-LIMITING, and treatment is decisive. An anaphylactic episode either resolves, spontaneously or with adrenaline, within minutes to hours, or it kills. There is no cure of an event; there is treatment of one. The predisposition splits. Hymenoptera venom anaphylaxis: CURABLE. Drug allergy with an incorrect label: CURABLE by diagnosis. Food allergy: CONTROLLABLE by avoidance.

Venom immunotherapy is curative for Hymenoptera venom anaphylaxis, which is the strongest cure claim in allergy. After a three-to-five-year course, the risk of systemic reaction to a subsequent sting falls from roughly 40 to 60 per cent to 5 to 10 per cent, and protection persists for years to decades after treatment stops. The evidence is randomised trials plus sting challenge studies. This is a genuine cure for a potentially fatal condition, achieved with an off-patent biological extract.

Drug allergy is often curable by correct diagnosis. A large majority of people labelled penicillin-allergic are not; direct oral challenge, or skin testing followed by challenge, delabels roughly 90 to 95 per cent of people carrying a penicillin allergy label†. The cure is removing an incorrect diagnosis.

**Prevention.** Prompt intramuscular adrenaline. Delay in administration is the most consistently identified factor in fatal cases. STRONG — no randomised trial exists and none is possible; the evidence is from fatality series and is accepted universally.

Lying the person flat, or flat with legs raised, and not standing or sitting them up. Fatality series document deaths occurring on sudden assumption of an upright posture, through the empty-ventricle mechanism. MODERATE, from case series.

Prescription and carriage of two adrenaline autoinjectors, with a written plan and training. MODERATE.

Venom immunotherapy for people with systemic sting reactions, reducing subsequent systemic reaction risk from roughly 40 to 60 per cent to 5 to 10 per cent. STRONG.

Penicillin allergy de-labelling, which removes both the risk from the alternative antibiotics and the false constraint. STRONG.

Asthma control in food-allergic patients, since poorly controlled asthma is a consistent risk factor for fatal food anaphylaxis. MODERATE.

Drug allergy prevention: accurate allergy records, test-before-prescribe for high-risk drugs, and perioperative protocols following the NAP6 recommendations on chlorhexidine and neuromuscular blockers. MODERATE.

Allergen labelling law and school and restaurant policy. MODERATE, from before-and-after national data.

Early allergen introduction in infancy, which prevents the food allergy that causes paediatric anaphylaxis. STRONG for peanut in high-risk infants.

Avoiding beta-blockers and ACE inhibitors in patients on venom immunotherapy or at high anaphylaxis risk is traditional advice; the evidence is weak and the guidance has softened. CONTESTED.

**Treatment.** Adrenaline (epinephrine), 0.3 to 0.5 mg intramuscularly into the anterolateral thigh in adults, 0.01 mg/kg in children, repeated after five to 15 minutes if needed. First-line,

and there is no substitute. The molecule has been off-patent for a century. An ampoule of 1 mg/mL adrenaline costs well under one dollar (2024) at international generic prices†. An autoinjector two-pack runs US$300 to US$700 on United States list (2024), generic autoinjectors US$100 to US$300, and in Europe €50 to €150†. The device, not the drug, is the cost. Intranasal adrenaline was approved in the United States in August 2024 and is priced as a branded product. Epinephrine's listing status needs checking against the 24th List†.

Positioning the patient flat, legs raised if hypotensive, on the side if vomiting, sitting up only if breathing is the dominant problem. Free, with evidence from fatality series.

Oxygen and intravenous fluids, with large-volume crystalloid for distributive shock. Sodium chloride and Ringer's lactate are off-patent and cost cents to dollars; listing status needs checking against the 24th List†.

Inhaled salbutamol for bronchospasm, as an adjunct only, off-patent at two to ten dollars an inhaler (2024)†. Listing status needs checking against the 24th List†.

Antihistamines and corticosteroids are adjuncts, not treatments. They do not reverse airway obstruction or hypotension. Evidence that corticosteroids prevent biphasic reactions is weak and recent reviews question the practice. Giving them instead of adrenaline is a recognised contributor to death.

Glucagon for patients on beta-blockers who do not respond to adrenaline. Off-patent; listing status needs checking against the 24th List†.

Observation after the episode for a biphasic reaction, four to six hours or longer depending on severity. Biphasic reactions occur in roughly 1 to 5 per cent of episodes†.

After the episode: serum tryptase taken within one to two hours and again at baseline, referral for allergy investigation, autoinjector prescription, a written plan, and trigger identification. The follow-up is where the next episode is prevented, and it is the step most often omitted.

Venom immunotherapy for venom anaphylaxis, at US$1,000 to US$3,000 a patient-year for three to five years at lowest available acquisition cost, 2024† — against a cured, potentially fatal condition, which makes it one of the better-value interventions in this chapter. These are biological extracts and standardised products are manufacturer-specific. EML status needs checking against the 24th List†.

**Simple means.** Adrenaline in an ampoule with a 1 mL syringe. The drug costs under a dollar and has been off-patent for a century. Where autoinjectors cost hundreds, this is the difference between having adrenaline available and not. Several countries train patients and health workers to draw up and inject. The trade-off — delay and dosing error under stress — is real and should be stated, and so should the price.

Lying the person down. Free, and documented in fatality series as decisive.

Giving the injection into the outer thigh through clothing if necessary. No preparation needed.

Calling for help and not letting the person walk. Knowing not to wait for antihistamines to work.

Avoidance of the identified trigger, and a written card naming it.

Removing a bee sting by scraping rather than squeezing.

In alpha-gal syndrome, avoiding mammalian meat and preventing tick bites — long trousers, tick checks, prompt removal.

Early allergen introduction in infancy, which is prevention upstream of the whole entry.

**Gaps.** Incidence estimates span roughly two-fold and lifetime prevalence estimates roughly seventeen-fold, from 0.3 to 5.1 per cent, because case definition and ascertainment differ; there is no agreed clinical definition applied consistently across studies. Whether the several-fold rise in admissions is a real rise in incidence or improved recognition and coding is unresolved, and case fatality fell over the same period, which argues for ascertainment. No global incidence or mortality estimate exists. No test predicts reaction severity, which is the field's central unsolved problem and determines how the condition is managed worldwide. Corticosteroids for preventing biphasic reactions: long-standing practice, weak evidence, increasingly questioned, and sources disagree. Whether beta-blockers and ACE inhibitors

meaningfully worsen outcomes is contested. The autoinjector price gap — under a dollar of drug against hundreds of dollars of device — is a market phenomenon rather than a manufacturing one, and no public figure for autoinjector production cost exists comparable to the published insulin analysis.

---

## Drug allergy

**What it is.** An immune reaction to a medicine. It ranges from a rash to anaphylaxis to severe skin and organ reactions that kill. Most people who believe they are allergic to a drug are not, and the wrong label does its own harm.

**Measured.** Penicillin allergy label prevalence is roughly 6 to 10 per cent of the general population in high-income countries, and higher in hospital inpatient populations. Roughly 90 to 95 per cent of those labels are wrong: direct oral challenge, or skin testing followed by challenge, de-labels about nine in ten people carrying a penicillin allergy label. This is one of the best-replicated findings in clinical allergy. True immediate, IgE-mediated penicillin allergy accounts for roughly 1 to 5 per cent of labelled patients†.

The measured harm of the incorrect label: patients labelled penicillin-allergic have longer hospital stays, roughly 10 per cent longer in a large United States cohort; roughly 14 per cent more meticillin-resistant *Staphylococcus aureus*; roughly 23 per cent more *Clostridioides difficile*; and more vancomycin, clindamycin and fluoroquinolone use (Macy and Contreras, *J Allergy Clin Immunol*, 2014; Blumenthal et al., *BMJ*, 2018). Surgical site infection rates are higher because of second-line surgical prophylaxis.

Severe cutaneous adverse reactions: Stevens-Johnson syndrome and toxic epidermal necrolysis occur at roughly one to six cases per million person-years, with mortality of roughly 5 to 10 per cent for Stevens-Johnson syndrome and 25 to 50 per cent for toxic epidermal necrolysis†. Drug reaction with eosinophilia and systemic symptoms occurs in roughly 1 in 1,000 to 1 in 10,000 exposures for high-risk drugs, with mortality roughly 5 to 10 per cent†. Acute generalised exanthematous pustulosis occurs at roughly one to five per million per year with low mortality.

Commonest culprits for severe reactions: allopurinol, carbamazepine, lamotrigine, phenytoin, nevirapine, abacavir, sulfonamides including co-trimoxazole, NSAIDs and beta-lactams.

Perioperative drug anaphylaxis occurs in roughly 1 in 10,000 to 1 in 20,000 anaesthetics; NAP6 found antibiotics, neuromuscular blockers and chlorhexidine as the leading agents and mortality of about 4 per cent†. Drug allergy labels accumulate with age and healthcare exposure, and women carry more labels than men.

**Where it starts.** Four established and distinct mechanisms. Type I, IgE-mediated: immediate urticaria, angioedema, bronchospasm and anaphylaxis, with beta-lactams, neuromuscular blockers and chlorhexidine. Types II and III: cytopenias, serum sickness, vasculitis. Type IV, T-cell-mediated: delayed maculopapular exanthem, Stevens-Johnson syndrome and toxic epidermal necrolysis, drug reaction with eosinophilia and systemic symptoms, and acute generalised exanthematous pustulosis. And non-immune pharmacological hypersensitivity: NSAID-exacerbated respiratory disease via COX-1 inhibition, MRGPRX2-mediated direct mast cell activation by vancomycin, fluoroquinolones and neuromuscular blockers, and ACE-inhibitor angioedema via bradykinin. The last group are not allergies and do not involve IgE, which matters for testing.

The HLA associations are among the strongest gene-drug associations in all of medicine, and they are actionable. *HLA-B*57:01* and abacavir hypersensitivity: the PREDICT-1 randomised trial showed that prospective screening eliminated immunologically confirmed hypersensitivity, 0 per cent against 2.7 per cent†. Screening before abacavir is now standard worldwide, and this is the clearest pharmacogenomic prevention success in medicine. *HLA-B*15:02* and carbamazepine-induced Stevens-Johnson syndrome and toxic epidermal necrolysis in Han Chinese, Thai and other Southeast Asian populations: odds ratios of roughly 25 to 100, and Taiwan's national screening programme before carbamazepine reduced carbamazepine-induced cases to near zero. *HLA-B*58:01* and allopurinol-induced Stevens-Johnson syndrome and toxic epidermal necrolysis: odds ratio roughly 80 to 100 in Han Chinese†. *HLA-A*31:01*

and carbamazepine-induced drug reaction with eosinophilia in Europeans. *HLA-B*13:01* and dapsone hypersensitivity.

The HLA associations mean severe cutaneous reactions have a strong, population-specific genetic component with very large effect sizes, which is unusual in this field. But penetrance is low: most carriers of *HLA-B*15:02* exposed to carbamazepine do not develop Stevens-Johnson syndrome, so the allele is necessary but not sufficient in most cases.

Established risk factors: concurrent viral infection, with Epstein-Barr virus and amoxicillin rash and HIV and sulfonamide reactions; high drug dose and parenteral route; repeated intermittent exposure; female sex; and prior reaction to a structurally related drug.

*Not known*: why most carriers of a high-risk HLA allele never react. Whether the allergy label applied in childhood after an amoxicillin rash during a viral illness has any immunological basis — mostly it does not. What triggers Stevens-Johnson syndrome or toxic epidermal necrolysis in the individual. No test reliably predicts delayed severe reactions prospectively except the HLA alleles.

**Cure status.** Incorrect penicillin allergy labels, roughly 90 to 95 per cent of them: CURABLE by diagnosis. True IgE-mediated allergy: CONTROLLABLE by avoidance. Severe cutaneous adverse reactions: RELIEF ONLY for the acute event, with absolute avoidance thereafter. Aspirin-exacerbated respiratory disease: CONTROLLABLE.

A direct oral amoxicillin challenge in a low-risk patient, or skin testing followed by challenge, removes the label permanently. The patient leaves without the disease because they never had it. De-labelling is durable, with low relabelling rates after documented de-labelling, provided the record is actually updated.

For true IgE-mediated allergy, drug desensitisation is available where the drug is essential — aspirin in coronary disease, chemotherapy agents, insulin, antibiotics in resistant infection. Desensitisation produces temporary tolerance for the duration of continuous administration and is lost when the drug is stopped.

For severe cutaneous reactions there is no cure and no desensitisation, and re-exposure after Stevens-Johnson syndrome or toxic epidermal necrolysis can be fatal. Acute management is supportive: withdrawal of the drug, burn-unit-level care, fluid and electrolyte management, and eye and mucosal care. Specific immunomodulation with ciclosporin, intravenous immunoglobulin, etanercept or corticosteroids is used and the evidence is weak and conflicting; observational data and small trials suggest ciclosporin and etanercept may reduce mortality, and immunoglobulin meta-analyses are inconsistent.

In aspirin-exacerbated respiratory disease, aspirin desensitisation followed by daily aspirin improves nasal polyposis and asthma outcomes in randomised trials.

**Prevention.** This entry contains two of the strongest prevention measures in the chapter.

HLA screening before high-risk drugs. *HLA-B*57:01* before abacavir: PREDICT-1 found immunologically confirmed hypersensitivity in 0 per cent of the screened arm against 2.7 per cent unscreened†. STRONG, and it is a randomised trial, which is rare in this field. *HLA-B*15:02* before carbamazepine in Southeast Asian populations, where Taiwan's national programme reduced cases to near zero. STRONG. *HLA-B*58:01* before allopurinol in Han Chinese and related populations. MODERATE. A single HLA test costs tens to hundreds of US dollars (2024), once and for life†.

Penicillin allergy de-labelling programmes, which reduce broad-spectrum antibiotic use, *C. difficile*, meticillin-resistant *S. aureus* and length of stay. STRONG.

Accurate allergy documentation — recording what happened, when, and with what drug, rather than the word allergy. The commonest preventable cause of an incorrect lifelong label. MODERATE, with a large effect at zero cost.

Not labelling a viral exanthem during amoxicillin treatment as penicillin allergy. MODERATE.

Avoiding unnecessary antibiotic prescribing, which reduces exposure and therefore reactions. MODERATE.

Perioperative measures following the NAP6 recommendations on chlorhexidine documentation and neuromuscular blocker choice. MODERATE.

Avoiding re-exposure after a severe cutaneous reaction, and avoiding structurally related drugs, given aromatic anticonvulsant cross-reactivity. STRONG.

Not using a drug with a known high-risk HLA association in a population where that allele is common, when an alternative exists — preferring other urate-lowering or anticonvulsant agents in high-prevalence populations where screening is unavailable. MODERATE.

**Treatment.** Stop the drug. First, and decisive, particularly in severe cutaneous reactions where time to withdrawal correlates with mortality.

For anaphylaxis, intramuscular adrenaline, off-patent, under one dollar an ampoule (2024)†. Listing status needs checking against the 24th List†.

For urticarial and mild cutaneous reactions, second-generation antihistamines, off-patent at US$2 to US$20 a patient-year at generic or lowest available acquisition cost, 2024†, with short corticosteroid courses for extensive rash. Listing status needs checking against the 24th List†.

Diagnostic evaluation is the main intervention. Direct oral challenge in low-risk penicillin allergy labels is safe in validated risk-stratification pathways such as PEN-FAST, performable by non-allergists, and the cheapest effective tool here; the cost is clinic time and a dose of amoxicillin. Amoxicillin is a selected medicine on the 24th List, section 6.2.1, Access group antibiotics, core list. Skin prick and intradermal testing for immediate reactions to beta-lactams, neuromuscular blockers and chlorhexidine. Patch testing and delayed intradermal testing for delayed reactions. Serum specific IgE and basophil activation testing, of limited sensitivity and adjunctive. Serum tryptase during an acute reaction.

Drug desensitisation protocols where the drug is essential — aspirin, platinum and taxane chemotherapy, biologics, antibiotics, insulin, antituberculous drugs. Temporary tolerance, and standard practice in specialist centres.

Severe cutaneous adverse reactions: withdrawal, supportive care in a burn or intensive care setting, fluid and electrolyte management, nutritional support, ophthalmology and mucosal care, and infection surveillance without prophylactic antibiotics. Specific immunomodulation is contested. Ciclosporin, with observational data and small trials suggesting reduced mortality, off-patent at US$50 to US$300 a course at generic or lowest available acquisition cost, 2024†; its listing status needs checking against the 24th List†. Etanercept, where a randomised trial against corticosteroids showed faster re-epithelialisation and lower mortality, with biosimilars available at US$1,000 to US$5,000 a course at lowest available acquisition cost, 2024†. Intravenous immunoglobulin, with inconsistent meta-analyses, expensive and plasma-constrained. Corticosteroids, long-standing and contested.

An updated medical record and a patient-held card. The treatment that prevents the next reaction, and the step most often omitted.

**Simple means.** Asking what actually happened. A rash as a child during a chest infection is not an allergy. A two-minute history de-labels a large share of patients before any test. It costs nothing and has the largest measured effect in this entry.

Direct oral challenge in low-risk patients. One dose of amoxicillin and an hour of observation. No specialist allergy service, no skin testing, no laboratory. This is the instrument that makes de-labelling feasible at scale.

Writing down the reaction, not the word allergy. Free.

Carrying a card naming the drug and the reaction, particularly after a severe cutaneous reaction, where re-exposure can kill.

Stopping the drug early. In Stevens-Johnson syndrome and toxic epidermal necrolysis, time to withdrawal is a measured determinant of mortality, and recognising a spreading painful rash with mucosal involvement as an emergency costs nothing.

Avoiding unnecessary antibiotics — fewer exposures, fewer reactions. Not using a known cross-reacting drug, such as another aromatic anticonvulsant after a reaction to one of them.

Eye care in the acute phase: lubrication and early ophthalmology review prevent the blindness that is the commonest permanent sequela.

**Gaps.** Nearly all de-labelling and HLA data come from high-income countries, and the global burden of incorrect allergy labels and of severe cutaneous reactions is unmeasured. HLA

allele frequencies are population-specific, so screening recommendations do not transfer: *HLA-B*15:02* screening before carbamazepine is cost-effective in Southeast Asia and not in northern Europe, guidelines differ accordingly, and this is a real rather than apparent disagreement. Severe cutaneous reaction incidence figures rest on registry and spontaneous reporting, which under-ascertain. Treatment of Stevens-Johnson syndrome and toxic epidermal necrolysis is genuinely contested: ciclosporin, etanercept, immunoglobulin and corticosteroids all have advocates, the trials are small or observational, and mortality figures for toxic epidermal necrolysis span 25 to 50 per cent between series. No prospective test predicts delayed severe reactions except the HLA alleles, and those have low penetrance. De-labelling durability depends on record systems actually being updated, which is an informatics problem rather than a clinical one, and is poorly measured.

---

## Sarcoidosis

**What it is.** Clumps of immune cells called granulomas form in organs, most often the lungs and lymph nodes. In many people they go away on their own. In others they scar the lung or damage the heart, eyes, skin, nerves or liver. The cause is unknown.

**Measured.** The variation by ancestry is the central measured finding. Incidence and prevalence per 100,000, by source, setting and period:

| Source | Setting and period | Group | Rate |
|---|---|---|---|
| Baughman et al. | US managed care, 2010–2013 | Black / White / Hispanic / Asian | Incidence 17.8 / 8.1 / 4.3 / 3.2 |
| Baughman et al. | US managed care, 2009–2013 | Black / White | Prevalence 141.4 / 49.8 |
| Rybicki et al. | Detroit HMO, 1990–1994 | Black / White | Incidence 35.5 / 10.9 |
| Dumas et al. | Nurses' Health Study II, 1989–2011 | Black / White | Incidence 43 / 11 |
| Cozier et al. | Black Women's Health Study, 1995–2007 | Black women | Incidence 71 |
| Ungprasert et al. | Olmsted County MN, 1976–2013 | Male / Female, 90% white | Incidence 10.5 / 11 |
| Arkema et al. | Sweden, 2003–2013 | not reported | Incidence 11.5 |
| Hillerdal et al. | Uppsala, Sweden, 1966–1980 | Male / Female | Incidence 16.5 / 21.7, 19 overall |
| Coquart et al. | Guadeloupe, 2003–2010 | Afro-Caribbean | Incidence 2.3 |
| Duchemann et al. | Greater Paris, 2012 | Afro-Caribbean / North African / Other / European | Incidence 16.9 / 9.7 / 6.4 / 2.4 |

These come from different countries, periods and case definitions and are not directly comparable. Black-to-White incidence ratios in the United States run roughly 2.2:1 in managed care, 3.3:1 in Detroit and 3.9:1 in the Nurses' Health Study II, with a prevalence ratio about 2.8:1†; the literature commonly states as high as 4:1. The highest age-specific rate recorded is 107 per 100,000 in Black women aged 30 to 39 in Detroit†.

Peak onset is at 25 to 45, with a second peak in women over 50 in Scandinavian data. Age-adjusted sarcoidosis mortality in United States NCHS data for 1999 to 2010 was 16 per million in Black patients against 1.3 per million in White patients, about twelve-fold; a 1979–1991 analysis gave a Black-to-White ratio of 14:1. All-cause sarcoidosis mortality rose about 3 per cent a year between 1988 and 2007, with the largest absolute increase in Black women at 10 per million, then Black men at 3 per million, and White men and women at most 1 per million.

Roughly 60 to 70 per cent of patients with acute presentations remit spontaneously within two to three years; roughly 10 to 30 per cent develop chronic progressive disease; and roughly 1 to 5 per cent die of it, mostly from pulmonary fibrosis, and in Japan from cardiac sarcoidosis. Löfgren syndrome — acute presentation with erythema nodosum, bilateral hilar lymphadenopathy, fever and arthralgia — carries a spontaneous remission rate above 90 per cent and is strongly associated with *HLA-DRB1*03*†.

The highest reported rates are in northern Europe and among African-descended populations in the United States and France. The Guadeloupe incidence of 2.3 against the Paris Afro-Caribbean incidence of 16.9 in the same ancestry group is a striking and unexplained environment effect.

**Where it starts.** The cause is unknown, and that must be stated first. The leading model is an exaggerated Th1/Th17 granulomatous response to one or more poorly cleared antigens in a genetically susceptible person, and no antigen is established.

Candidate antigens, none proven: *Cutibacterium acnes*, the most consistently recovered organism and found in a majority of sarcoid lymph nodes in Japanese studies; *Mycobacterium tuberculosis* catalase-peroxidase and ESAT-6, to which immune responses are found more often in patients than controls; and inorganic antigens — silica, aluminium, zirconium and beryllium. Chronic beryllium disease is clinically indistinguishable from sarcoidosis and is caused by a defined exposure plus *HLA-DPB1* Glu69, which is the closest thing to a model of sarcoidosis causation.

Measured occupational and environmental associations: the World Trade Center responder cohort showed a markedly raised incidence of sarcoidosis-like granulomatous disease after dust exposure. Agricultural dust, mould, musty odours, metal dust, firefighting and insecticide use show consistent positive associations in the ACCESS case-control study. Silica exposure associates with granulomatous lung disease.

Smoking is inversely associated with sarcoidosis — one of the few diseases where smoking appears protective, consistent across studies and unexplained.

The strongest genetic associations are in the HLA region: *HLA-DRB1*03* with Löfgren syndrome and good prognosis, *HLA-DRB1*15* with chronic disease, *HLA-DQB1*0601* with cardiac and multi-organ disease in Japanese patients. Non-HLA: *BTNL2*, *ANXA11*, *RAB23*, *IL23R*, *NOTCH4*. Familial relative risk is roughly 5 to 6 in siblings and roughly 4 in parents, from ACCESS and Swedish registry data, and heritability from Swedish twin and family data is roughly 0.4 to 0.7†.

Ancestry alone does not explain it: the Guadeloupe-against-Paris difference in the same population, and the Scandinavian peak, point to environment.

*Not known*: the cause. Why the same disease remits spontaneously in most and progresses in a minority. Why mortality is twelve-fold higher in Black Americans — whether this reflects disease biology, later presentation, access, or all three, is unresolved and is the most consequential unknown in the entry. Why smoking is protective. Why Afro-Caribbean people in Paris have seven times the incidence of Afro-Caribbean people in Guadeloupe.

**Cure status.** Acute presentations, including Löfgren syndrome: SELF-LIMITING in roughly 60 to 70 per cent, who remit spontaneously within two to three years, and in over 90 per cent of Löfgren syndrome†. Many patients need no treatment at all, and treating them exposes them to corticosteroid harm for no benefit; observation is an evidence-based management strategy, which is unusual. Progressive disease: CONTROLLABLE — corticosteroids and steroid-sparing agents suppress granulomatous inflammation and preserve organ function without curing, and relapse on withdrawal is reported in roughly one-third to two-thirds depending on organ and duration of treatment. Established fibrosis: RELIEF ONLY — pulmonary fibrosis does not reverse, and lung transplantation is the end-stage option.

Corticosteroids have never been shown to change long-term outcome. This is a genuine and important negative: Cochrane reviews of corticosteroids in pulmonary sarcoidosis find improvement in chest radiograph appearance and some lung function measures over six to 24 months, and no evidence of improved long-term outcome. Treatment is given for symptoms and for threatened organ function, not because it is known to alter the disease course.

**Prevention.** No established primary prevention. The cause is unknown, and that should be stated plainly.

Reducing occupational dust, silica, metal and mould exposure, supported by the ACCESS case-control associations and the World Trade Center cohort. MODERATE for the association, WEAK as a demonstrated prevention measure, since no intervention study exists.

Beryllium exposure control prevents chronic beryllium disease, the one sarcoidosis-like granulomatous disease with a known cause and an established exposure limit. STRONG — and it prevents beryllium disease rather than sarcoidosis.

Smoking: here the evidence runs the other way, since smoking is inversely associated with sarcoidosis. Nobody recommends smoking, and the finding is reported as an unexplained epidemiological observation rather than as advice. CONTESTED and not actionable.

Prevention of harm from over-treatment, by observation rather than corticosteroids in asymptomatic stage I disease and in Löfgren syndrome. MODERATE, and it prevents iatrogenic harm, which in this disease is substantial.

Prevention of complications: ophthalmological screening at diagnosis and periodically, because ocular sarcoidosis is often asymptomatic and causes blindness; electrocardiography and, where indicated, cardiac imaging, because cardiac sarcoidosis causes sudden death and is the leading cause of sarcoidosis death in Japan; calcium and vitamin D caution, because the disease causes hypercalcaemia through extrarenal 1-alpha-hydroxylation; and bone protection in patients on prolonged corticosteroids. STRONG for each.

**Treatment.** Observation, for asymptomatic stage I disease, Löfgren syndrome and mild disease. Evidence-based and free.

Oral prednisolone, first-line for symptomatic pulmonary disease and for cardiac, neurological, ocular and renal involvement and hypercalcaemia. It improves radiographic and some functional measures with no demonstrated long-term outcome benefit. Off-patent, at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024†. Harm from prolonged use — diabetes, osteoporosis, weight gain, infection, cataract — is substantial and is the main reason for steroid-sparing agents. Listing status needs checking against the 24th List†.

Methotrexate, the best-evidenced steroid-sparing agent, with randomised and large observational data supporting steroid dose reduction. Off-patent, at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024, plus folic acid and monitoring blood tests†. Methotrexate is a selected medicine on the 24th List, in section 8.2.1 cytotoxic medicines, complementary list, for leukaemias, lymphomas, early stage breast cancer, gestational trophoblastic neoplasia, Langerhans cell histiocytosis and osteosarcoma, and in section 13.4 for disorders of skin differentiation and proliferation, complementary list. Sarcoidosis is not among the listed indications.

Azathioprine, mycophenolate mofetil and leflunomide as second-line steroid-sparing agents, off-patent, with azathioprine at US$50 to US$200 a patient-year at generic or lowest available acquisition cost, 2024†. Listing status needs checking against the 24th List†.

Hydroxychloroquine for cutaneous disease and hypercalcaemia, off-patent at US$30 to US$150 a patient-year at generic or lowest available acquisition cost, 2024†. Listing status needs checking against the 24th List†.

TNF inhibitors — infliximab and adalimumab — for refractory disease including neurosarcoidosis and cardiac sarcoidosis. Randomised evidence for infliximab in pulmonary sarcoidosis shows a modest forced vital capacity improvement. Both have biosimilars widely available, at US$2,000 to US$10,000 a patient-year for a biosimilar at lowest available acquisition cost, 2024, down from originator prices five to twenty times higher†; the biosimilar price collapse is the main access change in this disease in the past decade. On the 24th List, **adalimumab is a selected medicine**, in section 8.1 immunomodulators for non-malignant disease, complementary, in section 13.4, and under medicines for juvenile joint diseases, for axial spondyloarthritis, Crohn disease, rheumatoid arthritis, juvenile idiopathic arthritis and psoriasis. **Infliximab is on the list only as a therapeutic equivalent to adalimumab for those same indications, not as a selected medicine**. Sarcoidosis is not among the listed indications for either.

Inhaled corticosteroids for cough, with little effect on disease.

Antifibrotics in fibrotic sarcoidosis: the INBUILD trial included progressive fibrosing interstitial lung diseases other than idiopathic pulmonary fibrosis, among them sarcoidosis, and showed slowed forced vital capacity decline in the overall population. Sarcoidosis-specific evidence is thin. Pirfenidone is off-patent, nintedanib is not. Listing status needs checking against the 24th List†.

Organ-specific treatment: an implantable defibrillator in cardiac sarcoidosis; and antimicrobial regimens targeting *C. acnes* and mycobacteria, trialled in cutaneous and pulmonary sarcoidosis with some positive results — notable because the drugs are cheap and off-patent, and because they test the infectious hypothesis directly. The evidence is preliminary.

Lung transplantation for end-stage fibrosis.

Efzofitimod, a neuropilin-2 agonist, is in phase 3 for pulmonary sarcoidosis, with the EFZO-FIT trial reporting in 2025. Not approved at the time of writing.

**Simple means.** Doing nothing, deliberately. For most patients the correct initial management is observation, and it is free. In a disease where 60 to 70 per cent remit spontaneously and corticosteroids have no proven long-term benefit, restraint is the intervention.

An eye examination. Ocular sarcoidosis is often asymptomatic and causes blindness, and a slit-lamp examination at diagnosis is cheap and prevents a major permanent harm.

An electrocardiogram. Cardiac sarcoidosis causes sudden death, and a resting electrocardiogram costs almost nothing and is the entry point to detecting it.

Avoiding vitamin D and calcium supplements unless concentrations are checked. Sarcoid granulomas convert 25-hydroxyvitamin D to the active form, so supplementation can cause hypercalcaemia and kidney stones. A simple means that prevents harm, and one routinely missed because patients on corticosteroids are usually given calcium and vitamin D.

Sun exposure in moderation rather than supplementation, for the same reason, where bone health is a concern — though this interacts with the hypercalcaemia risk and needs monitoring.

Stopping occupational dust exposure where one is identified.

Not smoking. Notwithstanding the inverse association with developing sarcoidosis, smoking worsens every pulmonary outcome once the disease exists.

Pulmonary rehabilitation and graded exercise for fatigue and deconditioning. Fatigue is the most common and most disabling symptom and responds poorly to immunosuppression; exercise programmes show measurable improvement in fatigue and exercise capacity in small trials.

Weight and bone protection during corticosteroid treatment.

**Gaps.** The incidence and prevalence figures in the table come from different countries, periods and case definitions and are not directly comparable; race was not reported in the Swedish data; and only a few regions outside the United States have been studied at all. The twelve-fold mortality disparity between Black and White Americans is reported consistently and explained nowhere. The Guadeloupe-against-Paris Afro-Caribbean incidence difference in one ancestry group is unexplained and points to an environmental cause that has not been identified. There is no cause, no antigen and no diagnostic test: this remains a diagnosis of exclusion requiring compatible clinical and imaging findings, non-caseating granulomas on biopsy, and exclusion of alternatives — so prevalence figures depend on how hard clinicians look. Corticosteroids have no demonstrated long-term outcome benefit despite being standard treatment for seventy years, which is a genuine evidence gap rather than an interpretive one. The inverse smoking association is unexplained. Lifetime risk is not reported in the literature reviewed. Antimicrobial therapy testing the *C. acnes* and mycobacterial hypothesis uses cheap off-patent drugs and has preliminary positive trials, and has not been definitively tested — an unusual case where the cheap hypothesis is under-investigated.

---

## Systemic lupus erythematosus

**What it is.** The immune system attacks the body’s own cell nuclei. Almost any organ can be affected — skin, joints, kidneys, blood, brain, lungs, heart. It flares and settles, mostly in young women.

**Measured.** From the global systematic review and modelling study (Tian et al., *Annals of the Rheumatic Diseases*, 2023), the best current global synthesis: pooled incidence 5.14 per 100,000 person-years (range 1.4–15.13), about 0.40 million newly diagnosed people a year; pooled prevalence 43.7 per 100,000 (range 15.87–108.92), about 3.41 million people living with the disease.

By sex: incidence 8.82 per 100,000 person-years in women against 1.53 in men, a ratio of about 5.8:1; prevalence 78.73 against 9.26 per 100,000, a ratio of about 8.5:1†. In adults alone, incidence 7.31 and prevalence 61.08 per 100,000†.

Regionally, incidence is lowest in central Asia at 1.18 and highest in central Europe at 13.74; prevalence is lowest in southern Asia at 15.9 and highest in tropical Latin America at 110.85†. By country, the highest incidence is Poland at 81.84 and the lowest Kazakhstan at 0.57; the highest prevalence the United Arab Emirates at 166.92 and the lowest Argentina at 5.05†. The disease is recorded as more common in high-income countries, which is at least partly ascertainment. **Data are missing for 79.8 per cent of countries**†.

Peak onset is at 15 to 45. Childhood-onset disease is roughly 10 to 20 per cent of cases and is more severe, with more renal involvement†.

In national health-system data, incidence and severity are substantially higher in people of African, Hispanic, South Asian and Indigenous ancestry than in those of European ancestry; United States figures commonly report two- to four-fold higher incidence in Black women than White women, with earlier onset, more lupus nephritis and higher mortality. The global review could not assess ethnicity, because the included studies did not report it.

Standardised mortality ratios run roughly 2 to 3 against the general population in modern cohorts†. Five-year survival has risen from roughly 50 per cent in the 1950s to over 90 per cent now†. Causes of death are bimodal: early deaths from active disease and infection, later deaths from cardiovascular disease. Cardiovascular risk in young women with the disease is raised roughly five- to fifty-fold depending on age band, with the largest relative excess in women in their thirties and forties (Framingham Offspring comparison, Manzi et al.).

Lupus nephritis develops in roughly 30 to 50 per cent of patients, higher in non-European ancestry and in childhood-onset disease, and roughly 10 to 20 per cent of those progress to end-stage kidney disease despite treatment.

**Where it starts.** Loss of tolerance to nuclear antigens, impaired clearance of apoptotic debris, type I interferon pathway activation, and autoantibody and immune complex deposition with complement activation and tissue injury. The type I interferon signature is present in the majority of patients and is now a drug target.

Twin concordance is roughly 24 to 57 per cent in monozygotic twins against 2 to 5 per cent in dizygotic twins; sibling relative risk is roughly 8 to 29; and heritability is estimated at roughly 0.4 to 0.66†. Over 100 risk loci are identified, individually small except for: complement deficiencies in C1q, C1r/s, C4 and C2, among the strongest single-gene risks, with homozygous C1q deficiency giving a very high lifetime risk; *TREX1*, *DNASE1L3*, *ACP5* and *SAMHD1*, monogenic interferonopathies presenting as early-onset lupus; low copy number of *C4*; *HLA-DRB1*03:01* and *HLA-DRB1*15:01, *with odds ratios roughly 2; and* STAT4, IRF5, ITGAM, BLK, TNFSF4, TNFAIP3* and *PTPN22*.

X chromosome dose matters: men with Klinefelter syndrome (47,XXY) have a lupus risk roughly fourteen-fold that of 46,XY men, and 47,XXX women roughly 2.5-fold that of 46,XX women (Scofield et al.; Liu et al.). This is direct evidence that X chromosome number, not only hormones, drives the female predominance, and it is one of the cleanest findings explaining the sex ratio.

Established environmental risk factors with effect sizes: cigarette smoking, odds ratio roughly 1.5 for onset and stronger for anti-dsDNA-positive disease†; silica exposure, odds ratio roughly 2 to 4 in occupational studies†; Epstein-Barr virus, where seroconversion is near-universal in patients and viral load is higher, with a strong association and unsettled causal direction; ultraviolet light, which triggers cutaneous and systemic flares through UV-induced apoptosis and interferon induction; oestrogen exposure, with postmenopausal hormone therapy and oral contraceptives associated with modestly increased risk at hazard ratios roughly 1.2 to 1.9 in the Nurses' Health Study†; drug-induced lupus from hydralazine, procainamide, isoniazid, minocycline, TNF inhibitors and checkpoint inhibitors, which resolves on withdrawal and is distinguished by that; and low vitamin D, associated with causality unresolved.

Autoantibodies precede disease by years. Anti-nuclear, anti-Ro, anti-La and anti-dsDNA antibodies are detectable a median of several years before clinical onset in military serum repository studies (Arbuckle et al., *NEJM*, 2003), so there is a long preclinical window.

*Not known*: what triggers the transition from preclinical autoimmunity to clinical disease. Most people with a positive anti-nuclear antibody never develop lupus — positivity at 1:80 is present in roughly 10 to 15 per cent of healthy people against a prevalence of 0.04 per cent†. Why organ involvement differs so radically between patients. Why ancestry-associated

severity differences exist, and how much is genetic rather than social and access-related. Whether the preclinical window can be used for prevention.

**Cure status.** CONTROLLABLE. No cure exists, and the honest statement has two further parts.

Survival has transformed: five-year survival from roughly 50 per cent in the 1950s to over 90 per cent now, through corticosteroids, antimalarials, immunosuppression and dialysis. The disease is not cured and mortality remains roughly two to three times the general population.

Sustained drug-free remission is achieved in a minority. Definitions vary; roughly 5 to 25 per cent of patients achieve prolonged remission off all treatment in long-term cohorts, and whether that is cure or quiescence is unresolved.

Hydroxychloroquine is the one drug shown to improve survival. Observational cohort data consistently show lower mortality, fewer flares, less renal damage, less thrombosis and better pregnancy outcomes in patients taking it. It is off-patent and costs tens of dollars a year.

CAR-T cell therapy against CD19 has produced drug-free remission in a small number of patients with refractory disease (Erlangen group; first report *NEJM* 2021, subsequent series 2022 to 2024): profound B-cell depletion followed by reconstitution with a naive B-cell repertoire, with patients remaining in drug-free remission for years in the published cohorts. The numbers are very small, tens of patients worldwide, follow-up is short, and the procedure requires lymphodepleting chemotherapy. This is the first credible candidate for cure and it must be reported as preliminary, not established.

**Prevention.** No established primary prevention. State plainly.

Not smoking, at an odds ratio of about 1.5, so smoking cessation is the clearest modifiable risk factor for onset. MODERATE.

Reducing occupational silica exposure, at an odds ratio of 2 to 4. MODERATE.

Prevention of flares, where the evidence is strong. Hydroxychloroquine continuation: withdrawal roughly doubles to triples flare risk in randomised withdrawal studies (Canadian Hydroxychloroquine Study Group, *NEJM*, 1991). STRONG. Sun protection with clothing, shade and broad-spectrum sunscreen. MODERATE, mechanistically explained with consistent patient-level evidence. Vitamin D repletion in deficient patients, with a modest effect on disease activity in trials. WEAK.

Prevention of the things that kill. Cardiovascular risk management — blood pressure, lipids, smoking, weight. Given that cardiovascular risk is raised five- to fifty-fold in young women, this is arguably the highest-yield prevention in the entry. MODERATE, extrapolated from general-population trials, since disease-specific trial evidence is thin. Infection prevention by vaccination — inactivated influenza, pneumococcal, COVID-19, HPV, recombinant herpes zoster — and *Pneumocystis* prophylaxis with co-trimoxazole in patients on high-dose immunosuppression, since infection is a leading cause of early death. STRONG. Corticosteroid minimisation, since cumulative corticosteroid dose is the single largest driver of irreversible organ damage in damage-index studies. STRONG. Bone protection during corticosteroid use. STRONG. Avoiding oestrogen-containing contraception in antiphospholipid-positive patients. STRONG.

Pregnancy outcomes: hydroxychloroquine continuation, low-dose aspirin, and planning conception during quiescent disease measurably reduce pre-eclampsia, fetal loss and flare. MODERATE.

Prevention of congenital heart block in anti-Ro-positive pregnancy: hydroxychloroquine reduces recurrence in observational and open-label prospective data. MODERATE.

**Treatment.** Hydroxychloroquine, for essentially all patients, indefinitely. It reduces flares, thrombosis, renal damage and mortality. Off-patent, at US$30 to US$150 a patient-year at generic or lowest available acquisition cost, 2024†. It requires annual-to-biennial retinal screening because of a cumulative-dose-dependent retinopathy risk, roughly 1 per cent at five years and up to 20 per cent at 20 years at former higher doses, and much lower at 5 mg/kg a day or below†. This is the best-value drug in chapter 04. Listing status needs checking against the 24th List†.

Corticosteroids: prednisolone for flares, pulsed methylprednisolone for severe organ disease. Effective and fast, and cumulative dose drives permanent damage, so the current standard

is the lowest effective dose and a defined taper. Off-patent, at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024†. Listing status needs checking against the 24th List†.

Immunosuppressive and steroid-sparing agents. Mycophenolate mofetil, first-line for lupus nephritis in most guidelines; the Aspreva Lupus Management Study showed equivalence to cyclophosphamide for induction with less gonadal toxicity. Off-patent, at US$200 to US$1,000 a patient-year at generic or lowest available acquisition cost, 2024†; teratogenic, which is a major practical constraint in young women. Azathioprine for maintenance, and the preferred agent in pregnancy, off-patent at US$50 to US$200 a patient-year at generic or lowest available acquisition cost, 2024†. Cyclophosphamide for severe nephritis and neuropsychiatric disease, where the Euro-Lupus low-dose regimen of 500 mg fortnightly for six doses is as effective as high-dose with much less toxicity; off-patent, at US$50 to US$300 per induction course at generic or lowest available acquisition cost, 2024†, with dose-related gonadal toxicity and bladder cancer risk. Methotrexate for arthritis and skin disease, off-patent at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†; methotrexate is a selected medicine on the 24th List in sections 8.2.1 and 13.4, and lupus is not among the listed indications. The listing status of mycophenolate, azathioprine and cyclophosphamide needs checking against the 24th List†.

Calcineurin inhibitors: tacrolimus, and voclosporin, approved in 2021 for lupus nephritis. In AURORA-1, voclosporin achieved complete renal response at 52 weeks in 41 per cent against 23 per cent on standard therapy†. Voclosporin is patented and priced at roughly US$90,000 to US$110,000 a patient-year on United States list (2024), while generic tacrolimus achieves a similar mechanism at US$300 to US$1,500 a patient-year (2024), and Asian trials of multitarget tacrolimus-based therapy show comparable results. This price gap is notable.

Biologics. Belimumab, an anti-BAFF antibody, was the first drug licensed for lupus in 50 years, in 2011; the BLISS trials showed modest improvement in the SLE Responder Index, roughly 43 to 58 per cent against 34 to 44 per cent on placebo, and BLISS-LN showed renal benefit†. Patented, at US$40,000 to US$60,000 a patient-year at lowest available acquisition cost, 2024†. Anifrolumab, an anti-type-I- interferon-receptor antibody: TULIP-2 gave a BICLA response of 47.8 per cent against 31.5 per cent†. Patented, at US$60,000 to US$90,000 a patient-year at lowest available acquisition cost, 2024†. The listing status of both needs checking against the 24th List†. Rituximab: randomised trials in lupus (EXPLORER) and lupus nephritis (LUNAR) were both negative on their primary endpoints, yet rituximab is widely used off-label for refractory disease on observational grounds — a genuine disagreement between trial and practice. Biosimilar course US$1,500 to US$5,000 at lowest available acquisition cost, 2024†. Rituximab is a selected medicine on the 24th List in sections 5.1.2 and 8.2.2, and lupus is not among the listed indications. Obinutuzumab: the REGENCY trial in 2025 reported improved renal response in lupus nephritis.

Supportive and preventive treatment: antihypertensives with renin-angiotensin blockade in proteinuric nephritis, at US$5 to US$50 a patient-year at generic or lowest available acquisition cost†, with the listing status of ACE inhibitors and angiotensin receptor blockers needing checking against the 24th List†; statins; anticoagulation in antiphospholipid syndrome; SGLT2 inhibitors under study in lupus nephritis; and dialysis and transplantation for end-stage kidney disease, with good graft outcomes.

**Simple means.** Sun protection. Clothing, a hat, shade, and staying out of midday sun. Free, and ultraviolet light is an established flare trigger with a clean mechanism. For many patients this is the single most effective daily measure available.

Hydroxychloroquine. Not quite no-chain, and off-patent, oral, tens of dollars a year, and the only drug shown to improve survival. In any resource-limited setting this plus prednisolone is the backbone of care.

Not smoking, at an odds ratio of about 1.5 for onset, and it worsens cutaneous disease and cardiovascular risk.

Vaccination with inactivated vaccines, before immunosuppression where possible.

Blood pressure measurement and a urine dipstick. Lupus nephritis is often silent. A dipstick for protein costs cents and is the cheapest way to detect the complication that causes most of the organ failure. In settings without serology, this is the monitoring tool.

Co-trimoxazole prophylaxis during high-dose immunosuppression, at dollars a year, which prevents *Pneumocystis* pneumonia.

Rest and pacing during flares, and recognising fatigue as part of the disease.

Contraception planning: avoiding pregnancy during active disease and during mycophenolate or cyclophosphamide treatment measurably improves outcomes, and it is a conversation rather than a drug.

Dental and skin care, and prompt treatment of infection.

**Gaps.** Data are missing for 79.8 per cent of countries in the global review, so the regional figures rest on a minority of the world's populations. The global review could not assess ethnicity, because the included studies did not report it — yet ancestry-associated differences in incidence, severity and mortality are among the largest effects in the disease, and this is a major measurement gap. The apparently higher prevalence in high-income countries is confounded by ascertainment. Classification criteria changed across ACR 1997, SLICC 2012 and EULAR/ACR 2019, so incidence and prevalence figures are criteria-dependent and not comparable across eras. Rituximab: negative randomised trials, widespread use — trial and practice disagree. Voclosporin at about US$100,000 a year at lowest available acquisition cost, against generic tacrolimus at under 1,500 with a similar mechanism and no head-to-head trial. No biomarker predicts which patients will develop nephritis or neuropsychiatric disease. CAR-T data come from tens of patients with short follow-up. Whether the long preclinical autoantibody window can be used for prevention is untested. Disease-specific cardiovascular prevention trial evidence is thin, despite cardiovascular disease being a leading cause of death.

---

## Sjögren syndrome

**What it is.** The immune system attacks the glands that make tears and saliva. Eyes and mouth go dry, teeth decay, and most patients are profoundly tired. It can also affect joints, nerves, lungs and kidneys, and it raises the risk of lymphoma.

**Measured.** Prevalence is between 0.2 and 1.2 per cent of the population, roughly half primary and half secondary to another autoimmune disease, with some broader studies using looser criteria suggesting up to 3 per cent†. United States estimates range from 500,000 to 2 million people depending on criteria used†; the width of that range is the finding. Incidence is roughly three to six cases per 100,000 a year†.

The sex ratio is roughly 10:1 female to male — nine out of ten patients are women, the most skewed sex ratio of any common autoimmune disease — and primary disease in men tends to be more severe. It is the third most common rheumatic autoimmune disorder, after rheumatoid arthritis and lupus. Secondary occurrence is reported in 30 to 50 per cent of people with rheumatoid arthritis and 10 to 25 per cent of people with lupus†. As many as half of all cases may be undiagnosed or unreported.

Peak onset is in the fourth to sixth decades; childhood-onset occurs and often presents with recurrent parotitis.

On the hard outcome, lymphoma, the figures conflict. An increased lymphoma risk of about 15 per cent is quoted in some sources; roughly 5 per cent of patients develop a lymphoid malignancy; and standardised incidence ratios for non-Hodgkin lymphoma in large cohorts are roughly 9 to 19†. These are three different quantities reported as though interchangeable, and only the standardised incidence ratios are comparable between studies. The characteristic tumour is mucosa-associated lymphoid tissue lymphoma of the parotid, and severe cases carry a much higher lymphoma risk than mild or moderate cases.

Measured predictors of lymphoma: persistent parotid enlargement, purpura, low C4, cryoglobulinaemia, monoclonal gammopathy, lymphopenia, high focus score on labial biopsy, and a high EULAR disease activity score. Patients with several of these have lymphoma risk an order of magnitude above those with none.

Overall mortality is close to the general population in patients without systemic features, and raised in those with lymphoma, cryoglobulinaemic vasculitis, interstitial lung disease or pulmonary hypertension.

**Where it starts.** Lymphocytic infiltration of exocrine glands with formation of ectopic germinal centres, epithelial cell activation, a type I interferon signature, B-cell hyperactivity with autoantibody production against Ro/SSA, La/SSB and rheumatoid factor, and local BAFF overproduction. Established. The B-cell hyperactivity explains both the autoantibodies and the lymphoma risk.

The strongest genetic signals are in the HLA region: the *HLA-DRB1*03:01, DQA1*05:01*, *DQB1*02:01* haplotype, with odds ratios roughly 2 to 4†. Non-HLA loci overlap with lupus: *IRF5*, *STAT4*, *IL12A*, *BLK*, *TNIP1*, *CXCR5*. Sibling relative risk is raised and heritability is not well estimated, which is a genuine gap for a disease this common.

The 10:1 sex ratio is unexplained. X chromosome dose effects are reported — Klinefelter syndrome and 47,XXX are over-represented, as in lupus — and X-linked gene dosage including *TLR7* is a leading hypothesis.

Viral triggers have been proposed and none is established: Epstein-Barr virus, HTLV-1 with a clear association in endemic Japanese populations, hepatitis C which causes a Sjögren-like syndrome with cryoglobulinaemia, and coxsackievirus. HTLV-1 and hepatitis C are the only ones with a defined causal claim, and both produce a mimic rather than primary disease.

Drug-induced dryness is a confounder rather than a cause: anticholinergics, antidepressants, antihistamines, diuretics and opioids cause dryness in a large share of older adults and are the commonest reason for a false diagnosis. Other causes of dry eyes and mouth must be excluded: head and neck radiotherapy, hepatitis C, HIV with diffuse infiltrative lymphocytosis syndrome, IgG4-related disease, sarcoidosis, amyloidosis, and graft-versus-host disease.

*Not known*: the cause. Why the sex ratio is 10:1. Why fatigue — the symptom patients rank as most disabling — correlates poorly with glandular inflammation, autoantibody status or any measured immune parameter, and does not respond to immunosuppression. No treatment has been shown to restore glandular secretion, which is the central therapeutic unknown. Why some patients progress to lymphoma.

**Cure status.** Glandular disease: RELIEF ONLY — and this is one of the few entries in the chapter where that is the honest answer. Systemic manifestations: CONTROLLABLE, since corticosteroids and immunosuppression control arthritis, vasculitis, interstitial lung disease and renal involvement.

No cure exists, and no treatment is known to restore gland secretion. Management of the dryness is substitution and stimulation of residual function, not repair. Where glandular tissue has been replaced by fibrosis, nothing recovers it.

Secretagogues — pilocarpine, cevimeline — stimulate residual gland function, with a real effect in randomised trials, roughly a doubling of salivary flow in responders, and they do nothing where no functioning tissue remains, and sweating and flushing limit the dose.

Hydroxychloroquine: the JOQUER randomised trial in 2014 found no significant benefit on dryness, pain or fatigue at 24 weeks against placebo. It continues to be prescribed widely for arthralgia and fatigue on the basis of observational data and the lupus analogy, which is a clear case where a negative trial has not changed practice.

B-cell depletion: randomised trials of rituximab (TEARS, TRACTISS) were negative on their primary endpoints for dryness and fatigue, with some benefit on objective glandular measures in subgroups. Rituximab is used for systemic and cryoglobulinaemic disease.

Emerging: ianalumab, an anti-BAFF-receptor antibody with B-cell depleting activity, received Breakthrough Therapy designation in January 2026 and reported positive phase 2 and phase 3 data; telitacicept and dazodalibep are in phase 3. If these replicate, the status of this entry changes. At the time of writing nothing is licensed specifically for Sjögren syndrome anywhere, which is itself a notable fact for a disease affecting up to 1 per cent of the population.

**Prevention.** No primary prevention. The cause is unknown. State plainly.

Prevention of dental destruction is the highest-yield prevention in this entry. Saliva protects teeth; without it, rampant caries follows. Topical fluoride — high-concentration toothpaste, varnish, trays: STRONG in caries prevention generally, MODERATE in this disease specifically. Frequent professional dental cleaning and review: MODERATE. Avoiding sugar and acidic drinks, and avoiding sipping sweetened drinks for dry mouth relief, which is the com-

monest avoidable cause of caries in these patients: STRONG mechanistically. Chlorhexidine and xylitol: MODERATE.

Prevention of corneal damage by regular ocular lubrication, punctal occlusion, treating meibomian gland dysfunction, and humidification. MODERATE.

Avoiding drugs that worsen dryness — anticholinergics, tricyclic antidepressants, antihistamines, diuretics. Free, and often the largest single improvement available. MODERATE.

Lymphoma risk stratification and surveillance of patients with the measured risk factors — persistent parotid swelling, purpura, low C4, cryoglobulinaemia. Whether surveillance changes outcome is not established. CONTESTED.

Hydroxychloroquine for prevention of systemic complications: CONTESTED — JOQUER was negative, and cohort data suggest lower lymphoma incidence in treated patients.

In anti-Ro-positive women planning pregnancy, hydroxychloroquine reduces recurrence of congenital heart block in observational and open-label prospective data: MODERATE. Fetal echocardiographic surveillance in anti-Ro-positive pregnancies: MODERATE.

**Treatment.** Ocular surface management. Preservative-free artificial tears, as often as needed, off-patent, at US$50 to US$400 a patient-year at generic or lowest available acquisition cost, 2024, depending on frequency and whether preservative-free unit doses are used; for many patients this is the single largest out-of-pocket cost. Not listed as such on the EML. Topical ciclosporin 0.05 to 0.1 per cent, which improves tear production modestly in randomised trials, off-patent with generics available, at US$300 to US$1,500 a patient-year at generic or lowest available acquisition cost, 2024†; listing status needs checking against the 24th List†. Lifitegrast and perfluorohexyloctane, patented and more expensive. Punctal plugs, which mechanically occlude tear drainage at a one-off cost of tens of dollars and are among the best value interventions here. Autologous serum eye drops for severe disease, made from the patient's own blood. Moisture chamber spectacles and goggles.

Oral dryness management. Pilocarpine, 5 mg three to four times daily, or cevimeline — muscarinic agonists, with randomised trials showing increased salivary flow and improved subjective dryness. Off-patent, at US$100 to US$600 a patient-year at generic or lowest available acquisition cost, 2024†; listing status needs checking against the 24th List†. Saliva substitutes, gels and sprays, and sugar-free gum. Topical and systemic antifungals for the oral candidiasis that complicates dry mouth: nystatin and fluconazole, off-patent, at dollars a course, with listing status needing checking against the 24th List†.

Vaginal dryness: lubricants and, where appropriate, topical oestrogen.

Musculoskeletal pain: NSAIDs; hydroxychloroquine, widely used although JOQUER was negative; and methotrexate for inflammatory arthritis. Methotrexate is a selected medicine on the 24th List in sections 8.2.1 and 13.4; this indication is not among those listed. The listing status of hydroxychloroquine and of NSAIDs needs checking against the 24th List†.

Systemic disease — vasculitis, interstitial lung disease, renal tubular acidosis, peripheral neuropathy, cytopenias. Corticosteroids, off-patent at US$5 to US$30 a year at generic or lowest available acquisition cost, 2024†; immunosuppressants — azathioprine, mycophenolate, cyclophosphamide — all off-patent, with listing status needing checking against the 24th List†; rituximab for cryoglobulinaemic vasculitis and severe systemic disease, with a biosimilar course at US$1,500 to US$5,000 at lowest available acquisition cost, 2024, though the randomised trials for dryness and fatigue were negative; and intravenous immunoglobulin for severe neuropathy.

Dental care: high-concentration fluoride, frequent cleaning, restorative work. Dental care is the largest unmet and uncovered cost in this disease in most health systems.

Exercise: a 12-week moderate exercise programme showed measurable benefit for fatigue, depression and aerobic capacity. One of the few interventions with a positive trial for fatigue.

Investigational: ianalumab, telitacicept and dazodalibep, in phase 3.

**Simple means.** Water, sipped frequently; sugar-free gum; xylitol lozenges. These stimulate residual flow and relieve dryness at negligible cost.

Fluoride toothpaste used twice daily and not rinsed out afterwards. The cheapest protection against the rampant caries that is this disease's most destructive everyday consequence.

Not sipping sweetened or acidic drinks for dry mouth. Free, and it prevents the commonest avoidable harm.

Humidifying the bedroom; a bowl of water on a radiator works.

Wrap-around glasses or goggles in wind and air conditioning.

Warm compresses and lid hygiene for meibomian gland dysfunction. A large share of the ocular discomfort in these patients is evaporative rather than aqueous-deficient, and lid hygiene addresses it at no cost.

Stopping anticholinergic and other drying medications where possible. Free, and often the single largest improvement available.

Punctal plugs: a one-off procedure costing tens of dollars that reduces artificial tear use substantially.

Moderate exercise, the one intervention with a positive randomised result for fatigue, which is the symptom patients rate as most disabling and which no drug touches.

Petroleum jelly or lip balm, and nasal saline for nasal dryness.

**Gaps.** Prevalence estimates span six-fold, 0.2 to 1.2 per cent and up to 3 per cent on loose criteria, and the United States count spans four-fold, 500,000 to 2 million. The reason is criteria: the AECG 2002 and ACR/EULAR 2016 criteria classify different populations, and symptom-based estimates include large numbers of people with drug-induced or age-related dryness. Half of cases may be undiagnosed. Heritability is not well estimated for a disease affecting up to 1 per cent of the population. The 10:1 sex ratio is unexplained. The lymphoma risk figures conflict, with three different quantities reported interchangeably. JOQUER was negative for hydroxychloroquine and it continues to be prescribed; TEARS and TRACTISS were negative for rituximab and it continues to be used. Trial and practice disagree openly. No treatment restores gland function, and no drug is licensed for the condition in most jurisdictions despite its prevalence. Fatigue, the dominant symptom, has no established mechanism and no effective drug. Whether lymphoma surveillance changes outcome is unknown. The pipeline agents may change the cure status of this entry within one to two years.

---

## Systemic sclerosis

**What it is.** Skin and internal organs become thickened and scarred, and small blood vessels narrow and close. Fingers go white and painful in the cold and can ulcerate. The lungs stiffen, the gut slows, and the kidneys or heart can fail. It has the highest mortality of the systemic autoimmune diseases.

**Measured.** Incidence runs from 3.7 to 43 new cases per million a year across published studies†: United Kingdom and Europe 3.7 to 43, Japan 7.2, Taiwan 10.9, Australia 12.0 to 22.8, the United States 13.9 to 21.0, Buenos Aires 21.2. Prevalence is about 31.0 to 658.6 per million globally, a twenty-fold range†.

The sex ratio is about 3:1 female to male overall, rising to about 8:1 in mid- to late childbearing years†. Incidence is about twice as high among African Americans, with earlier onset and more diffuse disease. Choctaw Native Americans in Oklahoma have the highest reported prevalence in the world, at 469 per 100,000 — a founder effect, and the single most striking ancestry finding in this disease. Peak onset is at ages 30 to 50.

Limited cutaneous disease confines skin involvement to below the elbows and knees, with or without the face, is associated with the CREST features, carries anticentromere antibodies in roughly 80 to 90 per cent of that subset, carries a higher risk of pulmonary arterial hypertension, and has a better overall prognosis. Diffuse cutaneous disease involves skin above the elbows and knees and on the trunk, carries anti-topoisomerase I antibodies in roughly 30 to 40 per cent, carries a higher risk of interstitial lung disease and scleroderma renal crisis, and has a worse prognosis. Anti-RNA polymerase III antibodies associate with rapidly progressive skin disease, renal crisis, and an increased risk of coincident cancer.

Ten-year survival was about 88 per cent in a 2018 study, which gives no separate subtype figures†; earlier cohorts gave 10-year survival around 55 to 70 per cent for diffuse disease†. Survival has improved, principally through ACE inhibitors for renal crisis.

Pulmonary causes — interstitial lung disease and pulmonary arterial hypertension — are now the leading cause of death, having overtaken renal crisis after ACE inhibitors became available; then cardiac, then gastrointestinal. Scleroderma renal crisis mortality fell from roughly 85 per cent at one year before ACE inhibitors to roughly 10 to 25 per cent after† — one of the clearest single-drug mortality effects in rheumatology.

Worse prognosis associates with diffuse disease, internal organ involvement and older age at diagnosis.

**Where it starts.** Three processes run together: endothelial injury with microvascular obliteration, immune activation with autoantibody production, and fibroblast activation with excess collagen deposition. Which comes first is unresolved; the vascular lesion is generally held to be earliest, and Raynaud phenomenon typically precedes skin change by months to years.

Heritability is low for a disease with such strong autoantibody associations. Monozygotic twin concordance is roughly 4.7 per cent, essentially the same as dizygotic, while antinuclear antibody concordance is high. This is a striking finding: the autoimmunity is heritable, the disease is largely not. Sibling relative risk is roughly 10 to 15 and first-degree relative risk roughly 13 to 15†. HLA associations: *HLA-DRB1*11:04*,* DPB1*13:01*, *DQB1*. Non-HLA: *STAT4*, *IRF5*, *CD247*, *TNFSF4*, *BANK1*, *IRF8*, *NLRP1*. The Choctaw founder effect maps to a haplotype on chromosome 15 containing *FBN1*.

The established environmental causes are unusually strong for an autoimmune disease. Crystalline silica exposure: odds ratios of roughly 2 to 3 overall and up to 15 to 25 in heavily exposed occupations — mining, stone cutting, sandblasting, engineered stone benchtop fabrication. This is the most firmly established environmental cause of a systemic autoimmune disease. Organic solvents — trichloroethylene, white spirit, aromatic solvents — odds ratios roughly 1.5 to 3†. Vinyl chloride causes a scleroderma-like disease with acro-osteolysis and skin thickening at high occupational exposure. Epoxy resins and welding fumes. Bleomycin causes scleroderma-like skin fibrosis and is the basis of the standard animal model. Toxic epidemics: the Spanish toxic oil syndrome of 1981, from adulterated rapeseed oil, affecting about 20,000 people, and the L-tryptophan eosinophilia-myalgia syndrome of 1989, about 1,500 cases, both produced scleroderma-like illness from a defined ingested contaminant — the clearest proofs that an environmental agent can produce this phenotype. Silicone breast implants have been extensively studied and large cohort studies and meta-analyses have not found an association; it is recorded here because the claim persists.

Cancer association: anti-RNA polymerase III-positive patients have a markedly raised risk of cancer diagnosed within a few years of onset, suggesting a paraneoplastic mechanism in a subset.

*Not known*: what initiates the disease in the great majority who have no identified exposure. Why monozygotic twin concordance is so low when autoantibody concordance is high. Why some patients get lung fibrosis and others pulmonary hypertension and others renal crisis — the autoantibody subsets predict this statistically but not individually. Why skin fibrosis spontaneously regresses in many patients with diffuse disease after several years, which no treatment reliably achieves.

**Cure status.** Vascular and inflammatory manifestations: CONTROLLABLE. Established fibrosis: RELIEF ONLY — no treatment reverses it. Autologous stem cell transplantation, where accessible: CONTROLLABLE — durable improvement in skin score, lung function and survival, with an upfront mortality cost; whether to call it a cure is not established.

The one transformative treatment is for renal crisis: ACE inhibitors reduced one-year mortality in scleroderma renal crisis from roughly 85 per cent to roughly 10 to 25 per cent†. That is the single largest mortality effect of any drug in this disease, and captopril and enalapril are off-patent and cost dollars a year. Prophylactic ACE inhibitor use is explicitly not recommended, because observational data suggest it may worsen outcomes when a crisis occurs.

Autologous haematopoietic stem cell transplantation is the only intervention shown to improve long-term survival and to reverse skin fibrosis, and three randomised trials agree. ASTIS, a phase 3 trial of 156 patients published in 2014, had high treatment-related mortality and survival in the transplant group lower than control in the first year, but significantly higher at long-term follow-up, with event-free survival favouring transplant; cardiac disease and smoking predicted lower survival. SCOT, published in *NEJM* in 2018, compared myeloab-

lative autologous transplant with monthly cyclophosphamide: at 54 months the global rank composite score favoured transplant, and event-free survival was 79 per cent against 50 per cent and overall survival 86 per cent against 51 per cent at 72 months, with treatment-related mortality of 3 per cent at 54 months in the transplant arm. ASSIST, a phase 2 trial, also favoured transplant. So this is a time-limited intervention producing durable improvement in skin score, lung function and survival, with an upfront mortality cost. Whether to call it a cure is a judgement; it is the strongest disease-modifying evidence in the entry.

Everything else slows or relieves: immunosuppression reduces skin and lung progression modestly; antifibrotics slow lung function decline; vasodilators relieve Raynaud phenomenon and heal ulcers; proton pump inhibitors and prokinetics manage the gut.

**Prevention.** This entry has the strongest occupational prevention case of any disease in chapter 04.

Silica exposure control. Odds ratios of 2 to 3 overall and up to 15 to 25 in heavily exposed trades make this the clearest primary prevention target. The engineered stone benchtop industry has produced a recent epidemic of accelerated silicosis and autoimmune disease in Australia, Israel, Spain and the United States, and Australia banned the use, supply and manufacture of engineered stone from 1 July 2024 on those grounds. STRONG for the causal association; the Australian ban is a natural experiment whose preventive effect will be measurable within a decade.

Organic solvent exposure control, for trichloroethylene and white spirit. MODERATE.

Vinyl chloride exposure limits. STRONG for the vinyl chloride disease specifically.

Not smoking: smoking worsens digital vascular disease and predicted lower survival in the ASTIS transplant cohort. MODERATE.

Prevention of the complications is where most of the measurable benefit lies. Blood pressure monitoring for renal crisis, especially in early diffuse disease, anti-RNA polymerase III-positive patients, and anyone on corticosteroids — corticosteroids at prednisolone- equivalent doses above 15 mg a day are an established risk factor for renal crisis. STRONG for avoiding high-dose corticosteroids in early diffuse disease. Annual screening for pulmonary arterial hypertension by echocardiography, pulmonary function with diffusing capacity and NT-proBNP, using the DETECT algorithm, because earlier detection improves outcomes when treatment is started in an earlier functional class. MODERATE. Baseline and serial high-resolution computed tomography and pulmonary function testing for interstitial lung disease. MODERATE. Keeping warm, with gloves, hand and body warmers, and avoiding cold exposure, for Raynaud phenomenon. MODERATE, at zero cost. Avoiding vasoconstrictors — beta-blockers, triptans, decongestants, ergot derivatives. MODERATE. Smoking cessation for digital ulcers. STRONG mechanistically.

**Treatment.** Scleroderma renal crisis: ACE inhibitors, immediately and at full dose — captopril or enalapril. Off-patent, at US$5 to US$50 a patient-year at generic or lowest available acquisition cost, 2024†. This is the highest-value drug in this entry by a wide margin, and it is a generic antihypertensive. Enalapril's listing status needs checking against the 24th List†.

Interstitial lung disease. Mycophenolate mofetil, which Scleroderma Lung Study II found equivalent to oral cyclophosphamide with better tolerability and which is now first-line in most guidelines; off-patent, at US$200 to US$1,000 a patient-year (2024)†. Cyclophosphamide, where Scleroderma Lung Study I showed a modest forced vital capacity benefit over placebo that was lost by 24 months; off-patent, at US$50 to US$300 a course (2024)†. Tocilizumab, an anti-IL-6-receptor antibody, where the focuSSced trial missed its primary skin endpoint and showed preservation of forced vital capacity as a key secondary outcome, leading to United States approval in 2021 for slowing lung function decline; biosimilars have been available since 2023 to 2024, at US$5,000 to US$15,000 a patient-year biosimilar, down from originator 25,000 to 40,000. Nintedanib, where the SENSCIS trial gave an annual rate of forced vital capacity decline of 52.4 mL against 93.3 mL with placebo, a 44 per cent relative reduction, and which was approved by the United States Food and Drug Administration on 6 September 2019 for this indication; patented, at US$100,000 to US$130,000 a patient-year on United States list (2024)†. Rituximab, where the Japanese DESIRES randomised data show skin and lung benefit, at a biosimilar course of US$1,500 to US$5,000 (2024)†; rituximab is a selected medicine on the 24th List in sections 5.1.2 and 8.2.2, and this indication

is not among those listed. Autologous transplant, reserved for rapidly progressive diffuse disease without advanced organ damage. The listing status of mycophenolate, cyclophosphamide, tocilizumab and nintedanib needs checking against the 24th List†.

Pulmonary arterial hypertension. **Neither sildenafil nor bosentan is on the 24th List at all, for any indication: a live query of the electronic Model List returns zero recommendations, zero medicines and zero therapeutic equivalents for each**. Phosphodiesterase-5 inhibitors — sildenafil, tadalafil — are off-patent, with generic sildenafil at US$100 to US$600 a patient-year at lowest available acquisition cost, 2024†. Endothelin receptor antagonists — bosentan, ambrisentan, macitentan — are off-patent for bosentan and ambrisentan, at US$3,000 to US$30,000 a patient-year at generic or lowest available acquisition cost, 2024†. Prostacyclin analogues — epoprostenol, treprostinil, iloprost — and riociguat and selexipag are mostly patented, at US$50,000 to US$200,000 a patient-year at lowest available acquisition cost, 2024†. Combination therapy is standard.

Raynaud phenomenon and digital ulcers. Calcium channel blockers — nifedipine, amlodipine — first-line, off-patent, at US$5 to US$40 a patient-year at generic or lowest available acquisition cost, 2024†; listing status needs checking against the 24th List†. Phosphodiesterase-5 inhibitors, with generic sildenafil as above. Topical nitrates; intravenous iloprost for critical ischaemia; bosentan, which reduces new digital ulcers in RAPIDS-1 and RAPIDS-2 without healing existing ones. Botulinum toxin injection and digital sympathectomy for refractory ischaemia. Low-dose aspirin and statins are commonly used and the evidence is weak.

Gastrointestinal: proton pump inhibitors at high dose for reflux, with omeprazole off-patent at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024† and listing status needing checking against the 24th List†; prokinetics; rotating antibiotics for small intestinal bacterial overgrowth; octreotide for pseudo-obstruction; and enteral or parenteral nutrition for malabsorption.

Skin: methotrexate, where two randomised trials show modest skin score benefit in early diffuse disease, off-patent at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†, a selected medicine on the 24th List in sections 8.2.1 and 13.4 and not listed for this indication; mycophenolate; emollients; and physiotherapy and stretching for contractures.

Calcinosis: no effective treatment, with surgical removal for symptomatic lesions.

What should be avoided: prophylactic ACE inhibitors, which may worsen renal crisis outcome; high-dose corticosteroids in early diffuse disease, for renal crisis risk; and D-penicillamine, where a randomised trial showed no benefit of high over low dose.

**Simple means.** Keeping warm. Gloves, mittens over gloves, hats, layered clothing, a warm core temperature, chemical or reusable hand warmers, heated gloves. For Raynaud phenomenon, which affects nearly every patient and causes the digital ulcers and amputations, this is the first-line intervention and it costs almost nothing. Keeping the trunk warm matters as much as the hands, because the vasoconstriction is centrally mediated.

Stopping smoking. Digital vascular disease and survival both respond.

A blood pressure cuff at home. Scleroderma renal crisis presents with abrupt severe hypertension, is reversible with an ACE inhibitor started early, and is fatal if missed. Teaching a patient with early diffuse disease to check their own blood pressure weekly, and to present urgently if it rises, is the highest-yield free intervention in this entry.

ACE inhibitor availability. Generic enalapril or captopril, dollars a year, against a one-year mortality in renal crisis of roughly 85 per cent falling to 10 to 25 per cent.

Raising the head of the bed, eating smaller meals, not lying down after eating, avoiding late meals. Effective for the reflux that affects nearly all patients.

Hand exercises and stretching, and face stretching exercises. These prevent the contractures and microstomia that cause most of the functional disability. No equipment.

Emollients and avoiding soap, for the dry, taut skin.

Prompt attention to any finger wound. Digital ulcers in this disease become infected and lead to amputation, and early simple wound care prevents it.

Avoiding beta-blockers, decongestants and triptans.

Dental care: microstomia makes dental access progressively harder, so early and regular care prevents later problems that cannot be treated.

Avoiding occupational silica and solvent exposure, which is the primary prevention, and is regulatory rather than individual.

**Gaps.** Incidence spans 3.7 to 43 per million and prevalence 31 to 659 per million — an order of magnitude in each — because case definition, ascertainment method and classification criteria differ; the 2013 ACR/EULAR criteria classify more patients, including earlier disease, than the 1980 ACR criteria, so figures are not comparable across eras. Survival figures come from referral-centre cohorts with ascertainment weighted to severe disease, so the 2018 10-year survival of 88 per cent is not directly comparable with older figures of 55 to 70 per cent, and part of the apparent improvement is earlier and milder case capture. The 2018 study gives no separate figures by subtype, which is the clinically decisive split. Monozygotic twin concordance of about 4.7 per cent against a sibling relative risk of 10 to 15 and high autoantibody concordance is an unexplained and important discrepancy. Nearly all prevalence data come from high-income countries, and the Choctaw figure of 469 per 100,000 shows how much founder effects can matter and how little is known about most populations. The transplant trials used different conditioning regimens, different endpoints and different severities, and all excluded patients with significant cardiac disease, so the survival benefit applies to a selected population and the early mortality cost is real. No treatment reverses established fibrosis. Why skin fibrosis regresses spontaneously in many patients after several years is unknown, and it confounds the interpretation of every skin-score trial. Nintedanib at US$100,000 to US$130,000 a patient-year on United States list (2024) produces a 44 per cent relative reduction in forced vital capacity decline; mycophenolate at US$200 to US$1,000 a patient-year, at generic or lowest available acquisition cost, produces lung benefit. There is no head-to-head trial and no cost-effectiveness consensus.

---

## The vasculitides

**What it is.** Inflammation of blood vessel walls. Which vessels are affected determines the disease: the largest arteries in giant cell arteritis and Takayasu arteritis, medium arteries in polyarteritis nodosa and Kawasaki disease, small vessels in the ANCA-associated and IgA vasculitides. Untreated, several of them cause blindness, kidney failure or death within months.

**Measured.** Grouped by vessel size, with incidence per million per year unless stated.

*Large vessel.* Giant cell arteritis is the commonest primary vasculitis in people over 50, with incidence of 150 to 300 per million a year in people over 50 in northern Europe — Scandinavia highest at roughly 220 to 290 — falling to roughly 10 to 70 per million over 50 in southern Europe and much lower in Asian and African populations†. It is rare before age 50, with mean age at diagnosis roughly 75 and a female-to-male ratio of roughly 2 to 3:1†. Permanent visual loss occurs in roughly 10 to 20 per cent of patients and is almost entirely preventable by prompt corticosteroids, which makes it one of the few true medical emergencies in rheumatology. Polymyalgia rheumatica, closely related, has an incidence of roughly 500 to 1,000 per million a year over 50 in northern Europe; roughly 15 to 20 per cent of those patients have giant cell arteritis and roughly 40 to 60 per cent of giant cell arteritis patients have polymyalgia features†. Takayasu arteritis has an incidence of roughly one to three per million a year in Europe and North America and higher in Japan, India, Turkey and Mexico, roughly 15 to 40 per million in some Japanese and Indian series, with onset usually under 40 and a female-to-male ratio of roughly 8 to 9:1†.

*Medium vessel.* Kawasaki disease is the commonest vasculitis of childhood. Incidence in Japan is the highest in the world at roughly 3,000 to 3,700 per 100,000 children under five a year — roughly 1 in 30 Japanese children by age five at current rates — against roughly 20 to 25 per 100,000 under five in the United States and Europe†. Peak age is six months to five years. Coronary artery aneurysms develop in roughly 25 per cent of untreated children and roughly 3 to 5 per cent of those treated with intravenous immunoglobulin within 10 days†, a reduction of roughly 80 per cent and the most clear-cut treatment effect in paediatric vasculitis. Polyarteritis nodosa now has an incidence of roughly zero to three per million a year in Europe, having fallen substantially with hepatitis B vaccination: hepatitis B-associated

disease was historically a large share of cases and has nearly disappeared where vaccination is universal. This is a measured, vaccine-driven reduction in an autoimmune disease.

*Small vessel, ANCA-associated.* Combined incidence is roughly 13 to 33 per million a year in Europe, with prevalence roughly 200 to 420 per million†. Granulomatosis with polyangiitis is more common in northern Europe and PR3-ANCA predominant; microscopic polyangiitis is more common in southern Europe and Japan and MPO-ANCA predominant, and the north-south gradient within Europe is consistent and unexplained. Eosinophilic granulomatosis with polyangiitis has an incidence of roughly one to three per million a year and always occurs with asthma and eosinophilia. Peak onset is at 60 to 75, with a roughly equal sex ratio. Untreated generalised disease has roughly 80 per cent one-year mortality; with treatment, five-year survival is roughly 75 to 85 per cent and standardised mortality ratios remain roughly 2 to 3†. Deaths in the first year come from active vasculitis and from treatment-caused infection in roughly equal measure. End-stage kidney disease occurs in roughly 20 to 25 per cent at five years, and relapse in roughly 30 to 50 per cent within five years, higher in PR3-ANCA disease and in granulomatosis with polyangiitis†.

*Small vessel, immune complex.* IgA vasculitis is the commonest childhood vasculitis after Kawasaki disease, with incidence roughly 100 to 270 per million children a year and peak age four to seven†. It is self-limiting in roughly 95 per cent of children, with nephritis in roughly 20 to 40 per cent, of whom roughly 1 to 7 per cent progress to chronic kidney disease†. Adult-onset disease is less common and more often renal and severe. Cryoglobulinaemic vasculitis was historically dominated by hepatitis C, and its incidence has fallen markedly where direct-acting antiviral treatment is available — another measured, treatment-driven reduction. Anti-glomerular basement membrane disease runs at roughly 0.5 to 1.8 per million a year†. Behçet disease, a variable vessel vasculitis, has a prevalence along the historic Silk Road of roughly 20 to 420 per 100,000, highest in Turkey at roughly 80 to 420, against roughly 0.3 to 5 per 100,000 in northern Europe and the United States† — one of the steepest geographic gradients of any disease in this chapter.

**Where it starts.** The established infectious and environmental causes are unusual in autoimmunity and important because they are preventable. Hepatitis B and polyarteritis nodosa: causal, and the disease has nearly disappeared where vaccination is universal. Hepatitis C and cryoglobulinaemic vasculitis: causal, and the vasculitis resolves in the majority after viral cure with direct-acting antivirals. Silica exposure and ANCA-associated vasculitis: odds ratios roughly 2 to 4†. Drug-induced ANCA vasculitis from propylthiouracil, hydralazine, levamisole-adulterated cocaine, minocycline and allopurinol, which resolves on withdrawal in many cases; levamisole-adulterated cocaine produces a characteristic retiform purpura with dual ANCA positivity. *Staphylococcus aureus* nasal carriage and relapse of granulomatosis with polyangiitis: carriage roughly doubles to triples relapse risk, and co-trimoxazole reduces relapses. IgA vasculitis follows upper respiratory infection in roughly half of children, commonly streptococcal. Kawasaki disease has a strongly suspected infectious trigger, with seasonal and epidemic clustering and wind-borne transmission hypotheses, and no agent identified; the 2020–2021 emergence of multisystem inflammatory syndrome in children after SARS-CoV-2 is the clearest demonstration that a defined infection can produce a Kawasaki-like vasculitis.

Genetics. In ANCA-associated vasculitis, the genome-wide association study by Lyons and colleagues (*NEJM*, 2012) showed that the genetic associations follow the ANCA serotype rather than the clinical diagnosis — *HLA-DP*, *SERPINA1* and *PRTN3* with PR3-ANCA, *HLA-DQ* with MPO-ANCA. This finding reorganised how the diseases are classified. Giant cell arteritis: *HLA-DRB1*04*, odds ratio roughly 2 to 3†. Behçet disease:* HLA-B*51*, odds ratio roughly 5 to 6, which explains a large part of the Silk Road distribution, with *IL23R*, *IL10* and *ERAP1* contributing†. Kawasaki disease: *ITPKC*, *CASP3*, *FCGR2A*, *BLK*; siblings of affected children have roughly a ten-fold increased risk, and Japanese ancestry carries high risk even in children born outside Japan, which separates genetic from environmental contribution. Takayasu arteritis: *HLA-B*52*, odds ratio roughly 3†. Heritability is not well estimated for most of these diseases, and familial clustering is modest except in Kawasaki and Behçet disease.

Monogenic vasculitis mimics matter because they change treatment entirely: deficiency of adenosine deaminase 2, a recessive cause of childhood polyarteritis-nodosa-like disease and stroke, treatable with TNF inhibitors; haploinsufficiency of A20; STING-associated vascu-

lopathy; and VEXAS syndrome, from a somatic *UBA1* mutation in older men, described in 2020.

*Not known*: the cause of giant cell arteritis, Takayasu arteritis and Kawasaki disease. Why ANCA-associated vasculitis has a north-south gradient within Europe. Why relapse occurs in 30 to 50 per cent and what predicts it beyond ANCA serotype. Whether ANCA causes the disease or marks it — though the neonatal transfer of MPO-ANCA causing pulmonary-renal disease in an infant, and animal transfer models, argue strongly for causation in MPO-ANCA disease.

**Cure status.** The range within this entry is the widest in the chapter.

IgA vasculitis in children: SELF-LIMITING, with roughly 95 per cent resolving. Treatment is supportive; corticosteroids shorten abdominal pain but do not prevent nephritis, and randomised trials and a Cochrane review agree, which is a clear and frequently ignored negative finding.

Kawasaki disease, febrile illness: SELF-LIMITING. Coronary aneurysm risk, with immunoglobulin within 10 days of fever onset: CURABLE. The fever resolves on its own. The aneurysms do not, and they are what kills. Immunoglobulin prevents them. Intravenous immunoglobulin at 2 g/kg within 10 days of fever onset reduces coronary aneurysm incidence from roughly 25 per cent in untreated children to roughly 3 to 5 per cent in treated children†, a reduction of roughly 80 per cent. About 3 to 5 in every 100 treated children still develop an aneurysm†. This is one of the cleanest prevention-of-permanent-damage effects in medicine.

Hepatitis B-associated polyarteritis nodosa and hepatitis C-associated cryoglobulinaemic vasculitis: CURABLE by treating the virus. Direct-acting antivirals cure hepatitis C in over 95 per cent of patients and the vasculitis remits in the majority. WHO's own hepatitis C fact sheet of 28 July 2026 gives the cure rate as more than 95 per cent with direct-acting antivirals in Key Facts, while the body says only "most persons" and "nearly all patients" without a percentage.

Drug-induced ANCA vasculitis: CURABLE by stopping the drug in many cases.

Giant cell arteritis: CONTROLLABLE, and the visual loss is preventable. Corticosteroids started on clinical suspicion, before biopsy, prevent blindness. Most patients can eventually stop treatment — roughly half to three-quarters achieve lasting remission off corticosteroids after one to two years, though relapse during taper is common. Tocilizumab roughly quadruples sustained corticosteroid-free remission, 56 per cent against 14 per cent at 52 weeks in the GiACTA trial, and halves cumulative corticosteroid dose.

ANCA-associated vasculitis: CONTROLLABLE, with remission in the great majority and relapse in 30 to 50 per cent. Untreated one-year mortality is roughly 80 per cent and treated five-year survival 75 to 85 per cent†. This is one of the largest treatment effects on survival of any disease in this chapter, and the drugs that achieve it — cyclophosphamide and corticosteroids — are off-patent and cost hundreds of dollars.

Takayasu arteritis and Behçet disease: CONTROLLABLE.

Anti-glomerular basement membrane disease: CONTROLLABLE if caught early; once dialysis-dependent with extensive crescents, renal recovery is unlikely, so RELIEF ONLY at that point.

**Prevention.** This entry contains two of the clearest preventions in the whole chapter.

Hepatitis B vaccination has nearly eliminated hepatitis B-associated polyarteritis nodosa where coverage is universal. STRONG — a vaccine that prevents an autoimmune vasculitis, demonstrated by national before-and-after incidence data.

Hepatitis C treatment with direct-acting antivirals prevents and reverses cryoglobulinaemic vasculitis. STRONG.

Prompt corticosteroids on clinical suspicion of giant cell arteritis, before temporal artery biopsy, prevents blindness. Visual loss is irreversible and occurs in 10 to 20 per cent, and once it has occurred nothing restores sight. The prevention is a dose of prednisolone and it costs cents. STRONG — no trial exists and none is possible; the evidence is observational and universally accepted.

Intravenous immunoglobulin within 10 days in Kawasaki disease prevents coronary aneurysms, from 25 per cent to 3 to 5 per cent. STRONG.

Co-trimoxazole in granulomatosis with polyangiitis reduces relapse: a randomised trial found relapse-free survival at 24 months of 82 per cent against 60 per cent with placebo (Stegeman et al., *NEJM*, 1996). It also prevents *Pneumocystis* pneumonia, the commonest treatment-related infection death. Off-patent, at dollars a year; listing status needs checking against the 24th List†. MODERATE.

Silica exposure control. MODERATE.

Avoiding propylthiouracil, hydralazine and levamisole-adulterated cocaine, and recognising drug-induced disease. MODERATE.

Prevention of treatment harm is the largest avoidable burden in these diseases. Reduced-dose corticosteroid regimens: the PEXIVAS trial found a reduced-dose glucocorticoid regimen non-inferior for death or end-stage kidney disease, with significantly fewer serious infections in the first year. STRONG. *Pneumocystis* prophylaxis with co-trimoxazole during induction. STRONG. Avoiding cumulative cyclophosphamide above roughly 25 to 36 g, since bladder cancer and infertility risk are dose-related, and using rituximab instead in young patients and in relapsing disease. STRONG. Bone protection, vaccination and cardiovascular risk management. STRONG.

PEXIVAS also found that plasma exchange did not reduce death or end-stage kidney disease in severe ANCA-associated vasculitis — a negative finding that changed practice and removed an expensive, resource-intensive intervention from routine use.

**Treatment.**

*Giant cell arteritis.* Prednisolone 40 to 60 mg a day, started immediately on suspicion, with 500 to 1,000 mg intravenous methylprednisolone for visual involvement. Off-patent, at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024†; listing status needs checking against the 24th List†. Tocilizumab, with sustained corticosteroid-free remission of 56 per cent against 14 per cent in GiACTA; biosimilars since 2023 to 2024, at US$5,000 to US$15,000 a patient-year biosimilar (2024)†; listing status needs checking against the 24th List†. Methotrexate, with a modest corticosteroid-sparing effect in meta-analysis, off-patent at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†; a selected medicine on the 24th List in sections 8.2.1 and 13.4, and not listed for this indication. Low-dose aspirin, where observational data suggest reduced ischaemic events and the evidence is contested.

*Kawasaki disease.* Intravenous immunoglobulin 2 g/kg as a single infusion, with aspirin, within 10 days. Plasma-derived and supply-constrained, at US$2,000 to US$10,000 a child at lowest available acquisition cost, 2024† — and it prevents a lifetime of coronary disease. Normal immunoglobulin's listing status needs checking against the 24th List†. Aspirin, high dose during the acute phase then low dose, off-patent and costing cents; listing status needs checking against the 24th List†. Corticosteroids added to immunoglobulin in high-risk children reduced coronary abnormalities in the Japanese RAISE trial; infliximab and ciclosporin are used for immunoglobulin-resistant disease. Infliximab is on the 24th List only as a therapeutic equivalent to adalimumab, for axial spondyloarthritis, Crohn disease, rheumatoid arthritis, juvenile idiopathic arthritis and psoriasis, and not as a selected medicine; Kawasaki disease is not among those indications.

*ANCA-associated vasculitis.* Induction with rituximab or cyclophosphamide plus corticosteroids. Rituximab, which RAVE and RITUXVAS found non-inferior to cyclophosphamide for induction and superior in relapsing disease, at a biosimilar induction course of US$1,500 to US$5,000 (2024)†; rituximab is a selected medicine on the 24th List in section 5.1.2, for multiple sclerosis, and section 8.2.2, for Burkitt lymphoma, diffuse large B-cell lymphoma, chronic lymphocytic leukaemia and follicular lymphoma, both complementary list — ANCA-associated vasculitis is not among the listed indications. Cyclophosphamide, orally or by the CYCLOPS pulsed intravenous regimen with less cumulative dose and equivalent remission, off-patent at US$50 to US$300 a course (2024)†; listing status needs checking against the 24th List†. Reduced-dose corticosteroids on the PEXIVAS regimen, off-patent. Avacopan, an oral C5a receptor antagonist, where the ADVOCATE trial gave sustained remission at 52 weeks of 65.7 per cent against 54.9 per cent on prednisone taper, with less glucocorticoid toxicity; approved in the United States in 2021 and the European Union in 2022, patented,

at US$150,000 to US$200,000 a patient-year on United States list (2024)†. The mechanism — replacing corticosteroids rather than adding to them — is the significant part. EML status needs checking against the 24th List†. Plasma exchange: PEXIVAS found no reduction in death or end-stage kidney disease, and it is retained for anti-glomerular basement membrane disease and for diffuse alveolar haemorrhage on weaker grounds.

Maintenance with rituximab, which MAINRITSAN found superior to azathioprine, or azathioprine or methotrexate or mycophenolate, for at least two years and often longer in PR3-ANCA disease. All except rituximab are off-patent and cost US$50 to US$1,000 a patient-year at generic or lowest available acquisition cost, 2024†. That range excludes rituximab, for which this material gives no price; another dossier in this project gives rituximab biosimilars at thousands of US dollars a patient-year as the compiler's own estimate, with no source consulted, so it is not printed here as a figure. The discrepancy between the two treatments of one drug is recorded and unresolved.

Co-trimoxazole for relapse reduction and *Pneumocystis* prophylaxis, off-patent at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024†; listing status needs checking against the 24th List†.

Mepolizumab, an anti-IL-5 antibody, for eosinophilic granulomatosis with polyangiitis, where the MIRRA trial showed more weeks in remission and corticosteroid reduction; benralizumab was non-inferior to mepolizumab in MANDARA in 2024. Patented, at US$30,000 to US$50,000 a patient-year at lowest available acquisition cost, 2024†. EML status needs checking against the 24th List†.

Dialysis and transplantation for end-stage kidney disease, where graft outcomes are good and recurrence in the graft is uncommon.

*Takayasu arteritis and Behçet disease.* Corticosteroids plus methotrexate, azathioprine or mycophenolate; TNF inhibitors and tocilizumab for refractory Takayasu arteritis; colchicine for Behçet mucocutaneous disease, off-patent at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024† with listing status needing checking against the 24th List†; azathioprine and ciclosporin for ocular Behçet disease; infliximab or adalimumab for refractory uveitis and for gastrointestinal and neurological Behçet disease — adalimumab is a selected medicine on the 24th List and infliximab a therapeutic equivalent to it, and Behçet disease is not among the listed indications for either; and apremilast for oral ulcers. Vascular intervention and stenting for Takayasu stenoses, ideally during quiescent disease.

*IgA vasculitis.* Supportive care, hydration and analgesia. Corticosteroids shorten abdominal pain but do not prevent nephritis — Cochrane review and randomised trials agree. Immunosuppression only for established significant nephritis.

**Simple means.** Hepatitis B vaccination. It prevents hepatitis B-associated polyarteritis nodosa, and it is part of routine infant immunisation almost everywhere, at cents a dose. This is a simple means that is the prevention of an autoimmune disease.

Prednisolone tablets, immediately, on clinical suspicion of giant cell arteritis. New headache with scalp tenderness, jaw claudication or visual symptoms in a person over 50, with a raised erythrocyte sedimentation rate or C-reactive protein, should be treated before confirmation. Prednisolone costs cents and prevents permanent blindness. No investigation is needed to start.

Co-trimoxazole, at dollars a year, which reduces relapse in granulomatosis with polyangiitis — 82 per cent against 60 per cent relapse-free at 24 months — and prevents *Pneumocystis* pneumonia.

Colchicine for Behçet mouth and genital ulcers. Tens of dollars a year, oral, ancient, and effective.

A urine dipstick. In ANCA-associated vasculitis and IgA vasculitis, renal involvement is silent until it is advanced. A dipstick for blood and protein costs cents and is the whole monitoring strategy where laboratory access is limited. In children with IgA vasculitis, weekly then monthly dipsticks for six to 12 months is the standard follow-up and needs nothing else.

Measuring blood pressure, because renal vasculitis presents with hypertension.

Not smoking, and avoiding occupational silica.

Recognising the drug causes — propylthiouracil, hydralazine, levamisole-adulterated cocaine — and stopping them. Free, and sometimes curative.

Vaccination before immunosuppression, and treating infection promptly. In ANCA-associated vasculitis, infection kills as many people in the first year as the vasculitis does.

Not giving corticosteroids to prevent nephritis in childhood IgA vasculitis. A simple means of avoiding harm, supported by trials, and routinely ignored.

**Gaps.** Incidence figures for every one of these diseases come almost entirely from northern Europe, North America, Japan and a few other countries. Most of the world is unmeasured, and the apparent geographic gradients — giant cell arteritis and ANCA disease north-south, Behçet along the Silk Road, Kawasaki in Japan — conflate real biology with ascertainment. Nomenclature and classification changed, in the Chapel Hill 2012 revised nomenclature and the 2022 ACR/EULAR classification criteria, so figures across eras are not comparable; and the Lyons finding that genetics follow ANCA serotype rather than clinical diagnosis implies the clinical categories themselves may be the wrong unit of measurement. Heritability is not well estimated for most of these diseases. No cause is identified for giant cell arteritis, Takayasu arteritis or Kawasaki disease, despite Kawasaki's epidemic and seasonal behaviour pointing unmistakably at an environmental trigger. Corticosteroids in childhood IgA vasculitis: trials say they do not prevent nephritis, and they continue to be given. Plasma exchange in ANCA-associated vasculitis: PEXIVAS negative, and it is still used for alveolar haemorrhage on weak grounds. Avacopan at US$150,000 to US$200,000 a patient-year on United States list (2024) against reduced-dose prednisolone at five to 30: the trial showed a modest difference in sustained remission and a real difference in glucocorticoid toxicity, and there is no cost-effectiveness consensus and no head-to-head against the PEXIVAS reduced-dose regimen alone. What predicts relapse beyond ANCA serotype is unknown, so maintenance duration is decided empirically.

---

## Antiphospholipid syndrome

**What it is.** Antibodies against phospholipid-binding proteins make the blood clot abnormally. Clots form in veins, arteries or the placenta. It causes strokes in young people, deep vein thrombosis, and repeated miscarriage.

**Measured.** Incidence is roughly one to two per 100,000 a year and prevalence roughly 40 to 50 per 100,000 in the best-studied populations; in Olmsted County, Minnesota, Duarte-García and colleagues in 2019 gave incidence 2.1 per 100,000 a year and prevalence 50 per 100,000.

Antiphospholipid antibodies are present at low titre in roughly 1 to 5 per cent of healthy people, rising with age, and most of those people never have a clotting event. This is the central measurement problem: antibody positivity is common and the syndrome is rare.

Among people with clinical events: roughly 13 to 15 per cent of strokes in people under 50 are associated with antiphospholipid antibodies; roughly 9 to 10 per cent of deep vein thrombosis; roughly 6 per cent of pregnancy morbidity; and roughly 10 to 15 per cent of women with recurrent miscarriage†.

Female predominance is roughly 3.5 to 5:1 for primary disease, with onset in the thirties and forties; in one series of 1,000 patients, about 12.7 per cent were diagnosed after age 50†. Antiphospholipid antibodies are present in roughly 30 to 40 per cent of lupus patients, and roughly 10 to 15 per cent of lupus patients develop the syndrome†.

The risk of a first thrombotic event in asymptomatic antibody-positive people is roughly zero to 5 per cent a year, concentrated in those with high-risk antibody profiles. Recurrence without anticoagulation after a first event is roughly 10 to 30 per cent a year in the first year, which is why indefinite anticoagulation is standard.

Catastrophic antiphospholipid syndrome affects roughly 1 per cent of patients, with multi-organ thrombosis over days to weeks and mortality roughly 30 to 50 per cent even with treatment†.

Untreated, live birth rates in women with obstetric disease are roughly 10 to 30 per cent; with low-dose aspirin plus heparin, roughly 70 to 80 per cent†.

**Where it starts.** Autoantibodies against beta-2 glycoprotein I, the principal antigen, prothrombin, and phospholipid-protein complexes. These activate endothelium, platelets, monocytes and complement, inhibit natural anticoagulants and fibrinolysis, and in pregnancy impair trophoblast invasion. Complement activation is required in animal models, which is why complement inhibition is being tried in catastrophic disease.

The antibodies are necessary but not sufficient: a second hit — infection, surgery, immobilisation, oestrogen, pregnancy, smoking — typically precipitates the event. This is established and is the basis of perioperative and peripartum prophylaxis.

The risk stratification by antibody is firm. Lupus anticoagulant has the closest association with clotting and is the single strongest predictor. Anti-beta-2 glycoprotein I antibodies are more strongly linked to thrombosis than anti-prothrombin antibodies. Anticardiolipin antibodies at moderate to high titre are associated with thrombosis while low titres largely are not. Having both lupus anticoagulant and moderate-to-high anticardiolipin confers greater risk than either alone. Triple positivity, moderate-to-high titres and IgG isotype each raise the likelihood of future clots and pregnancy complications, and triple-positive patients have the highest recurrence rates and are the group in which direct oral anticoagulants fail. Persistence on repeat testing at least 12 weeks apart is required, because transient antibodies after infection are common and not associated with thrombosis.

Oestrogen-based contraceptives significantly increase clot risk in people with the syndrome — established and clinically decisive.

The most common manifestations are lower-extremity deep vein thrombosis on the venous side and stroke on the arterial side.

HLA associations exist, with *HLA-DRB1*04*,* DRB1*07* and *DQB1* linked to antibody production, and there is no strong monogenic contribution. Heritability is not well estimated. Familial antiphospholipid antibodies occur.

Infectious triggers of transient antibodies include syphilis, the original association, hepatitis C, HIV, parvovirus B19, cytomegalovirus and COVID-19. These are mostly not thrombogenic, which is why persistence testing matters.

*Not known*: why most antibody-positive people never clot. What the second hit is in patients who clot without an obvious provocation. Why some patients have arterial and others venous events. Whether seronegative antiphospholipid syndrome exists as an entity. The mechanism of the non-thrombotic manifestations — thrombocytopenia, valve disease, livedo, cognitive dysfunction, nephropathy — which are not obviously explained by clotting and are not prevented by anticoagulation.

**Cure status.** Thrombotic and obstetric disease: CONTROLLABLE. Catastrophic antiphospholipid syndrome: RELIEF ONLY, with mortality roughly 30 to 50 per cent.

No treatment eliminates the antibodies or cures the syndrome; anticoagulation prevents the events for as long as it continues. Recurrence after stopping is high, roughly 10 to 30 per cent in the first year, so treatment is lifelong in nearly all patients.

In obstetric disease, treatment produces live births, which is as close to a cure of the clinical problem as exists here. Low-dose aspirin plus low-molecular-weight heparin raises live birth rates from roughly 10 to 30 per cent untreated to roughly 70 to 80 per cent in cohort and trial data†. Cochrane reviews of heparin plus aspirin against aspirin alone in recurrent miscarriage with antiphospholipid antibodies find a significant reduction in pregnancy loss, though trial quality is mixed and the effect size varies between reviews.

Antibody titres sometimes fall or disappear spontaneously or with treatment of an associated disease such as lupus or hepatitis C. Whether anticoagulation can then be stopped is unresolved and is an active clinical question without trial evidence.

In catastrophic disease, triple therapy — anticoagulation, corticosteroids, and plasma exchange or immunoglobulin — plus treatment of the trigger is standard, with eculizumab and rituximab used in refractory cases on case-series grounds. Mortality remains roughly 30 to 50 per cent.

**Prevention.** No primary prevention of the antibodies.

Prevention of a first thrombotic event in antibody-positive people. Low-dose aspirin in asymptomatic antibody carriers: CONTESTED. The APLASA randomised trial found no signifi-

cant benefit of aspirin over placebo for first thrombosis in asymptomatic antiphospholipid-antibody-positive individuals, while observational data and guidelines nonetheless support aspirin in high-risk profiles — triple positivity, lupus anticoagulant, coexisting lupus. Trial negative, guidelines positive, sources disagree openly. Hydroxychloroquine in lupus patients with antiphospholipid antibodies, where observational data consistently show lower thrombosis rates: MODERATE. Avoiding oestrogen-containing contraception and hormone replacement: STRONG. Thromboprophylaxis around surgery, immobilisation, long travel and pregnancy, the second-hit periods: STRONG. Cardiovascular risk factor control — smoking, hypertension, lipids, diabetes — since antiphospholipid antibodies and conventional risk factors are multiplicative for arterial events: MODERATE.

Prevention of recurrence: indefinite warfarin with an international normalised ratio of 2.0 to 3.0 after a first venous event. STRONG.

Prevention of pregnancy loss: low-dose aspirin from before conception plus low-molecular-weight heparin from confirmation of pregnancy. MODERATE.

Prevention of catastrophic disease: not interrupting anticoagulation without cover, and treating infection promptly, since infection precedes a large share of catastrophic episodes. MODERATE.

Correct antibody testing — persistence at 12 weeks, standardised assays, and not testing during an acute event or on anticoagulation where lupus anticoagulant results are unreliable. This prevents both over- and under-diagnosis. MODERATE, at zero marginal cost.

**Treatment.** Warfarin, target international normalised ratio 2.0 to 3.0, indefinitely, after venous thrombosis. Higher targets of 3.0 to 4.0 were tested in two randomised trials and were not superior while causing more bleeding, so 2.0 to 3.0 is standard. For arterial events, practice varies between 2.0 to 3.0 plus aspirin and a higher target, and the evidence is weak. Off-patent, at US$10 to US$50 a patient-year for the drug at generic or lowest available acquisition cost, 2024, plus monitoring, which is the real cost and the real access barrier; point-of-care devices and self-monitoring reduce it. Listing status needs checking against the 24th List†.

Low-molecular-weight heparin — enoxaparin, dalteparin — in pregnancy, perioperatively, and where warfarin is unsuitable. Off-patent with generics and biosimilars, at US$500 to US$3,000 a patient-year at generic or lowest available acquisition cost, 2024, with prophylactic dosing much less than therapeutic†. Listing status needs checking against the 24th List†.

Low-dose aspirin in obstetric disease, and in arterial disease alongside anticoagulation. Off-patent, at one to five dollars a patient-year (2024)†. Listing status needs checking against the 24th List†.

Direct oral anticoagulants are a clear negative, and it is important. TRAPS, comparing rivaroxaban with warfarin in triple-positive disease, was terminated early for excess thromboembolic events and major bleeding in the rivaroxaban arm. RAPS and a Spanish randomised trial by Ordi-Ros and colleagues also failed to show non-inferiority for arterial events, and rivaroxaban was associated with more arterial thrombosis, particularly stroke. Consequently these drugs should not be used in triple-positive patients or in patients with prior arterial thrombosis, and regulatory warnings were issued in the European Union and elsewhere. They may be an option in selected low-risk venous patients who cannot take warfarin, and that remains contested. This is one of the clearest instances in modern medicine where a newer, more convenient, more expensive drug class is worse than the sixty-year-old generic alternative.

Hydroxychloroquine for disease with lupus, and increasingly in primary disease on observational grounds. Off-patent, at US$30 to US$150 a patient-year at generic or lowest available acquisition cost, 2024†. Listing status needs checking against the 24th List†.

Obstetric disease: low-dose aspirin pre-conception plus prophylactic low-molecular-weight heparin from a positive pregnancy test to six weeks postpartum, with live birth roughly 70 to 80 per cent. Hydroxychloroquine is added in refractory obstetric disease on observational grounds. Corticosteroids and immunoglobulin have been used in refractory cases with weak evidence.

Catastrophic disease: therapeutic anticoagulation, high-dose corticosteroids, and plasma exchange or immunoglobulin, plus treatment of the trigger. Rituximab at a biosimilar course of US$1,500 to US$5,000 at lowest available acquisition cost, 2024, and eculizumab at roughly US$400,000 to US$600,000 a patient-year (2024) in refractory disease, on case-series evidence only†. Rituximab is a selected medicine on the 24th List in sections 5.1.2 and 8.2.2, and this indication is not among those listed; eculizumab's status needs checking against the 24th List†.

Statins reduce endothelial activation markers with no outcome trial.

Non-thrombotic manifestations: thrombocytopenia treated as immune thrombocytopenia, valve disease by surveillance with surgery carrying high thrombotic risk, and nephropathy by anticoagulation plus renin-angiotensin blockade.

**Simple means.** Warfarin. The best treatment for this disease is a drug discovered in the 1940s that costs tens of dollars a year, and the newer oral anticoagulants are demonstrably worse in the high-risk group. The constraint is monitoring, not the drug.

Stopping oestrogen-containing contraception. Free, and among the largest single risk reductions available.

Not smoking, because arterial risk is multiplicative. Low-dose aspirin, at cents a year.

Compression stockings, walking, hydration and avoiding prolonged immobility, especially on long journeys and after surgery. Free.

Knowing the diagnosis and carrying a card, so that anticoagulation is not stopped casually before a procedure, and so that unexplained thrombosis is treated correctly.

Treating infection promptly, because infection precedes a large share of catastrophic episodes.

Pregnancy planning. A conversation plus aspirin plus prophylactic-dose heparin takes live birth rates from roughly 10 to 30 per cent to roughly 70 to 80 per cent. The aspirin costs cents; the heparin is the expensive part, and prophylactic-dose heparin in pregnancy is substantially cheaper than therapeutic dosing.

Repeat antibody testing at 12 weeks before accepting the diagnosis. This prevents lifelong anticoagulation given for a transient post-infectious antibody. It costs one blood test and prevents a large iatrogenic harm.

Self-monitoring of the international normalised ratio with a point-of-care device where available, which reduces the monitoring burden that is the real cost of warfarin.

**Gaps.** Population incidence and prevalence rest largely on a single well-characterised United States county population, and there is no global estimate. Antibody positivity, at 1 to 5 per cent of healthy people, and syndrome prevalence, at about 0.05 per cent, differ by two orders of magnitude, and no test distinguishes who will clot; this is the central unresolved problem. Assay standardisation for lupus anticoagulant, anticardiolipin and anti-beta-2 glycoprotein I is poor between laboratories, so antibody-based prevalence figures are not comparable, and lupus anticoagulant cannot be reliably measured on anticoagulation. Classification criteria changed between the Sydney 2006 criteria and the 2023 ACR/EULAR criteria, which classify different populations, so figures are criteria-dependent and the newer criteria are more specific. Aspirin for primary prophylaxis: APLASA negative, guidelines recommend it, sources disagree. In arterial disease, the optimal anticoagulation target and whether to add aspirin are not established by trial. Whether anticoagulation can be stopped if antibodies become persistently negative is unknown. The non-thrombotic manifestations have no established mechanism and are not prevented by anticoagulation, which suggests the thrombosis-only model of the disease is incomplete. Obstetric trial quality is mixed, and effect sizes for heparin plus aspirin against aspirin alone differ between Cochrane reviews and later meta-analyses. Catastrophic disease treatment rests entirely on registry and case-series data; no trial exists and none is feasible.

# Endocrine, nutritional and metabolic diseases

## ICD-11 chapter 05

Twenty-three entries. The diabetes group, obesity and undernutrition, the four great micronutrient deficiencies, the thyroid and adrenal and pituitary disorders, bone and urate disease, the lipid disorders, and the inherited metabolic conditions that newborn screening exists to find.

---

### Type 1 diabetes

**What it is.** The immune system destroys the insulin-producing beta cells of the pancreas. Without insulin, glucose cannot enter cells, blood sugar rises, and the body burns fat into acid. Without injected insulin the person dies within weeks.

**Measured.** The IDF Diabetes Atlas, 11th edition (2025), gives 1.8 million children and young adults under 20 living with type 1 diabetes worldwide†. Broader estimates including adults, from the Type 1 Diabetes Index (Gregory et al., *Lancet Diabetes & Endocrinology*, 2022), give roughly 8.4 million people of all ages in 2021, projected to 13.5 to 17.4 million by 2040. The two measure different populations and are not interchangeable.

The same analysis estimated that in 2021 roughly 35,000 people died within a year of onset from undiagnosed type 1 diabetes, and that roughly 3.1 million additional people would be alive had they received the care available in high-income settings. This is the central measured injustice of the disease.

Incidence varies more than 100-fold between countries. Highest: Finland, at roughly 60 to 65 per 100,000 children a year, and Sardinia at roughly 45 to 50; Sweden, Norway, Kuwait and Saudi Arabia are also high. Lowest: China, Venezuela, parts of South America and sub-Saharan Africa, at under one to two per 100,000 a year†. That gradient is the strongest argument for an environmental component and it is unexplained.

Incidence is rising by roughly 3 to 4 per cent a year globally in children, consistently measured across the EURODIAB and DIAMOND/SEARCH registries over three decades, with the sharpest relative increase in the under-five age group. Rising incidence in a genetic disease, over a period too short for allele frequencies to change, is itself a finding.

Onset peaks at five to seven years and again around puberty, and roughly half of all new cases occur in adults, which is systematically under-recognised and leads to misclassification as type 2†. The sexes are roughly equal in childhood, with a slight male excess in adult-onset disease.

Median survival after diagnosis in some low-income settings has been estimated at under one year historically where insulin is unavailable, against near-normal life expectancy in well-resourced settings. Current high-income cohorts show life expectancy roughly eight to 13 years shorter than the general population in Scottish and Australian registry data, narrowing over time.

Type 2 accounts for over 90 per cent of all diabetes, and type 1 for roughly 5 to 10 per cent†. The IDF 2025 total for all diabetes is 589 million adults aged 20 to 79, about 11 per cent

of adults†. Another dossier in this project dates the same 589 million figure and the same Atlas edition to 2024 — the same figure, the same edition, two different years. Both stand, unresolved.

**Where it starts.** T-cell-mediated autoimmune destruction of pancreatic beta cells, preceded by the appearance of islet autoantibodies against insulin, GAD65, IA-2 and ZnT8. The presence of two or more persistent islet autoantibodies confers a lifetime risk of clinical type 1 diabetes approaching 100 per cent: pooled birth cohorts showed progression to diabetes in 69.7 per cent within 10 years and 84 per cent within 15 years of seroconversion in children with multiple autoantibodies (Ziegler et al., *JAMA*, 2013). This makes the disease predictable years in advance, and it is now formally staged — stage 1, two or more autoantibodies with normal glucose; stage 2, autoantibodies plus dysglycaemia; stage 3, clinical disease.

HLA class II accounts for roughly 40 to 50 per cent of the genetic risk†. HLA-DR3-DQ2 and DR4-DQ8 heterozygosity confers the highest risk, with odds ratios of roughly 15 to 30†. HLA-DQB1*06:02 is strongly protective, at an odds ratio of roughly 0.03 to 0.1† — near- absolute protection, and one of the strongest protective alleles known in human genetics. Over 60 non-HLA loci contribute individually small effects:* INS*,* PTPN22*,* IL2RA*,* CTLA4*,* IFIH1*,* SH2B3*,* ERBB3*.

Monozygotic twin concordance runs roughly 30 to 70 per cent depending on follow-up length, dizygotic roughly 6 to 10 per cent, and sibling risk roughly 6 to 7 per cent against a background population risk of roughly 0.4 per cent, a sibling relative risk of roughly 15†. Heritability estimates are roughly 0.7 to 0.9, and yet 85 to 90 per cent of new cases have no family history, because the risk alleles are common.

The environmental factors are the central unresolved question. Enteroviruses, particularly Coxsackievirus B, are the best-supported candidate: enterovirus RNA and protein are found in islets of recently diagnosed patients more often than in controls, and the DIPP and TEDDY prospective cohorts show associations between enterovirus infection and autoantibody seroconversion. A Coxsackievirus B vaccine entered clinical trials in 2023, which will be the direct test. Early cow's milk introduction was tested directly: the TRIGR randomised trial of 2,159 infants at genetic risk, comparing hydrolysed with standard cow's-milk formula, was negative, with no reduction in islet autoimmunity or diabetes. A long-standing hypothesis, directly tested, and refuted. Gluten and cereal introduction timing showed associations in observational data, and the BABYDIET trial of delayed gluten introduction was negative. Vitamin D has observational associations and no adequately powered prevention trial. Caesarean delivery, early antibiotics and gut microbiome composition show consistent but modest associations in TEDDY and other cohorts with no causal demonstration. Higher birthweight, rapid early growth and childhood obesity — the accelerator hypothesis — show consistent associations, and insulin resistance may hasten clinical onset in autoimmune individuals. The hygiene and microbial exposure line has its sharpest natural experiment in the north-south European gradient and the Finland-against-Russian-Karelia comparison: adjacent populations with similar HLA risk and roughly a six-fold difference in incidence, which points firmly at environment. Multiple national datasets reported increased incidence and more diabetic ketoacidosis at presentation during and after the SARS-CoV-2 pandemic; whether this is viral causation, delayed presentation, or both, is unresolved.

*Not known*: the environmental trigger. Why incidence has risen 3 to 4 per cent a year for decades. Why Finland has sixty times the incidence of China. Why the under-five group is rising fastest. Why only a minority of genetically at-risk children seroconvert. What determines the rate of progression from autoantibody positivity to clinical disease, which ranges from months to decades.

**Cure status.** CONTROLLABLE. Insulin is replacement, not cure, and this has been true since 1922.

Nothing restores endogenous insulin production durably except islet or pancreas transplantation, which requires lifelong immunosuppression and is therefore reserved for specific indications. Pancreas transplantation, usually simultaneous with a kidney in diabetic nephropathy, gives insulin independence in roughly 70 to 80 per cent at one year and 50 to 60 per cent at five years, at the cost of surgery and lifelong immunosuppression. Islet transplantation gives insulin independence in roughly 50 to 60 per cent at one year, declining thereafter†; the first licensed allogeneic islet product was approved in the United States in June 2023. Most

recipients regain some insulin requirement, and the durable benefit is abolition of severe hypoglycaemia.

Stem-cell-derived islet therapy is the live cure candidate. Zimislecel, allogeneic stem-cell-derived islets infused into the portal vein with immunosuppression, reported FORWARD trial results in 2025 showing 10 of 12 participants insulin-independent at one year, with all 12 free of severe hypoglycaemic events†. This is the first demonstration of insulin independence from a manufactured, scalable cell product. It still requires immunosuppression, which is the remaining barrier; encapsulated and hypoimmune-edited versions are in earlier trials.

Disease-modifying immunotherapy delays but does not prevent. Teplizumab, an anti-CD3 antibody approved in the United States in November 2022, was the first drug ever approved to delay type 1 diabetes: in the TN-10 trial, in relatives with stage 2 disease, a single 14-day course delayed clinical onset by a median of roughly two years, with median time to diagnosis 48.4 months against 24.4 months, and extended follow-up showing the delay persisting†. In new-onset disease, the PROTECT trial in 2023 showed teplizumab preserved C-peptide†. The price is roughly US$193,900 per 14-day course on United States list (2023)†. Other agents preserving C-peptide in new-onset disease: low-dose anti-thymocyte globulin, abatacept, rituximab, baricitinib (2023, *NEJM*), and verapamil (2018 and 2023). Verapamil is notable: an off-patent generic calcium channel blocker costing tens of dollars a year that preserved C-peptide in randomised trials in new-onset disease in children and adults. None of these prevents the disease; they slow beta-cell loss.

Technology has transformed control without curing. Automated insulin delivery systems increase time in range by roughly 10 to 15 percentage points, roughly 2.5 to 3.5 extra hours a day in range, against sensor-augmented pump therapy in randomised trials, and reduce hypoglycaemia.

**Prevention.** No established primary prevention. This must be stated plainly: there is no intervention demonstrated to prevent type 1 diabetes. TRIGR and BABYDIET were negative. Nicotinamide in ENDIT, oral insulin in DPT-1 and the Fr1da/POInT programme, and parenteral insulin have not prevented it.

Delay is now possible: teplizumab delays onset by roughly two years in screen-detected stage 2 disease. MODERATE for delay, randomised and replicated in extended follow-up — and not prevention.

Screening for islet autoantibodies in the general paediatric population. The Fr1da study in Bavaria screened over 90,000 children and found that screen-detected children presented with far less diabetic ketoacidosis at clinical onset. Preventing ketoacidosis at presentation is the clearest measurable benefit of screening, and ketoacidosis at presentation is associated with worse long-term glycaemic control and, in low-resource settings, with death. MODERATE for preventing ketoacidosis.

Prevention of diabetic ketoacidosis at diagnosis by public and professional awareness campaigns: the Parma campaign in Italy reduced ketoacidosis at presentation from roughly 83 per cent to 13 per cent over eight years using posters and leaflets in schools and paediatric practices. Replication attempts have had mixed results, the original effect is large, and the intervention costs almost nothing. MODERATE.

Prevention of complications is where almost all the measurable prevention lies. Tight glycaemic control: the Diabetes Control and Complications Trial of 1993 and its EDIC follow-up found that intensive therapy reduced retinopathy by 76 per cent in primary prevention, progression of retinopathy by 54 per cent, microalbuminuria by 39 per cent and clinical neuropathy by 60 per cent, and in long-term EDIC follow-up reduced cardiovascular events by 42 per cent and all-cause mortality significantly, with the benefit persisting for decades after the trial ended. STRONG. This is one of the most consequential trials in medicine. Blood pressure control and renin-angiotensin blockade in nephropathy: STRONG. Statins for cardiovascular risk: STRONG. Annual retinal screening with treatment of detected disease, which prevents blindness: STRONG. Annual foot examination, which prevents ulceration and amputation: STRONG. Not smoking: STRONG. Coeliac disease and autoimmune thyroid screening, since both cluster with type 1 diabetes: MODERATE.

**Treatment.** Insulin is the treatment, and the price picture is the central fact.

*Human insulin*, soluble (regular) and isophane (NPH), produced by recombinant DNA since the 1980s. **Human insulin is a selected medicine on the 24th List, in section 18.5.1, as two entries: "Insulin (human, short-acting)" and "Insulin (human, intermediate-acting)", each for type 1 and type 2 diabetes**. Off-patent for decades.

Hill and colleagues (*BMJ Global Health*, 2018) estimated the minimum sustainable production cost from the cost of active pharmaceutical ingredient plus formulation, packaging, a 10 per cent margin and tax: **biosimilar human insulin, regular and NPH, at US$72 a patient-year or less, falling to US$48 with high competition**, for the 10 mL vial formulation. Actual prices: in low- and middle-income country tenders, human insulin is available at roughly two to ten dollars per 10 mL vial, roughly US$50 to US$200 a patient-year (2024)† — in the range of the Hill estimate. In the United States, list prices for human insulin have run roughly US$25 to US$100 a vial, and one retailer's human insulin has been sold at roughly US$25 a vial for years, roughly US$300 to US$600 a patient-year†.

*Insulin analogues*, rapid-acting (lispro, aspart, glulisine) and long-acting (glargine, detemir, degludec). **On the 24th List the selected medicines are the two class entries, "Insulin (analogue, long-acting)" and "Insulin (analogue, rapid-acting)", both in section 18.5.1 for type 1 and type 2 diabetes. The six named analogues — degludec, detemir and glargine long-acting, and aspart, glulisine and lispro rapid-acting — are listed as therapeutic equivalents to those class entries, not as selected medicines in their own right**. A bare "on the EML" for the named analogues overstates the listing. The years in which long-acting and rapid-acting analogues were added have not been rechecked against the 24th List†.

Lispro, aspart and glargine are off-patent with biosimilars marketed; degludec is still patented in many markets.

Hill and colleagues estimated the minimum sustainable production cost for biosimilar analogues — lispro, aspart, glargine, glulisine, degludec — at **US$133 a patient-year or less, falling to US$78 to US$98 with high competition**, with estimated analogue cost 1.9 to 2.0 times the human insulin cost, except detemir at 5.1 to 5.9 times†.

Actual prices: United States list prices for analogue insulins reached roughly US$275 to US$340 per 10 mL vial by 2019, roughly US$3,000 to US$6,000 a patient-year at typical usage†. After public and legislative pressure, the three major manufacturers each announced list price cuts of roughly 70 to 78 per cent in 2023, and a 35-dollar monthly out-of-pocket cap applies to Medicare beneficiaries under the Inflation Reduction Act from 2023, with manufacturer programmes extending similar caps more broadly†. In Europe, analogue insulin costs roughly €300 to €700 a patient-year (2024)†. In India and other biosimilar-manufacturing markets, analogue biosimilars sell for roughly US$100 to US$400 a patient-year (2024)†.

**The gap, stated plainly:** the published minimum production cost of analogue insulin is US$133 a patient-year†; the United States list price before the 2023 cuts was roughly US$3,000 to US$6,000 a patient-year† — a factor of roughly 23 to 45. Even after the cuts the gap is roughly five- to ten-fold. Three manufacturers hold roughly 90 to 95 per cent of the global insulin market by value†.

On the clinical difference: Cochrane and other systematic reviews find small or no difference in HbA1c and a modest reduction in nocturnal hypoglycaemia with long-acting analogues against NPH. WHO's own analysis supported including analogues on the list on the basis of the hypoglycaemia benefit while noting the price. The honest statement is that analogues are somewhat better, by a margin far smaller than the price difference.

*Delivery and monitoring.* Syringes and needles cost cents each, and the recurring cost of needles and strips exceeds the cost of human insulin in many low-income settings. Blood glucose test strips run roughly US$0.10 to US$0.50 each (2024); at four tests a day that is US$150 to US$700 a patient-year, often more than the insulin†. Continuous glucose monitoring runs US$1,000 to US$4,000 a patient-year (2024) and reduces HbA1c and severe hypoglycaemia in randomised trials; it is a device and not on the Model List. Insulin pumps and automated insulin delivery run US$3,000 to US$8,000 upfront plus US$1,500 to US$4,000 a patient-year in consumables (2024)†. Insulin requires refrigeration before use, and clay-pot evaporative coolers and simple insulated containers have been validated for storage in hot climates — a genuine simple-means solution to a real access barrier.

Teplizumab for stage 2 disease, roughly US$193,900 a course on United States list (2023), patented†. EML status needs checking against the 24th List†.

Adjuncts: metformin does not improve HbA1c in type 1 diabetes but modestly reduces insulin dose and weight in the REMOVAL trial; SGLT2 inhibitors reduce HbA1c and weight but substantially raise the risk of euglycaemic diabetic ketoacidosis and are not generally recommended; and verapamil preserves C-peptide in new-onset disease, is off-patent at tens of dollars a year, and is not yet standard. Metformin is a selected medicine on the 24th List, in section 18.5.2, hypoglycaemic agents, for type 2 diabetes mellitus, for adolescents and adults, first added in 1997; type 1 diabetes is not the listed indication.

Treatment of diabetic ketoacidosis: intravenous fluids, insulin infusion and potassium replacement, all costing dollars. Insulin human is on the 24th List as above; the listing status of sodium chloride and potassium chloride needs checking against the 24th List†. Ketoacidosis mortality is roughly 0.2 to 2 per cent in well-resourced settings and far higher where these are unavailable.

Complication management: ACE inhibitors or angiotensin receptor blockers for nephropathy; statins; laser photocoagulation and anti-VEGF agents for retinopathy; SGLT2 inhibitors and finerenone for diabetic kidney disease; dialysis and transplantation.

**Simple means.** Human insulin rather than analogue, where cost is the binding constraint. The clinical difference is small and the price difference is large. This is the single most consequential substitution available in this disease.

Clay-pot and evaporative cooling for insulin storage. Validated in field studies in hot climates, it keeps insulin within an acceptable temperature range without electricity. It solves a real access barrier with a pot, sand and water.

Reuse of syringes by a single patient, practised widely out of necessity, with low infection rates in reported series when done with care. Not recommended, and it is what happens.

Urine ketone strips, at cents each, which detect impending ketoacidosis without a laboratory. In settings without blood ketone meters this is the tool that prevents death.

Public awareness of the four presenting symptoms — thirst, passing urine, weight loss, tiredness. The Parma campaign reduced ketoacidosis at presentation from 83 per cent to 13 per cent with posters and leaflets. This is the cheapest life-saving intervention in this entry.

A written sick-day plan — never stopping insulin during illness, which is the commonest cause of avoidable ketoacidosis. Free.

Carbohydrate counting and dose adjustment skills: education, not technology. Structured education programmes such as DAFNE and its equivalents improve HbA1c and reduce severe hypoglycaemia.

Daily foot inspection and well-fitting shoes, which prevent the ulceration that leads to amputation. Free. And not smoking.

There is no simple-means substitute for insulin. A person with type 1 diabetes without insulin dies. Everything in this section is about making insulin work with less infrastructure, not about replacing it.

**Gaps.** The IDF figure of 1.8 million under 20 and the Type 1 Diabetes Index figure of roughly 8.4 million all ages measure different populations and are not interchangeable, and there is no authoritative global count of adults with type 1 diabetes, because adult-onset type 1 is routinely misclassified as type 2. Incidence varies more than 100-fold between countries and nobody knows why. Incidence has risen 3 to 4 per cent a year for three decades and nobody knows why; genetic change cannot account for it. The environmental trigger is unidentified, and the enterovirus hypothesis will be tested directly by the Coxsackievirus B vaccine trials. TRIGR and BABYDIET were negative, which refuted two long-standing prevention hypotheses, and some guidance material still reflects the pre-trial advice. Whether SARS-CoV-2 increased incidence, or only brought presentations forward and made them more severe, is unresolved and national datasets disagree. Insulin prices are confidential in most tendered markets, so the figures here are approximate, and the Hill production-cost estimates are modelled rather than audited; the authors state their estimates in 2018 terms, cite 2019 market data as context, and do not themselves state a reference year for the cost estimates. The clinical superiority of analogues over human insulin is modest and the magnitude is con-

tested between manufacturer-sponsored and independent analyses. Zimislecel and other stem-cell islet data come from fewer than 20 patients with one year of follow-up. No trial has tested whether screening the general population for islet autoantibodies improves long-term outcomes, as distinct from reducing ketoacidosis at presentation.

---

## Type 2 diabetes

**What it is.** The body's cells stop responding properly to insulin, and the pancreas cannot make enough to compensate. Blood glucose rises over years, damaging eyes, kidneys, nerves and arteries. It is closely tied to body fat, especially fat in the liver and pancreas.

**Measured.** From the IDF Diabetes Atlas, 11th edition (2025), for all diabetes, of which type 2 is over 90 per cent†: 589 million adults aged 20 to 79 living with diabetes, nearly one in nine adults and about 11 per cent of the adult population; 252 million adults undiagnosed, more than four in ten of all people with diabetes; over 3.4 million deaths a year; health expenditure surpassing one trillion US dollars in 2024, up from 966 billion in 2021; a projection of 853 million adults by 2050; one in eight adults at high risk of developing type 2 diabetes; three in four adults with diabetes living in low- and middle-income countries; and an 84 per cent higher risk of heart failure in people with type 2 diabetes than in those without.

The WHO diabetes fact sheet, printed 14 November 2024, uses a different method and gives larger all-age figures: 14 per cent of adults aged 18 and over had diabetes in 2022, up from 7 per cent in 1990; the total across all ages rose from 200 million in 1990 to 830 million in 2022; 59 per cent of adults aged 30 and over with diabetes were not taking any medication for it in 2022, with treatment coverage lowest in low- and middle-income countries; and deaths in 2021 were 1.6 million directly caused by diabetes plus 530,000 from diabetes-caused kidney disease. The WHO Key Facts section states that more than half of all people with diabetes were untreated in 2022, while the body applies the 59 per cent figure only to adults aged 30 and over — a scope mismatch within the same page. The IDF and WHO global figures are not interchangeable and the difference is not reconciled in either publication.

Incidence rises steeply with age, and type 2 diabetes in children and adolescents is now established and rising, at roughly one to five per 100,000 a year in United States and United Kingdom youth, concentrated in specific ancestry groups and with a more aggressive course than adult-onset disease; the TODAY study showed rapid glycaemic failure and early complications.

At any given body size, risk is substantially higher in South Asian, East Asian, African, Hispanic, Middle Eastern, Pacific Islander and Indigenous populations than in European populations, and WHO recommends lower action points for Asian populations in consequence. The highest national prevalences are in Pacific Island nations, the Gulf states and parts of South and Southeast Asia, with adult prevalence above 20 per cent in several†.

Diabetes is a leading cause of blindness, end-stage kidney disease and non-traumatic lower-limb amputation worldwide, and roughly doubles cardiovascular mortality. In the GBD 2023 cycle, diabetes ranks fifth among causes of disability-adjusted life years at 90.2 million (95% UI 75.2–107) and seventh among causes of years lived with disability at 44.2 million (95% UI 31.0–59.7).

**Where it starts.** Insulin resistance in muscle, liver and adipose tissue, plus progressive beta-cell dysfunction. Hyperglycaemia appears when beta-cell compensation fails. Ectopic fat in the liver and pancreas is central: the twin cycle hypothesis holds that excess liver fat drives hepatic insulin resistance and excess pancreatic fat impairs insulin secretion, and that both are reversible with sufficient weight loss. This hypothesis generated the DiRECT and DIADEM-I trials and is the main reason remission is now a recognised outcome.

Adiposity is the dominant modifiable risk factor. GBD attributable-risk analyses attribute roughly 50 per cent of type 2 diabetes DALYs to high body mass index†. Relative risk rises roughly log-linearly with body mass index: in the Nurses' Health Study and the Health Professionals Follow-up Study, risk at the upper end of the measured range was roughly 20 to 40 times that at the lower end in women and roughly 20 times in men†. Weight gain in adulthood predicts risk independently of attained body size, and waist circumference and visceral fat predict risk beyond body mass index.

Physical inactivity is independently associated, with roughly 20 to 30 per cent higher risk in the least active against the most active, adjusted for body size.

Diet: higher risk with sugar-sweetened beverages, at roughly 13 to 26 per cent higher risk per serving a day in meta-analyses; with processed red meat; and with refined grains. Lower risk with whole grains, coffee, nuts, and dietary patterns high in vegetables, legumes and unsaturated fat. Effect sizes are modest individually.

Smoking: roughly 30 to 40 per cent higher risk in smokers†. Short and long sleep duration and shift work are associated with higher risk. Gestational diabetes in the mother carries roughly a ten-fold higher subsequent maternal risk and higher risk in the offspring. Low birthweight and intrauterine undernutrition: the Dutch Hunger Winter and other famine cohorts show raised later glucose intolerance, and the developmental origins association is consistent. Lower income and education are associated with higher risk in high-income countries, and with higher risk in urban populations in low-income countries.

Over 600 loci have been identified by genome-wide association, individually small. *TCF7L2* is the strongest common variant at an odds ratio of roughly 1.4 per risk allele†. Monozygotic twin concordance is roughly 70 per cent, dizygotic roughly 20 to 30 per cent, and heritability estimates roughly 0.3 to 0.7; first-degree relative risk is roughly 2 to 3, and roughly 5 to 6 with both parents affected†. Common polygenic risk scores explain under 20 per cent of heritability and perform worse in non-European populations. Monogenic diabetes is roughly 1 to 4 per cent of diabetes and is routinely misdiagnosed as type 1 or type 2 — *HNF1A*, *HNF4A*, *GCK*, *HNF1B* — which matters because *HNF1A* disease responds dramatically to low-dose sulfonylurea and *GCK* disease needs no treatment at all.

Drug-induced: glucocorticoids, thiazides, atypical antipsychotics, statins (small effect), protease inhibitors, calcineurin inhibitors.

*Not known*: why some people with severe obesity never develop type 2 diabetes and others develop it at ordinary body size. What determines individual beta-cell reserve. Why ancestry groups differ so markedly at equal body size — the thin-fat South Asian phenotype is described and not explained. Whether the common polygenic architecture will ever be clinically useful.

**Cure status.** CONTROLLABLE. In a substantial minority of recent-onset cases remission is achievable and sometimes durable, and the word used in the literature is remission rather than cure, because the underlying susceptibility persists and relapse follows weight regain.

*DiRECT* (Diabetes Remission Clinical Trial; Lean, Taylor and colleagues, Scotland; cluster-randomised in primary care, 306 participants with type 2 diabetes of up to six years' duration, not on insulin). The intervention was total diet replacement followed by structured food reintroduction and weight-loss maintenance, delivered in primary care.

- **Remission at 12 months: 46 per cent of the intervention group against 4 per cent of the control group**†.
- **Remission at 24 months: 36 per cent against 3 per cent**†.
- **Remission at five years, in the extension study: 11 of the 48 participants who were in remission at the start of the extension, 23 per cent, remained in remission. The control group's five-year remission rate was 3.4 per cent**†.
- Remission was defined as HbA1c below 48 mmol/mol (6.5 per cent) while off all antidiabetes drugs.
- Weight change at five years: intervention group mean −6.1 kg; those still in remission at five years −8.9 kg; control group −4.6 kg†.
- Remission depended strongly on the weight loss achieved. At 12 months, remission occurred in roughly 86 per cent of those who lost 15 kg or more, roughly 57 per cent of those losing 10 to 15 kg, roughly 34 per cent of those losing 5 to 10 kg, and roughly 7 per cent of those losing under 5 kg†. This dose-response is the central finding.

*DIADEM-I* (Qatar; randomised controlled trial, 147 participants with type 2 diabetes of up to three years' duration, aged 18 to 50). The intervention was total diet replacement followed by structured food reintroduction and physical activity.

- **Diabetes remission at 12 months: 61 per cent of the intervention group against 12 per cent of the control group**†. It is widely reported as both 61 and 60 per cent.

- Normoglycaemia, defined as HbA1c below 5.7 per cent off medication, in 33 per cent of the intervention group against 4 per cent of control†.
- Mean weight loss at 12 months: 11.98 kg in the intervention group against 3.98 kg in control†.

The DIADEM-I participants were younger and had shorter disease duration than those in DiRECT, which is the likeliest reason for the higher remission rate.

*Other remission evidence.* Bariatric and metabolic surgery produces the highest and most durable remission rates. STAMPEDE, a five-year randomised trial of 150 patients, found HbA1c of 6.0 per cent or below off medication in roughly 29 per cent of gastric bypass and 23 per cent of sleeve gastrectomy patients against 5 per cent of intensive medical therapy patients at five years†. The Swedish Obese Subjects matched cohort found diabetes remission in 72 per cent at two years and 36 per cent at 10 years after surgery, against 21 and 13 per cent in matched controls†. Mingrone and colleagues, at 10-year randomised follow-up, found 37.5 per cent of biliopancreatic diversion and 25 per cent of gastric bypass patients maintained remission at 10 years against 5.5 per cent on medical therapy†. Surgery also reduces diabetes-related mortality and microvascular complications in cohort data.

Look AHEAD, an intensive lifestyle intervention in 5,145 participants with type 2 diabetes and overweight or obesity, achieved partial or complete remission in 11.5 per cent at one year and 7.3 per cent at four years, against 2.0 and 2.0 per cent in the control group† — lower rates than DiRECT because the weight loss achieved was smaller, roughly 8.6 per cent at year one and 4.7 per cent at year four†, and participants had longer disease duration. **Look AHEAD did not reduce cardiovascular events**, its primary endpoint, which is an important negative.

Determinants of remission are consistently measured: shorter diabetes duration, lower baseline HbA1c, not using insulin, greater weight loss, and better preserved beta-cell function. Remission is largely a window-of-opportunity phenomenon in the first few years. Relapse follows weight regain; in DiRECT, relapse tracked weight regain closely.

Stated precisely: CONTROLLABLE in all; remission achievable in roughly 30 to 60 per cent† of people with recent-onset disease given substantial weight loss, with roughly a quarter of those in remission still in remission at five years; and remission is not cure, because susceptibility and relapse risk persist.

**Prevention.** This entry has the strongest primary-prevention trial evidence of any condition in chapter 05.

*Intensive lifestyle intervention in people with impaired glucose tolerance.* The US Diabetes Prevention Program (*NEJM*, 2002; 3,234 participants with impaired glucose tolerance, mean follow-up 2.8 years):

| Arm | Incidence per 100 person-years | Cumulative incidence at 3 years |
|---|---|---|
| Placebo | 11.0 | **28.9 per cent** |
| Metformin | 7.8 | **21.7 per cent** |
| Intensive lifestyle | 4.8 | **14.4 per cent** |

- **Lifestyle intervention reduced incidence by 58 per cent (95% CI 48–66)**.
- **Metformin reduced incidence by 31 per cent (95% CI 17–43)**.
- **Number needed to treat over three years: 6.9 for lifestyle (95% CI 5.4–9.5) and 13.9 for metformin (95% CI 8.7–33.9)**.

Those two numbers needed to treat are correct as published and follow exactly from the cumulative-incidence row above: for lifestyle, 28.9 − 14.4 = 14.5 percentage points, and 1 ÷ 0.145 = 6.90; for metformin, 28.9 − 21.7 = 7.2 percentage points, and 1 ÷ 0.072 = 13.89. They do not follow from the per-100-person-year rates, which is why the cumulative-incidence row is printed here: a reader working from the rates alone would get 5.4 and 10.4 and conclude the published figures were wrong. The 58 and 31 per cent relative reductions are hazard-based, from the proportional-hazards model, as the paper states, and the crude cumulative-incidence ratios are 50.2 and 24.9 per cent. Lifestyle was significantly more effective than metformin.

The Diabetes Prevention Program Outcomes Study at 15 years found diabetes incidence remained 27 per cent lower in the lifestyle group and 18 per cent lower in the metformin group than placebo† — the benefit persisted long after the intensive intervention ended.

The Finnish Diabetes Prevention Study, in 522 participants, found a 58 per cent relative risk reduction, the same figure arrived at independently. The Da Qing study in China, 577 participants with 30-year follow-up, found that diet and exercise interventions reduced diabetes incidence, and at 30 years the intervention group had lower cardiovascular events, fewer microvascular complications, lower all-cause mortality, and roughly 1.44 years greater life expectancy† — the only diabetes prevention trial with mortality benefit demonstrated at three decades. The Indian Diabetes Prevention Programme and others replicate the effect at smaller magnitude. STRONG: replicated in multiple countries and ancestries, with long-term follow-up and, in Da Qing, mortality benefit.

Metformin for prevention: 31 per cent reduction, greater in those with higher body mass index and in women with prior gestational diabetes. Off-patent, cents a day. STRONG for the effect; it is not licensed for prevention in most countries.

Weight loss by any means. In the Diabetes Prevention Program, each kilogram of weight lost was associated with roughly a 16 per cent reduction in diabetes risk†. This is the clearest dose-response in the field. STRONG.

Bariatric surgery for prevention: in the Swedish Obese Subjects study, surgery reduced incident type 2 diabetes by roughly 78 to 87 per cent over 10 to 15 years against matched controls†. STRONG.

GLP-1 receptor agonists for prevention: in SCALE, liraglutide in prediabetes substantially delayed diabetes onset; in STEP 1 extension data and in the SELECT trial, semaglutide reduced progression to diabetes. MODERATE for the effect; cost and durability after stopping are the constraints, since glycaemic and weight benefits largely reverse on discontinuation.

Population-level measures. Sugar-sweetened beverage taxes produced measured reductions in purchases of roughly 10 to 20 per cent following taxes in Mexico, Chile, the United Kingdom and several United States cities; effects on diabetes incidence are modelled rather than directly measured. MODERATE for consumption, WEAK for diabetes incidence. The United Kingdom Soft Drinks Industry Levy produced substantial reformulation, reducing the sugar content of soft drinks by roughly 30 per cent across the market†. MODERATE for reformulation. Front-of-pack labelling, marketing restrictions and trans fat elimination are WHO-recommended, with effects demonstrated on intermediate measures and modelled on diabetes incidence. WEAK. Built environment and physical activity infrastructure: WEAK, observational.

Not smoking. MODERATE.

Screening for diabetes detects the 252 million undiagnosed. Whether screening itself reduces mortality is contested: the ADDITION-Cambridge trial found no mortality reduction from population screening over 10 years, while early treatment of detected cases clearly reduces complications. CONTESTED for screening as a mortality intervention, STRONG for treating what is found.

**Treatment.** Metformin, first-line everywhere. It reduces HbA1c by roughly 1.0 to 1.5 percentage points, and UKPDS showed reduced diabetes-related death and myocardial infarction in overweight patients. **Metformin is a selected medicine on the 24th List, in section 18.5.2, hypoglycaemic agents, for type 2 diabetes mellitus, as oral solid 500 mg hydrochloride, for adolescents and adults, first added in 1997**. Off-patent, at US$2 to US$15 a patient-year at generic or lowest available acquisition cost, 2024†. The best-value drug in chapter 05.

Sulfonylureas — gliclazide, glibenclamide, glimepiride — reduce HbA1c by roughly 1.0 to 1.5 points, with hypoglycaemia and weight gain as the drawbacks and modified-release gliclazide carrying the lowest hypoglycaemia risk of the class. Off-patent, at US$3 to US$20 a patient-year at generic or lowest available acquisition cost, 2024†. These two drug classes treat the large majority of the world's type 2 diabetes. Gliclazide's listing status needs checking against the 24th List†.

SGLT2 inhibitors — empagliflozin, dapagliflozin, canagliflozin — reduce HbA1c by roughly 0.6 to 0.8 points, plus the outcome effects that changed practice: EMPA-REG OUTCOME gave a

38 per cent relative reduction in cardiovascular death, 32 per cent in all-cause death and 35 per cent in heart failure hospitalisation†; CREDENCE gave a 30 per cent reduction in the composite renal endpoint in diabetic kidney disease; and DAPA-CKD and EMPA-KIDNEY showed renal and mortality benefit extending beyond diabetes. Generics are available in India and several other markets; originator patents run to the late 2020s in the United States and Europe. United States list prices run US$6,000 to US$7,000 a patient-year (2024), European prices roughly €400 to €700 a patient-year, and Indian generics roughly US$30 to US$120 a patient-year (2024)† — a generic-to-originator ratio of roughly 50 to 200-fold. Their listing status needs checking against the 24th List†.

GLP-1 receptor agonists and the dual GIP/GLP-1 agonist are the class with the largest recent effect sizes. Semaglutide 1.0 mg subcutaneous weekly in type 2 diabetes reduces HbA1c by roughly 1.5 to 1.8 percentage points with weight loss of roughly 4 to 6 kg in the SUSTAIN programme†. SUSTAIN-6 gave a 26 per cent reduction in major adverse cardiovascular events†; LEADER, with liraglutide, a 13 per cent reduction in those events and 22 per cent in cardiovascular death†. STEP 1, with semaglutide 2.4 mg weekly in 1,961 adults without diabetes over 68 weeks, gave a mean weight change of −14.9 per cent against −2.4 per cent with placebo†. SURMOUNT-1, with tirzepatide in 2,539 adults without diabetes over 72 weeks, gave mean weight change of −15.0 per cent at 5 mg, −19.5 per cent at 10 mg and −20.9 per cent at 15 mg against −3.1 per cent on placebo, with at least 5 per cent weight loss in 85, 89 and 91 per cent against 35 per cent on placebo, and at least 20 per cent weight loss in 50 per cent at 10 mg and 57 per cent at 15 mg against 3 per cent†. The SURPASS programme in type 2 diabetes gave HbA1c reductions up to roughly 2.1 to 2.4 percentage points, the largest of any non-insulin agent†. SELECT, with semaglutide 2.4 mg in 17,604 participants with overweight or obesity and established cardiovascular disease but without diabetes, gave a 20 per cent reduction in major adverse cardiovascular events, hazard ratio 0.80, over a mean 39.8 months† — the first demonstration that treating obesity pharmacologically reduces cardiovascular events. FLOW gave a 24 per cent reduction in the composite kidney endpoint in type 2 diabetes with chronic kidney disease†, and SUMMIT, with tirzepatide in heart failure with preserved ejection fraction and obesity, reduced cardiovascular death or worsening heart failure.

On listing: GLP-1 receptor agonists were added to the WHO Model List of Essential Medicines in the 24th List (2025), specifically for adults with type 2 diabetes who also have established cardiovascular disease, chronic kidney disease or obesity, with semaglutide, dulaglutide, liraglutide and tirzepatide named. **That listing was not independently verified against the 24th List for this chapter, and carries a dagger pending a recheck.** The committee framed the listing as support for wider access as more affordable options become available. The counts sometimes quoted alongside it — 523 medicines for adults and 374 for children, with 20 added to the adult list, 15 to the children's list and new indications for seven already-listed products — are not printed on the list's title page and remain unconfirmed.

Liraglutide is off-patent with generics marketed; semaglutide, dulaglutide and tirzepatide are not, though semaglutide's primary patents expire in Canada, India, China and Brazil from 2026 and generic and biosimilar launches in those markets are expected from that year.

Prices, 2024 to 2025. Semaglutide on United States list: roughly US$1,000 to US$1,350 a month, roughly 12,000 to 16,000 a patient-year, with US$499 a month through direct-to-consumer cash channels from 2025, roughly 6,000 a patient-year†. Tirzepatide on United States list: roughly US$1,000 to US$1,080 a month, roughly 12,000 to 13,000 a patient-year, with US$349 to US$499 a month through direct cash channels†. Europe: semaglutide roughly €100 to €300 a month, roughly 1,200 to 3,600 a patient-year†. India: liraglutide generics have launched at roughly US$30 to US$100 a month†.

**Published minimum production cost estimate** (Barber, Hill and colleagues, *JAMA Network Open*, 2024): semaglutide could be manufactured and sold profitably at roughly US$0.89 to US$4.73 a month, roughly US$11 to US$57 a patient-year, at scale. Against a United States list price of roughly US$12,000 to US$16,000 a patient-year, that is a factor of roughly 250 to 1,500 — the largest price-to-production-cost gap in this chapter.

Gastrointestinal side effects are the main limitation. Discontinuation rates in real-world use are high, roughly 30 to 50 per cent within a year in United States claims data, and weight and glycaemic benefit largely reverse on stopping: the STEP 1 extension found roughly two-

thirds of lost weight regained within a year of discontinuation, with STEP 4 withdrawal data concordant†.

DPP-4 inhibitors — sitagliptin, linagliptin — reduce HbA1c by roughly 0.5 to 0.8 points, are weight neutral, and have no demonstrated cardiovascular benefit. Sitagliptin is off-patent in several markets, at US$30 to US$150 a patient-year at generic or lowest available acquisition cost, 2024†. EML status needs checking against the 24th List†.

Pioglitazone reduces HbA1c by roughly 1.0 point; the IRIS trial showed reduced stroke and myocardial infarction in insulin-resistant patients with prior stroke, against weight gain, fluid retention and fracture risk. Off-patent, at US$20 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†. EML status needs checking against the 24th List†.

Insulin for beta-cell failure. Human insulin remains the appropriate choice in most of the world for type 2 diabetes and is a selected medicine on the 24th List, in section 18.5.1, for type 1 and type 2 diabetes, at US$50 to US$200 a patient-year for human insulin at lowest available acquisition cost, 2024†. See the previous entry for the full price picture.

Acarbose has a modest effect with gastrointestinal side effects and is widely used in parts of Asia. Off-patent and cheap.

Metabolic surgery is the most effective intervention for remission and for weight, at US$10,000 to US$30,000 one-off in high-income settings (2024)†, with cohort data showing reduced mortality and microvascular complications.

Complication prevention carries most of the mortality benefit. Blood pressure control: UKPDS and subsequent trials found tight blood pressure control reduced diabetes-related death, stroke and microvascular endpoints, with effect sizes larger than those for glycaemic control. ACE inhibitors, angiotensin receptor blockers, calcium channel blockers and thiazides are all off-patent at US$5 to US$50 a patient-year at generic or lowest available acquisition cost, 2024†, with listing status needing checking against the 24th List†. Statins: the Cholesterol Treatment Trialists' meta-analyses give roughly a 21 per cent proportional reduction in major vascular events per 1 mmol/L reduction in LDL cholesterol, consistent in people with and without diabetes, at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024†; listing status needs checking against the 24th List†. Finerenone, in FIDELIO-DKD and FIGARO-DKD, reduced kidney and cardiovascular events in diabetic kidney disease; patented, at US$6,000 to US$8,000 a patient-year on United States list (2024)†. Annual retinal screening, annual foot examination and annual urine albumin-to-creatinine ratio are all cheap and all prevent irreversible outcomes. Aspirin for secondary prevention only.

**Simple means.** What the trials measured, with no protocol.

Weight loss, by any means. The DiRECT and DIADEM-I trials achieved remission with diet-based weight loss delivered in primary care, with no drug and no surgery. Remission occurred in roughly 86 per cent of DiRECT participants who lost 15 kg or more, and in roughly 7 per cent of those losing under 5 kg. In the Diabetes Prevention Program, each kilogram lost was associated with roughly 16 per cent lower diabetes risk. The intervention in both remission trials was a formula diet followed by structured food reintroduction, supported by a nurse or dietitian in ordinary primary care — a service, not an industrial chain.

Metformin. Off-patent, a selected medicine on the 24th List, at US$2 to US$15 a patient-year at generic or lowest available acquisition cost, reducing HbA1c by 1.0 to 1.5 points, with reduced diabetes-related death in UKPDS and a 31 per cent reduction in incident diabetes in prediabetes. The cheapest effective drug in this chapter.

Gliclazide. Off-patent, at US$3 to US$20 a patient-year at generic or lowest available acquisition cost.

Physical activity. Trial-measured: in the Diabetes Prevention Program and the Finnish study, physical activity was a component of interventions that reduced incidence by 58 per cent; in Da Qing, exercise alone was one of the effective arms, and the 30-year follow-up showed reduced mortality and increased life expectancy. Walking requires nothing.

Human insulin rather than analogue, where cost binds.

A urine dipstick for protein and a once-yearly look at the feet. Both cost almost nothing and both detect the complications that cause amputation and dialysis.

A blood pressure cuff. Blood pressure control delivers larger absolute risk reductions in type 2 diabetes than glycaemic control, and the drugs are generic.

Not smoking.

Case detection. 252 million people are undiagnosed, and 59 per cent of those aged 30 and over who have the disease are on no medication. A fasting glucose or an HbA1c costs a few dollars. The binding constraint is not technology.

Reduced sugar-sweetened beverage intake. Measured: each daily serving is associated with 13 to 26 per cent higher risk in meta-analyses; taxes reduced purchases by 10 to 20 per cent in Mexico, Chile, the United Kingdom and several United States cities; and the United Kingdom levy drove roughly a 30 per cent reduction in the sugar content of soft drinks through reformulation.

**Gaps.** The IDF and WHO give substantially different global figures — 589 million adults aged 20 to 79 (IDF, 2025) against 830 million all ages and 14 per cent of adults aged 18 and over (WHO, 2022 reference year). They use different age ranges, data sources and modelling, are not interchangeable, and the difference is not reconciled in either publication. Type 1 and type 2 are not reliably distinguished in most population datasets, so "over 90 per cent type 2" is an estimate. Monogenic diabetes, at 1 to 4 per cent, is routinely misclassified, and misclassification changes treatment radically. DiRECT and DIADEM-I enrolled people with short disease duration, not on insulin, within specified body-size ranges, so the remission rates do not generalise to long-standing or insulin-treated disease, and the trials say so. DiRECT's five-year figure of 23 per cent is reported on a subgroup of the original cohort rather than the original randomised population, so it is not directly comparable with the 46 and 36 per cent figures. Look AHEAD did not reduce cardiovascular events, which remains unexplained and sits awkwardly with the Da Qing mortality findings. ADDITION-Cambridge found no mortality benefit from population screening while treatment of detected disease clearly works, and sources disagree on what to conclude. GLP-1 discontinuation rates in real-world use are high and weight regain after stopping is substantial, and long-term effectiveness beyond five years outside trials is unmeasured. The semaglutide production-cost estimate is modelled from active pharmaceutical ingredient costs and is contested by manufacturers; no audited figure exists. SGLT2 inhibitor and GLP-1 prices differ by one to three orders of magnitude between United States list, European tendered and Indian generic markets, so any single price figure is misleading. Whether GLP-1 agonists' cardiovascular benefit is weight-mediated or independent is unresolved. Ancestry-specific anthropometric action points are empirically derived and the biological explanation for the difference is unknown.

---

## Gestational diabetes

**What it is.** Blood glucose that rises above normal during pregnancy and returns to normal after delivery. It raises the chance of a large baby, birth injury, caesarean delivery and pre-eclampsia, and it marks a high lifetime risk of type 2 diabetes in the mother.

**Measured.** The IDF Diabetes Atlas has given hyperglycaemia in pregnancy as affecting roughly one in six live births, about 16 to 17 per cent worldwide, of which roughly 75 to 80 per cent is gestational diabetes and the remainder pre-existing or first-detected diabetes in pregnancy; in the 9th and 10th editions this corresponded to roughly 20 to 21 million live births affected a year†. The 11th edition press materials do not restate a gestational diabetes figure.

Prevalence varies several-fold by diagnostic criteria, which is the dominant measurement problem. The IADPSG/WHO 2013 criteria — one abnormal value on a 75 g oral glucose tolerance test, fasting at or above 5.1, one hour at or above 10.0, or two hours at or above 8.5 mmol/L — classify roughly two to three times more women as having gestational diabetes than older criteria. Under IADPSG criteria prevalence is roughly 15 to 20 per cent in many populations; under the older Carpenter-Coustan or NICE criteria, roughly 5 to 9 per cent†. The ScreenR2GDM randomised trial (2021, *NEJM*) compared one-step IADPSG with two-step screening in over 23,000 women: the one-step approach doubled the diagnosis rate, 16.5 per cent against 8.5 per cent, with no significant difference in perinatal or maternal outcomes. This is the central negative finding in the field and it is unresolved.

Prevalence is highest in South Asia, the Middle East and North Africa, roughly 20 to 25 per cent under IADPSG criteria in several Indian and Gulf studies, and lowest in sub-Saharan Africa and parts of Europe. Risk rises steeply with maternal age; prevalence in women over 40 is roughly two to four times that in women under 25†.

The hard outcome is maternal progression to type 2 diabetes. A meta-analysis (Vounzoulaki et al., *BMJ*, 2020) found that women with gestational diabetes had nearly a ten-fold higher risk of subsequently developing type 2 diabetes than women with normoglycaemic pregnancies, relative risk 9.51. Cumulative incidence of type 2 diabetes reaches roughly 20 to 50 per cent within 10 years of the index pregnancy in cohort studies, varying by ancestry and body size.

Perinatal outcomes, from the Hyperglycemia and Adverse Pregnancy Outcome study of 25,505 women with blinded oral glucose tolerance tests and no treatment: the risk of large-for-gestational-age birthweight, cord C-peptide elevation, primary caesarean delivery and neonatal hypoglycaemia rose continuously with maternal glucose, with no threshold. This finding is why the diagnostic cut-offs are conventional rather than biological, and why the criteria dispute exists.

Offspring show higher childhood obesity and glucose intolerance in observational follow-up; whether this is causal or confounded by maternal body size is contested and the Mendelian randomisation evidence is mixed. Recurrence in a subsequent pregnancy runs roughly 40 to 50 per cent†.

**Where it starts.** Pregnancy is physiologically insulin-resistant from the second trimester, driven by placental hormones — human placental lactogen, placental growth hormone, progesterone, cortisol. Insulin sensitivity falls by roughly 50 to 60 per cent by the third trimester in normal pregnancy†. Gestational diabetes occurs when beta-cell compensation fails against that background, so it is mechanistically a stress test of beta-cell reserve, which is why it predicts later type 2 diabetes so strongly.

Established risk factors with effect sizes: pre-pregnancy overweight and obesity, the strongest modifiable factor, with relative risk roughly 2 for overweight, 3 to 4 for obesity and 5 to 9 for severe obesity in meta-analysis†; maternal age over 35, roughly two- to three-fold†; prior gestational diabetes, with recurrence 40 to 50 per cent; family history of type 2 diabetes in a first-degree relative, roughly two-fold; ancestry, with South Asian, East and Southeast Asian, Middle Eastern, Hispanic, Pacific Islander and Indigenous women at substantially higher risk at any given body size than European women, and South Asian women at roughly three- to four-fold higher risk than white European women in United Kingdom data at lower body size; polycystic ovary syndrome, roughly two- to three-fold; excessive gestational weight gain, dose-related; multiple pregnancy, prior macrosomic infant, prior stillbirth; and short stature and low birthweight of the mother herself, with consistent associations.

The risk loci overlap substantially with type 2 diabetes — *TCF7L2*, *MTNR1B*, *GCK*, *KCNJ11*, *CDKAL1* — with *MTNR1B* having a relatively larger effect in gestational than in type 2 diabetes. Heritability is not well estimated. First-degree family history roughly doubles risk.

*GCK*-linked monogenic diabetes is an important misdiagnosis: women with glucokinase mutations have mildly raised fasting glucose that does not respond to treatment and does not need it, and treating them to normal maternal glucose can cause fetal growth restriction. It accounts for roughly 1 to 2 per cent of gestational diabetes diagnoses†, and recognising it changes management entirely.

*Not known*: where the diagnostic threshold should be, given that the Hyperglycemia and Adverse Pregnancy Outcome study found a continuous relationship with no inflection. Whether treating the women identified by the lower IADPSG thresholds improves outcomes — ScreenR2GDM says no. Whether the offspring associations are causal. Whether gestational diabetes causes later maternal type 2 diabetes or simply reveals pre-existing susceptibility; the evidence favours revelation, which matters for how the condition is framed.

**Cure status.** SELF-LIMITING. The hyperglycaemia resolves after delivery in the great majority: gestational diabetes is defined as hyperglycaemia first detected in pregnancy that does not meet the criteria for overt diabetes, and it remits with delivery of the placenta. The honest statement has a second part, and it is the important one: it marks roughly a ten-fold lifetime risk of type 2 diabetes, relative risk 9.51†, with cumulative incidence of 20 to 50 per cent within 10 years†. So the condition is self-limiting and the risk it reveals is not.

Treatment during pregnancy prevents the adverse pregnancy outcomes, and this is established by two randomised trials. ACHOIS (Crowther et al., *NEJM*, 2005; 1,000 women) found that treatment reduced the composite of serious perinatal outcomes — death, shoulder dystocia, bone fracture, nerve palsy — from 4 per cent to 1 per cent, and reduced macrosomia and pre-eclampsia. Landon and colleagues (*NEJM*, 2009; 958 women with mild gestational diabetes) found treatment did not change the primary composite outcome and significantly reduced birthweight, large-for-gestational-age births, shoulder dystocia, caesarean delivery and pre-eclampsia.

Postpartum type 2 diabetes is preventable: in the Diabetes Prevention Program, women with a history of gestational diabetes had diabetes incidence reduced by roughly 50 per cent by lifestyle intervention and roughly 50 per cent by metformin† — notably, metformin was as effective as lifestyle in this subgroup, unlike in the trial overall. This is the key actionable finding.

**Prevention.** Pre-pregnancy weight is the dominant modifiable factor, at a relative risk of 3 to 4 for obesity. STRONG for the association; MODERATE for weight reduction before pregnancy as a demonstrated intervention, since trials of pre-conception weight loss are few.

Exercise during pregnancy: meta-analyses of randomised trials show roughly a 25 to 40 per cent reduction in gestational diabetes incidence with structured exercise programmes. MODERATE.

Dietary intervention in pregnancy: smaller and less consistent effects than exercise, with meta-analyses showing roughly 10 to 25 per cent reduction†. MODERATE.

Metformin from early pregnancy in obese women: the EMPOWaR and GRoW trials did not reduce gestational diabetes incidence or birthweight. CONTESTED to negative.

Myo-inositol supplementation: several small Italian trials reported substantial reductions, and larger independent replication is lacking. WEAK.

Probiotics: the SPRING trial was negative. WEAK to negative.

Vitamin D: no consistent effect. CONTESTED.

Prevention of the adverse pregnancy outcomes by treating the hyperglycaemia: ACHOIS, serious perinatal composite from 4 per cent to 1 per cent. STRONG.

Prevention of later type 2 diabetes is the highest-value prevention in this entry. Postpartum glucose testing at six to 13 weeks and then at least every one to three years for life. Uptake is poor almost everywhere, with reported postpartum testing rates of roughly 30 to 60 per cent even in well-resourced systems†. The test costs a few dollars and identifies a group with 20 to 50 per cent ten-year risk. Lifestyle intervention or metformin postpartum, roughly 50 per cent risk reduction each in the Diabetes Prevention Program gestational diabetes subgroup. STRONG. Breastfeeding: observational data consistently associate longer lactation with lower maternal type 2 diabetes incidence, roughly 25 to 50 per cent lower risk with longer duration in cohort studies including SWIFT, with a dose-response by months of lactation. MODERATE — observational, with confounding by indication possible, and the dose-response is consistent. Avoiding interpregnancy weight gain. MODERATE.

**Treatment.** Diet and physical activity as first-line, with self-monitoring of blood glucose. Roughly 70 to 85 per cent of women achieve target glucose without medication†. The resource requirement is dietitian and midwife time plus glucose strips, and strips at US$0.10 to US$0.50 each, four times daily, are a real cost in low-income settings and often the binding constraint.

Insulin is the standard pharmacological treatment and the only one with unambiguous safety data in pregnancy. Human insulin, soluble and isophane, is appropriate and is what is used in most of the world; rapid-acting analogues lispro and aspart have pregnancy safety data and are also used. **Human insulin, short-acting and intermediate-acting, is a selected medicine on the 24th List, section 18.5.1, for type 1 and type 2 diabetes; the named rapid-acting analogues are therapeutic equivalents to the rapid-acting analogue class entry rather than selected medicines**. At US$50 to US$200 a patient-year for human insulin at lowest available acquisition cost, 2024, and a pregnancy is a fraction of a year†.

Metformin crosses the placenta. The MiG trial (Rowan et al., *NEJM*, 2008; 751 women) found metformin non-inferior to insulin for the composite perinatal outcome, with less maternal weight gain and better patient acceptability, though roughly 46 per cent of metformin-treated women required supplemental insulin. Offspring follow-up at seven to nine years in MiG TOFU showed larger measures of subcutaneous fat in metformin-exposed children, which is why some guidelines remain cautious. **Metformin is a selected medicine on the 24th List, section 18.5.2, for type 2 diabetes mellitus**; gestational diabetes is not the listed indication. Off-patent, at US$2 to US$15 a patient-year at generic or lowest available acquisition cost, 2024†.

Glibenclamide (glyburide) crosses the placenta, and meta-analyses show higher rates of macrosomia and neonatal hypoglycaemia than insulin or metformin, so it is now a third-line option where insulin is unavailable. Off-patent, at cents a day. Its listing status needs checking against the 24th List†.

Obstetric management: ultrasound growth surveillance; timing of delivery, where induction at 38 to 40 weeks is common practice in treated gestational diabetes and the evidence for optimal timing is weak; intrapartum glucose management; and neonatal blood glucose monitoring and early feeding, because neonatal hypoglycaemia is the commonest complication and is preventable with early feeding and, where needed, buccal 40 per cent dextrose gel. The Sugar Babies and hPOD trials showed dextrose gel reduces admission to neonatal intensive care for hypoglycaemia, and it costs pennies.

Postpartum: oral glucose tolerance test or HbA1c at six to 13 weeks, lifelong periodic testing, metformin or lifestyle intervention for those with persisting prediabetes, and contraception and interpregnancy planning advice.

**Simple means.** Walking. Structured exercise in pregnancy reduces gestational diabetes incidence by roughly 25 to 40 per cent in randomised trial meta-analyses. It requires nothing.

Breastfeeding. Associated with roughly 25 to 50 per cent lower maternal type 2 diabetes risk in cohort studies, with a dose-response by duration, and it is free. It also reduces neonatal hypoglycaemia through early feeding. WHO's infant and young child feeding fact sheet of 4 August 2026 gives exclusive breastfeeding of infants aged nought to six months at about 47 per cent for 2018 to 2025.

Early feeding of the newborn, and buccal 40 per cent dextrose gel for neonatal hypoglycaemia. Dextrose gel costs pennies and reduced neonatal unit admissions in randomised trials.

Metformin. Off-patent, a selected medicine on the 24th List, at US$2 to US$15 a patient-year at generic or lowest available acquisition cost, non-inferior to insulin for perinatal outcomes in the MiG trial, and roughly 50 per cent effective in preventing later type 2 diabetes in the Diabetes Prevention Program gestational diabetes subgroup.

Human insulin rather than analogue where cost binds.

A postpartum glucose test. A few dollars, and it identifies a woman with 20 to 50 per cent ten-year risk of type 2 diabetes. Postpartum testing rates of 30 to 60 per cent mean this cheap test is the largest missed opportunity in the entry.

Diet change. DiRECT and DIADEM-I show what weight loss does for established type 2 diabetes; for a woman after gestational diabetes, the Diabetes Prevention Program shows roughly 50 per cent risk reduction from lifestyle intervention. The trials delivered this through nurses and dietitians in ordinary primary care.

Recognising *GCK*-linked monogenic diabetes — mildly raised fasting glucose with a family history, in a lean woman, that does not respond to treatment. Recognising it prevents harmful over-treatment.

**Gaps.** Prevalence depends on criteria and varies two- to three-fold between them. The IADPSG/WHO 2013 criteria and the older Carpenter-Coustan and NICE criteria classify different populations, and ScreenR2GDM found that doubling the diagnosis rate produced no outcome difference. This is an unresolved dispute at the centre of the field, and any prevalence figure is criteria-dependent. The Hyperglycemia and Adverse Pregnancy Outcome study found a continuous glucose-outcome relationship with no threshold, so the diagnostic cut-offs are conventions chosen at defined odds ratios rather than biological boundaries,

and that should be stated whenever a prevalence figure is given. The IDF 11th edition press materials do not restate a gestational diabetes figure, so the one-in-six and roughly 20-to-21-million figures come from earlier editions and were not re-verified against the 2025 Atlas. Whether the offspring associations are causal or confounded by maternal body size and shared environment is contested, and Mendelian randomisation results are mixed. MiG TOFU showed more subcutaneous fat at seven to nine years in metformin- exposed children, and guidelines differ on how much weight to give this. Optimal timing of delivery is not established by adequate trial. Postpartum testing uptake is poor everywhere and the reasons are system-level rather than clinical. Almost no data exist on gestational diabetes outcomes from sub-Saharan Africa, where both the screening and the treatment infrastructure are thinnest.

---

## Obesity

**What it is.** Body fat accumulated to a degree that raises the risk of disease. It is measured in populations by body mass index — weight divided by height squared — which is a crude proxy for fat mass and says nothing about where the fat sits. It raises the risk of type 2 diabetes, cardiovascular disease, several cancers, osteoarthritis, sleep apnoea and liver disease.

This entry reports epidemiology, physiology, trial outcomes and treatment evidence. Trial interventions are described as what the trials measured, not as instructions.

**Measured.** From the WHO obesity and overweight fact sheet, printed 7 October 2026, with data mainly for 2024:

- Adults aged 18 and over who were overweight: **2.6 billion, or 45 per cent of adults** — 44 per cent of men and 45 per cent of women — against 25 per cent in 1990. Regional prevalence runs from 32 per cent in the South-East Asia and African Regions to 68 per cent in the Americas.
- Adults with obesity: **940 million, about 16 per cent of adults**. Adult obesity more than doubled since 1990, and adolescent obesity quadrupled.
- Living with obesity in 2024, all ages: **one in seven, 1.1 billion people**.
- Children under five who were overweight: **35 million**, almost half of them in Asia, with the African figure up nearly 12 per cent since 2000.
- Children and adolescents aged five to 19 who were overweight: **400 million, 20 per cent** — 19 per cent of girls and 21 per cent of boys — against 8 per cent in 1990.
- Children and adolescents aged five to 19 with obesity: from **2 per cent, 31 million, in 1990 to 8 per cent, 170 million, in 2024**.
- **Deaths in 2023: 3.7 million attributed to higher-than-optimal body mass index.**
- Projected economic cost: **three trillion US dollars a year by 2030 and more than 18 trillion by 2060**.
- Return on investment: 14 times per unit invested in healthy-diet best buys; almost nine in ten countries have adopted obesity-reduction policy goals; and 34 frontrunner countries under the 2022 Acceleration Plan represent 1.3 billion people.

The “one in seven” all-ages figure and the 16 per cent adult figure use different denominators, and the deaths figure uses 2023 while the rest use 2024.

An earlier WHO malnutrition fact sheet, printed 1 March 2024 with 2022 data, gives 2.5 billion adults overweight including 890 million with obesity, 390 million underweight adults, 390 million overweight in ages five to 19 including 160 million with obesity, and 37 million under-fives overweight or with obesity. **The 2022 and 2024 figures are from the same organisation and are not interchangeable**: two WHO fact sheets live simultaneously with different counts, and a reference work must not mix them.

From the UNICEF/WHO/World Bank Joint Child Malnutrition Estimates, 2025 edition, 2024 reference year, children under five: overweight 5.5 per cent (95% CI 4.9–6.1), 35.5 million, against 5.3 per cent and 36.3 million in 2012. Under-five overweight prevalence is essentially unchanged since 2000, and the number affected is up about 2.4 million since then, with Asia holding 16.3 million affected children and Africa 9.7 million. Overweight is rising in several sub-regions including parts of Africa and Asia, and current progress is insufficient to meet the 2030 Sustainable Development Goal targets.

At any given body mass index, metabolic risk is higher in South Asian, East Asian and some other populations, and WHO recommends lower action points for Asian populations.

The limitations of body mass index are measured, not theoretical. It misclassifies muscular individuals and misses individuals of ordinary weight with high visceral fat and metabolic disease. In 2025 a *Lancet Diabetes & Endocrinology* Commission proposed distinguishing clinical obesity, with established organ dysfunction, from preclinical obesity, and recommended confirming excess adiposity by a second measure — waist circumference, waist-to-height ratio, or direct fat measurement — rather than body mass index alone.

The International Agency for Research on Cancer identifies 13 cancers with sufficient evidence of a causal link to body fatness: oesophageal adenocarcinoma, gastric cardia, colon and rectum, liver, gallbladder, pancreas, postmenopausal breast, corpus uteri, ovary, kidney, meningioma, thyroid and multiple myeloma.

**Where it starts.** Fat mass increases when energy intake exceeds expenditure over time. That is not in dispute. What is in dispute is what controls intake and expenditure, and why body weight is defended so strongly against change.

Weight is physiologically defended, and this is measured. After weight loss, resting energy expenditure falls below what would be predicted for the new body size: in the *Biggest Loser* cohort, resting metabolic rate was roughly 500 kcal a day lower than predicted six years after the intervention, and the suppression persisted despite substantial weight regain (Fothergill et al., 2016)†. Appetite hormones change in the direction favouring regain: after diet-induced weight loss, leptin falls, ghrelin rises, and peptide YY and cholecystokinin fall, and these changes persist for at least 12 months (Sumithran et al., *NEJM*, 2011). These are the measured reasons that weight loss by diet alone is usually not maintained, and they are physiological rather than behavioural findings.

Body mass index is among the most heritable common human traits. Twin studies give heritability of roughly 0.4 to 0.7, and in some twin studies up to 0.8 to 0.9 in childhood†. Adoption studies show adult body mass index tracks biological rather than adoptive parents. Genome-wide association studies have found over 1,000 loci, and the strongest common variant, *FTO*, carries an effect of roughly 1 to 1.5 kg per risk allele — small†. Common variants together explain only roughly 6 to 10 per cent of variance, which is the standing missing-heritability problem in this trait. Polygenic risk scores are meaningful at the extremes: individuals in the top centile of a polygenic score weigh roughly 13 kg more on average than those in the bottom centile (Khera et al., 2019)†.

Monogenic obesity: *MC4R* variants are the commonest, present in roughly 2 to 5 per cent of severe early-onset obesity, with leptin deficiency, leptin receptor, *POMC* and *PCSK1* deficiency rarer†. These matter because setmelanotide, an MC4R agonist approved between 2020 and 2022, produces substantial weight loss specifically in *POMC*, *PCSK1* and leptin receptor deficiency and in Bardet-Biedl syndrome, and recombinant leptin (metreleptin) is curative in congenital leptin deficiency — the clearest example in this field of a mechanism-matched treatment. Syndromic obesity: Prader-Willi, Bardet-Biedl, Alström and Cohen syndromes.

Food environment: the measured associations are with energy density, portion size, ultra-processed food availability and marketing. The best-controlled experiment is Hall and colleagues (*Cell Metabolism*, 2019), a randomised crossover metabolic-ward study in which participants given an ultra-processed diet consumed roughly 500 kcal a day more and gained roughly 0.9 kg over two weeks, against an unprocessed diet matched for presented macronutrients, sugar, sodium and fibre, with both diets eaten without restriction. This is the strongest causal evidence available that food processing itself, independent of nutrient composition, affects intake.

Other established contributors: short sleep duration, shift work, physical inactivity — though its causal contribution relative to intake is contested — certain drugs, particularly the antipsychotics olanzapine and clozapine with gains of 5 to 10 kg common, and corticosteroids, insulin, sulfonylureas, some antidepressants, valproate and beta-blockers; smoking cessation, with roughly a 4 to 5 kg average gain; hypothyroidism, a small effect; Cushing syndrome; and hypothalamic damage.

The socioeconomic gradient inverts with national income: in high-income countries obesity is inversely associated with income and education, while in low-income countries the associ-

ation is positive and inverts as the country's income rises. This is one of the most consistent findings in nutrition epidemiology and is unexplained in mechanistic terms.

Developmental factors: maternal obesity and gestational diabetes associate with offspring obesity, and low birthweight followed by rapid catch-up growth associates with later central adiposity.

Gut microbiome differences are consistently observed, and faecal transplant studies in humans have produced modest and inconsistent metabolic effects, so the causal contribution in humans remains unestablished despite strong mouse data.

*Not known*: why body weight is defended at a higher level in some people than others. Why the socioeconomic gradient inverts with national income. What specifically about ultra-processed food raises intake — energy density, texture, eating rate and hyper-palatability are all candidates and the Hall experiment could not separate them. Why heritability is 0.4 to 0.7 while common variants explain under 10 per cent. Whether physical activity's contribution is to prevention of gain rather than to loss.

**Cure status.** CONTROLLABLE. The term used in the literature is weight loss and maintenance, and the physiology of defended weight is why cure is not the right word.

Lifestyle intervention produces measured weight loss that is largely regained. Intensive behavioural programmes produce roughly 5 to 10 per cent weight loss at six to 12 months and roughly 3 to 5 per cent maintained at two to four years in trial settings†. In Look AHEAD, with 5,145 adults with type 2 diabetes and overweight or obesity, the intensive lifestyle group lost roughly 8.6 per cent at year one and maintained roughly 4.7 per cent at year four, against roughly 1 per cent in the control group, and the trial did not reduce its primary cardiovascular endpoint. In the Diabetes Prevention Program, roughly 7 per cent weight loss at six months accompanied a 58 per cent reduction in diabetes incidence† — the weight loss was modest and the metabolic effect was large.

GLP-1-based pharmacotherapy produces weight loss of a different order, and it is treatment-dependent. STEP 1, with semaglutide 2.4 mg weekly in 1,961 adults without diabetes over 68 weeks, gave a mean weight change of −14.9 per cent against −2.4 per cent with placebo†. SURMOUNT-1, with tirzepatide in 2,539 adults without diabetes over 72 weeks, gave −15.0 per cent at 5 mg, −19.5 at 10 mg and −20.9 at 15 mg against −3.1 per cent on placebo, with at least 5 per cent loss in 85, 89 and 91 per cent against 35 per cent, and at least 20 per cent loss in 50 per cent at 10 mg and 57 per cent at 15 mg against 3 per cent†. SELECT, with semaglutide 2.4 mg in 17,604 adults with overweight or obesity and established cardiovascular disease and no diabetes, gave a 20 per cent reduction in major adverse cardiovascular events, hazard ratio 0.80, over a mean 39.8 months† — the first trial showing that pharmacological treatment of obesity reduces cardiovascular events.

Withdrawal reverses it. The STEP 1 extension found roughly two-thirds of lost weight regained within a year of stopping, and STEP 4 showed weight regain on withdrawal and continued loss on continuation. So this is treatment of a chronic condition, not a cure. Real-world discontinuation is high, roughly 30 to 50 per cent within 12 months in United States claims analyses, mainly for cost, side effects and supply.

Bariatric and metabolic surgery produces the largest and most durable effect. Mean weight loss is roughly 25 to 30 per cent of baseline weight at one to two years, with roughly 20 to 25 per cent maintained at 10 years for gastric bypass and roughly 15 to 20 per cent for sleeve gastrectomy†. The Swedish Obese Subjects matched prospective cohort, followed over 20 years and more, found surgery reduced overall mortality by roughly 24 to 30 per cent, reduced incident type 2 diabetes by roughly 78 to 87 per cent, reduced cancer incidence in women, and reduced cardiovascular events. Perioperative mortality is roughly 0.1 to 0.3 per cent in contemporary series†.

The honest status: obesity behaves as a chronic, relapsing, physiologically defended condition. The interventions with the largest and most durable effects are surgical; the pharmacological effects are large while treatment continues and reverse when it stops; and lifestyle intervention produces modest durable weight change with disproportionately large metabolic benefit.

**Prevention.** Population-level fiscal and regulatory measures are where the measured before-and-after data are. Sugar-sweetened beverage taxes produced purchase reductions of

roughly 10 to 20 per cent after implementation in Mexico, with roughly a 7.6 per cent decline over two years, and in Chile, in Berkeley, Philadelphia and other United States cities, and in the United Kingdom. MODERATE for consumption change; WEAK for measured effect on obesity prevalence, because the follow-up is short and the effect size on body weight is small. The United Kingdom Soft Drinks Industry Levy of 2018 is the best-documented reformulation effect: manufacturers reduced sugar content rather than pay the levy, and the sugar content of soft drinks fell by roughly 30 per cent across the market, with subsequent analyses associating it with reduced obesity prevalence in older primary school girls. MODERATE. Chile's food labelling, marketing and school-sales law of 2016 produced measured reductions in purchases of high-in labelled products of roughly 24 to 27 per cent for sugary drinks†. MODERATE. Trans fat elimination, through WHO's REPLACE programme: by 2023, roughly 53 countries covering roughly 3.7 billion people had best-practice trans fat policies. A measured regulatory success, though its outcome is cardiovascular rather than obesity. Front-of-pack labelling, marketing restrictions to children and school food standards have demonstrated effects on purchasing and intake, with effects on obesity prevalence not demonstrated. WEAK.

Prevention in childhood: Cochrane reviews of school-based and community interventions find small effects on body mass index z-score, roughly 0.05 to 0.1 standard deviations, consistent in direction and small in magnitude†. MODERATE for the small effect, and no intervention has reversed a population trend.

Breastfeeding: associated with roughly 10 to 25 per cent lower odds of childhood obesity in meta-analyses, though residual confounding is likely and the PROBIT cluster-randomised trial of breastfeeding promotion found no effect on childhood body mass index. CONTESTED.

Sleep duration: short sleep in childhood is consistently associated with higher body mass index, and sleep extension trials in children show small reductions in intake. WEAK.

Pharmacological prevention of weight regain: GLP-1 agonists maintain loss while taken. STRONG for the effect during treatment.

The honest statement about prevention: no country has reversed its adult obesity trend. Adult obesity more than doubled globally between 1990 and 2024. The measures with demonstrated effects act on purchasing and product composition, and their demonstrated effect on body weight at population level is small. This is the central negative finding in the field.

**Treatment.** Structured behavioural and dietary intervention is the foundation of all guidelines and the comparator in all drug and surgery trials. Trial-measured effects: 5 to 10 per cent loss at six to 12 months, 3 to 5 per cent maintained at two to four years, with metabolic benefit disproportionate to the weight change, as the Diabetes Prevention Program's 58 per cent diabetes risk reduction shows. The resource requirement is trained personnel and contact time, which is the actual cost. Not a medicine.

GLP-1 receptor agonists and dual agonists, with effect sizes as above. GLP-1 receptor agonists were added to the Model List in the 24th List (2025) — semaglutide, dulaglutide, liraglutide and tirzepatide — for adults with type 2 diabetes who also have established cardiovascular disease, chronic kidney disease or obesity, and not for obesity alone. **That listing was not independently verified against the 24th List for this chapter, and carries a dagger pending a recheck.** The distinction between the listed indication and obesity alone matters and is frequently misreported. Liraglutide is off-patent with generics marketed; semaglutide, dulaglutide and tirzepatide are not, and semaglutide's primary patents expire in Canada, India, China and Brazil from 2026.

Prices, 2024 to 2025: semaglutide 2.4 mg on United States list roughly US$1,000 to US$1,350 a month, about 12,000 to 16,000 a patient-year, with a direct-to-consumer cash price of US$499 a month from 2025, about 6,000 a patient-year; tirzepatide on United States list roughly US$1,000 to US$1,080 a month, with direct cash 349 to 499; Europe roughly €150 to €350 a month, about 1,800 to 4,200 a patient-year; and generic liraglutide roughly US$30 to US$100 a month in some markets. The published minimum production cost estimate for semaglutide (Barber, Hill et al., *JAMA Network Open*, 2024) is roughly US$0.89 to US$4.73 a month, roughly US$11 to US$57 a patient-year at a scale of millions of patients — against the United States list price, a factor of roughly 250 to 1,500. Side effects: nausea, vomiting, diarrhoea and constipation in a large minority; gallstones; pancreatitis, rare; and

loss of lean mass alongside fat mass, which is measured and whose long-term significance is unresolved.

Bariatric and metabolic surgery — Roux-en-Y gastric bypass, sleeve gastrectomy, one-anastomosis gastric bypass — with effects as above including the Swedish Obese Subjects mortality reduction of roughly 24 to 30 per cent. At US$10,000 to US$30,000 one-off in high-income systems and far less in some middle-income settings (2024)†. Not a medicine. Long-term requirements are micronutrient supplementation for life — iron, B12, calcium, vitamin D, thiamine — and surveillance for internal hernia, dumping and hypoglycaemia.

Older pharmacotherapy. Orlistat, a lipase inhibitor, gives roughly 2.5 to 3.5 kg more weight loss than placebo at one year, and the XENDOS trial showed a 37 per cent reduction in incident type 2 diabetes over four years†. Off-patent and available over the counter in many countries, at US$100 to US$500 a patient-year at generic or lowest available acquisition cost, 2024†; gastrointestinal side effects limit use. EML status needs checking against the 24th List†. Phentermine, phentermine-topiramate and naltrexone-bupropion give roughly 5 to 10 per cent weight loss with limited or absent cardiovascular outcome data. Metformin gives roughly 2 to 3 kg, off-patent at US$2 to US$15 a patient-year at generic or lowest available acquisition cost†. Withdrawn for safety: sibutramine in 2010 for cardiovascular events, rimonabant in 2008 for psychiatric effects, and fenfluramine and dexfenfluramine in 1997 for valvular disease. That history is part of the evidence base for this class.

Mechanism-matched treatment for monogenic obesity: metreleptin for congenital leptin deficiency, effectively curative in that rare condition; and setmelanotide for *POMC*, *PCSK1* and leptin receptor deficiency and Bardet-Biedl syndrome, with substantial weight loss in the indicated genotypes, priced in the hundreds of thousands of dollars a patient-year.

Treatment of the complications regardless of weight change: metformin and the rest of the type 2 diabetes armamentarium; statins and antihypertensives; continuous positive airway pressure for obstructive sleep apnoea; joint replacement for osteoarthritis; and treatment of metabolic dysfunction-associated steatotic liver disease, where resmetirom, approved in the United States in 2024, is the first licensed drug for steatohepatitis.

Drug review — substituting a weight-neutral alternative for an obesogenic drug such as an antipsychotic, antidepressant or antiepileptic where clinically possible.

**Simple means.** What the trials measured, with no protocol.

Diet-based weight loss, delivered through primary care. DiRECT achieved diabetes remission in 46 per cent at 12 months and 36 per cent at 24 months using a formula diet followed by structured food reintroduction, delivered by practice nurses and dietitians in ordinary general practice, and DIADEM-I achieved 61 per cent remission at 12 months in a younger Qatari cohort†. The intervention required no drug, no device and no surgery; the resource was personnel time.

Physical activity. Trial-measured: exercise was a component of the Diabetes Prevention Program, Finnish and Da Qing interventions that reduced diabetes incidence by roughly 58 per cent, and in Da Qing the exercise-only arm was effective, with reduced mortality and roughly 1.44 years greater life expectancy at 30 years. The measured effect on weight alone is small, the measured effect on cardiometabolic outcomes is substantial, and the effect on prevention of weight gain is better established than the effect on weight loss.

Reduced consumption of sugar-sweetened beverages. Measured: each daily serving associated with 13 to 26 per cent higher type 2 diabetes risk in meta-analyses; taxes reduced purchases by 10 to 20 per cent; and the United Kingdom levy reduced the market's soft drink sugar content by roughly 30 per cent†.

Unprocessed rather than ultra-processed food. The Hall metabolic-ward crossover trial measured roughly 500 kcal a day lower intake and 0.9 kg weight loss over two weeks on an unprocessed diet eaten without restriction, compared with a matched ultra-processed diet. Cooking from whole ingredients requires no industrial chain; it requires time, fuel and skill.

Sleep. Short sleep is consistently associated with higher body mass index, and sleep extension trials measured reduced energy intake.

Breastfeeding. Associated with roughly 10 to 25 per cent lower childhood obesity odds in meta-analyses; the PROBIT randomised trial found no effect on body mass index. Reported as contested.

Metformin and orlistat. Both off-patent, both measured to reduce incident diabetes, by 31 and 37 per cent respectively†, and both costing hundreds of dollars a year or less.

Waist circumference measured with a tape. A tape measure costs cents and adds information that body mass index does not, particularly in populations where body mass index misclassifies risk. The 2025 *Lancet* Commission recommends confirming adiposity with a second measure rather than body mass index alone.

**Gaps.** WHO's own figures for 2022 and 2024 differ substantially — 2.5 billion against 2.6 billion overweight, and 890 million against 940 million with obesity — and come from different fact sheets using different reference years and, in part, different modelling. They are not interchangeable and the difference is not reconciled in either publication. Body mass index is a poor individual measure of adiposity: it misclassifies in both directions, its risk relationship differs by ancestry, and the 2025 Commission recommended abandoning it alone for individual diagnosis — and all the prevalence figures in this entry are based on it. Heritability is 0.4 to 0.7 while common variants explain under 10 per cent of variance†, and the missing heritability is unexplained. The socioeconomic gradient inverts with national income and the mechanism is unknown. Look AHEAD did not reduce cardiovascular events despite achieving and maintaining weight loss, which remains unexplained. PROBIT found no effect of breastfeeding promotion on childhood body mass index while observational meta-analyses find a protective association; sources disagree. The causal element in ultra-processed food is not identified — energy density, eating rate, texture and palatability were not separable in the Hall design, and the trial had 20 participants over four weeks. GLP-1 long-term outcome, safety and effectiveness data beyond five years do not exist; the drugs are too new, real-world discontinuation is 30 to 50 per cent within a year, and weight regain after stopping is substantial. Loss of lean mass with GLP-1 treatment is measured and its long-term significance is unknown. No country has reversed its adult obesity trend, and the population measures with demonstrated effects act on purchasing and product reformulation rather than on measured obesity prevalence. The semaglutide production-cost estimate is modelled and contested by manufacturers; no audited figure exists. Under-five overweight prevalence has been essentially flat since 2000 while adult obesity doubled, and the discordance is not explained. Attributable-death figures depend on counterfactual assumptions and differ between WHO and GBD methods.

---

## Protein-energy malnutrition

**What it is.** Not enough food energy and protein for the body's needs. In children it shows as wasting, too thin for height; stunting, too short for age; or the oedematous form, kwashiorkor. It kills both directly and by making every infection more dangerous.

**Measured.** From the UNICEF/WHO/World Bank Joint Child Malnutrition Estimates, 2025 edition, 2024 reference year, children under five:

| Condition | 2024 prevalence (95% CI) | 2024 number | 2012 prevalence | 2012 number |
|---|---|---|---|---|
| Stunting | 23.2 per cent (22.6–23.8) | 150.2 million | 26.4 per cent | 180.4 million |
| Wasting, moderate and severe | 6.6 per cent (5.3–8.1) | 42.8 million | 7.4 per cent | 50.9 million |
| Severe wasting | 1.9 per cent (1.4–2.5) | 12.2 million | 2.2 per cent | 15.0 million |
| Overweight | 5.5 per cent (4.9–6.1) | 35.5 million | 5.3 per cent | 36.3 million |

Stunting declined for more than two decades, and the 2025 report states that recent data show a halt and a possible rise, putting past progress at risk. Wasting is trending down, with about eight million fewer affected children than in 2012†.

Regionally in 2024, stunting affects 76.8 million children in Asia, down from 108.8 million in 2012, and 64.8 million in Africa, up from 61.7 million — Africa is the only region where the number significantly increased, and Africa's stunting prevalence is 30.3 per cent†. Wasting affects roughly 70 per cent of affected children in Asia, 30.0 million, and roughly 27 per

cent in Africa, 11.7 million, with Southern Asia having the highest wasting prevalence of any sub-region. Current progress is insufficient to meet the 2030 Sustainable Development Goal targets†.

The source states a caveat that matters: wasting figures are prevalence-based snapshots, so they underestimate the number of children affected over a full year, because wasting episodes are short and recurrent. Annual incidence is roughly two to three times point prevalence.

The WHO malnutrition fact sheet, printed 1 March 2024 with 2022 data, gives 45 million children under five wasted, 149 million stunted and 390 million underweight adults, and states that nearly half of deaths among children under five are linked to undernutrition without giving an absolute number. The WHO infant and young child feeding fact sheet of 4 August 2026 gives, for 2024, about 150 million children under five stunted, 43 million wasted and 36 million overweight, and states that maternal and child malnutrition was associated with 2.4 million child deaths annually in 2021, more than 50 per cent of all child deaths. **Two WHO fact sheets therefore live simultaneously with different child undernutrition counts for different reference years, and the 2022 figures are superseded**.

The standing attributable-mortality estimate, from the *Lancet* Maternal and Child Nutrition Series of 2013, updated 2021, is that undernutrition underlies roughly 45 per cent of all deaths in children under five, roughly three million child deaths a year, mostly through increased severity of pneumonia, diarrhoea, measles and malaria. Case fatality in untreated severe acute malnutrition is roughly 10 to 30 per cent in community settings and was historically 20 to 30 per cent in inpatient facilities before modern protocols†.

Adult undernutrition is measured by body mass index under 18.5 and is concentrated in South Asia and sub-Saharan Africa, at 390 million underweight adults (WHO, 2022 data).

The Integrated Food Security Phase Classification framework measures acute food insecurity, and in 2024 to 2025 it recorded famine conditions or risk in Sudan, Gaza, Haiti, South Sudan and Mali. These figures move monthly and are not stable enough to quote as prevalence.

**Where it starts.** The immediate cause is inadequate dietary intake and disease, acting together. The UNICEF conceptual framework of immediate, underlying and basic causes remains the standard analytic structure and is empirically supported.

Underlying causes with measured contributions. Household food insecurity — availability, access, affordability: the cost of a healthy diet exceeded the income of roughly 2.8 billion people in 2022 (FAO/WHO/UNICEF/WFP/IFAD, *State of Food Security and Nutrition in the World*). Inadequate care and feeding practices: exclusive breastfeeding for the first six months is practised for about 47 per cent of infants globally for 2018 to 2025 (WHO infant and young child feeding fact sheet, 4 August 2026), and inadequate complementary feeding from six months is near-universal in high-burden settings — roughly two-thirds of children aged six to 23 months do not receive a minimum acceptable diet, and only 30.8 per cent of children aged six to 23 months met minimum dietary diversity for 2018 to 2024, with only half having minimum meal frequency. Infection: diarrhoea, pneumonia, measles, malaria, HIV, tuberculosis, and environmental enteric dysfunction — chronic subclinical small-bowel inflammation from repeated faecal-oral exposure, which impairs absorption and is now considered a major contributor to stunting that food alone does not fix.

Water, sanitation and hygiene: the association with stunting is strong, yet the three large randomised trials — WASH Benefits Bangladesh, WASH Benefits Kenya and SHINE in Zimbabwe — found that water, sanitation and handwashing interventions did not reduce stunting, while nutrition interventions through complementary feeding did, modestly. This is a major and genuinely surprising negative result.

Maternal undernutrition and short maternal stature: maternal height and pre-pregnancy body size predict offspring birthweight and stunting, and low birthweight accounts for roughly 20 per cent of stunting in some analyses†. Adolescent pregnancy and short birth intervals. Women’s education and status, consistently among the strongest predictors in multi-country analyses.

Basic causes: poverty, conflict, displacement, governance, climate shocks and food price shocks. Conflict is the dominant driver of acute malnutrition emergencies, and the large majority of people in the most severe Integrated Food Security Phase Classification conditions are in conflict-affected areas.

Kwashiorkor against marasmus: the oedematous form has resisted explanation for seventy years. It is not simply protein deficiency — the classic protein hypothesis has not held up. Current candidate mechanisms involve aflatoxin exposure, oxidative stress and glutathione depletion, sulphur amino acid deficiency, gut microbiome composition and leaky gut, and none is established. Why two children in the same household with similar diets develop marasmus and kwashiorkor respectively is unknown, and it is one of the oldest unanswered questions in nutrition.

Stunting's window is the first 1,000 days, from conception to age two, when most stunting accrues; after about 24 months catch-up in linear growth is limited. This timing finding underpins all current programming.

*Not known*: the cause of kwashiorkor. Why the water, sanitation and hygiene trials failed to reduce stunting when the observational association is so strong. How much stunting is reversible after 24 months — some catch-up occurs in adolescence and its functional significance is contested. What proportion of stunting is attributable to environmental enteric dysfunction as opposed to diet.

**Cure status.** Severe and moderate acute malnutrition, that is wasting: CURABLE, and the cure is food. Stunting established by about 24 months: RELIEF ONLY. Adult undernutrition: CURABLE with food, except where the cause is an untreated disease — tuberculosis, HIV, cancer, malabsorption — in which case the disease must be treated.

Severe acute malnutrition is curable with ready-to-use therapeutic food. Community-based management of acute malnutrition using that food achieves recovery rates of roughly 80 to 90 per cent in programme data, with case fatality under 5 per cent, against historical inpatient case fatality of 20 to 30 per cent†. This shift — from inpatient milk-based treatment to outpatient therapeutic food — is among the largest advances in child survival of the past thirty years. The food is a lipid-based paste of peanut, milk powder, oil, sugar and micronutrients requiring no water, no refrigeration and no cooking, which is why it works outside facilities.

Complicated severe acute malnutrition, with medical complications, oedema, or a failed appetite test, requires inpatient stabilisation with F-75 then F-100 therapeutic milk and careful management of electrolytes and infection; case fatality remains roughly 10 to 20 per cent even in good facilities, because these children are critically ill.

Simplified and reduced-dose protocols, in ComPAS and OptiMA, show non-inferior recovery with roughly 25 to 35 per cent less therapeutic food in randomised and programme evidence†, which matters because the cost of that food is the binding constraint on coverage.

Moderate acute malnutrition is treated with supplementary feeding, with recovery rates roughly 70 to 85 per cent, and relapse is common†.

Stunting is largely not reversible after about 24 months. This is the honest limit: linear growth faltering that has already occurred by age two is mostly permanent, and the associated cognitive and economic deficits persist into adulthood. Prevention is therefore the only effective approach to stunting.

**Prevention.** Exclusive breastfeeding for the first six months, then continued breastfeeding with adequate complementary food. The single largest preventive intervention. Pooled analyses estimate that non-exclusively breastfed infants under six months have roughly two to five times the risk of death from diarrhoea and pneumonia, with the highest relative risks in the first months. The *Lancet* Breastfeeding Series of 2016 estimated that scaling up breastfeeding could prevent roughly 823,000 child deaths and 20,000 breast cancer deaths annually; WHO's own fact sheet of 4 August 2026 gives nearly 400,000 under-five deaths a year as preventable by exclusive breastfeeding for six months and continued breastfeeding to two years or beyond, and the two figures are not the same quantity and are not reconciled. The current exclusive breastfeeding rate is about 47 per cent globally for 2018 to 2025, against a WHO target of at least 60 per cent by 2030. STRONG.

Complementary feeding interventions: in WASH Benefits Bangladesh and Kenya and in SHINE, the nutrition arms reduced stunting modestly, roughly 0.1 to 0.25 standard deviations in length-for-age, while the water and sanitation arms did not. MODERATE, a small but replicated effect.

Small-quantity lipid-based nutrient supplements for children aged six to 23 months: an individual-participant-data meta-analysis of 14 randomised trials in roughly 37,000 children

found a 12 per cent reduction in stunting, 14 per cent in wasting, 13 per cent in anaemia, 27 per cent in severe stunting and 21 per cent in severe anaemia, plus reduced mortality in some analyses†. STRONG — this is the best-evidenced child nutrition supplement of the past decade.

Maternal nutrition: multiple micronutrient supplements in pregnancy outperform iron-folic acid alone, with meta-analysis showing roughly 8 to 12 per cent reductions in low birthweight and small-for-gestational-age births and reduced stillbirth in some analyses. WHO's 2020 recommendation permits them in the context of rigorous research, and many countries have adopted them. Balanced energy-protein supplementation in undernourished pregnant women reduces small-for-gestational-age births and stillbirth. MODERATE.

Cash transfers: conditional and unconditional transfers reduce stunting in several randomised and quasi-experimental evaluations, with effect sizes depending on transfer size and duration. MODERATE.

Food fortification of staples. STRONG for the specific micronutrient outcomes.

Immunisation, insecticide-treated nets, oral rehydration salts and zinc for diarrhoea, and antibiotics for pneumonia, all of which prevent the infections that drive wasting and stunting. STRONG.

Deworming: effects on growth are small and contested; Cochrane finds little or no effect on weight, haemoglobin or school performance in mass treatment. CONTESTED.

Water, sanitation and hygiene: the three large randomised trials did not reduce stunting. CONTESTED to negative for stunting, while remaining strongly justified for diarrhoea, cholera and other outcomes. This disagreement between observational and trial evidence is one of the most consequential in global health.

Family planning and birth spacing: short birth intervals are associated with higher stunting, and interventions reduce them. MODERATE.

Girls' education, among the strongest and most consistent predictors in multi-country analyses. MODERATE as a measured intervention.

**Treatment.** Ready-to-use therapeutic food for uncomplicated severe acute malnutrition in children aged six to 59 months, delivered through outpatient community programmes. The specification is public and local production exists in India, Ethiopia, Nigeria, Kenya, Madagascar, Niger and elsewhere. A full six-to-eight-week treatment course costs roughly US$35 to US$50 (2024), roughly US$0.30 to US$0.50 a sachet at 150 to 200 sachets a child, and UNICEF procures roughly four to five million cartons a year. Simplified protocols reduce this by 25 to 35 per cent. Recovery is roughly 80 to 90 per cent with case fatality under 5 per cent†. The listing status of ready-to-use therapeutic food on the 24th List and the Model List for Children needs checking†.

F-75 and F-100 therapeutic milks for inpatient stabilisation of complicated severe acute malnutrition, with reduced-osmolarity rehydration solution for malnutrition. Off-patent, at dollars a child a day. Listing status needs checking against the 24th List†.

Routine medicines in severe acute malnutrition. A broad-spectrum antibiotic, amoxicillin, for all children with uncomplicated severe acute malnutrition: randomised trials in Malawi and Niger gave discordant results, with the Malawi trial showing reduced mortality and improved recovery and the Niger trial showing no mortality benefit. WHO recommends routine amoxicillin and the evidence is contested. **Amoxicillin is a selected medicine on the 24th List, in section 6.2.1, Access group antibiotics, core list, with severe acute malnutrition among its named first-choice indications**. Off-patent, at cents a course; UNICEF's indicative price for 250 mg dispersible tablets, pack of ten, was US$0.54 in October 2026, about US$0.054 a tablet, and these are indicative prices refreshed against live tenders rather than a fixed price. Vitamin A; zinc, in the therapeutic food, with additional zinc for diarrhoea; folic acid; antimalarials where endemic; measles vaccination on admission; and deworming after stabilisation. **Not iron during the acute phase** — iron is withheld until the recovery phase, because free iron increases infection risk in severely malnourished children. A treatment point that is easy to get wrong.

Oral rehydration salts and zinc for diarrhoea. Off-patent. Oral rehydration salts cost roughly US$0.05 to US$0.20 a sachet and zinc roughly US$0.03 to US$0.10 a tablet (2024)†;

UNICEF's indicative price for low-osmolarity oral rehydration salts in a carton of 100 was US$4.80 in October 2026, about US$0.048 a sachet. Oral rehydration salts are among the highest-impact low-cost interventions in medicine. The listing status of both needs checking against the 24th List†.

Supplementary food for moderate acute malnutrition: fortified blended flours such as corn-soy blend plus, or lipid-based supplements, at roughly US$15 to US$30 a treatment course at procurement prices, 2024†.

Treatment of the underlying disease — tuberculosis, HIV, malaria, coeliac disease, congenital heart disease. In adults and older children, undernutrition without food scarcity is usually a symptom of disease.

Refeeding syndrome management in severely malnourished older children and adults: thiamine, phosphate, potassium and magnesium replacement, with slow energy increase. Cheap, and lethal if ignored.

**Simple means.** This entry is almost entirely simple means, and that is the point.

Breastfeeding. Exclusive for six months, continued to two years with complementary food. Non-exclusively breastfed infants have roughly two to five times the risk of death from diarrhoea and pneumonia, and scaling up breastfeeding could prevent roughly 823,000 child deaths annually†. It requires no product, and what it requires — maternity protection, time, support, and not being undermined by formula marketing — is social, not industrial.

Oral rehydration salts, or the home-made salt-and-sugar solution. The sachets cost cents and are one of the most effective medicines ever devised. The home solution of salt, sugar and clean water works where sachets are unavailable.

Zinc for diarrhoea, which reduces duration by 25 per cent and stool volume by 30 per cent (WHO diarrhoeal disease fact sheet, 7 March 2024), at cents a course.

Complementary food made from locally available ingredients — fermented and germinated cereals, legumes, groundnuts, eggs, small fish eaten whole, dark green leaves, orange-fleshed sweet potato. The measured interventions in WASH Benefits and SHINE that reduced stunting were complementary feeding interventions using local foods plus a lipid-based supplement.

Soaking, germinating and fermenting cereals and legumes, which reduces phytate and raises iron and zinc bioavailability. Traditional, free, measurable.

A mid-upper arm circumference tape. A paper or plastic strip costing cents that identifies severe acute malnutrition and can be used by a mother on her own child. Family MUAC programmes have been shown to identify cases earlier and at scale with no clinical staff. This is the single best example in the chapter of a simple means replacing an industrial chain.

Measles vaccination and insecticide-treated nets, which prevent the infections that precipitate wasting.

Handwashing with soap, which reduces diarrhoea substantially, even though the water, sanitation and hygiene trials did not show a stunting effect.

Keeping the child feeding during illness, and extra feeding during recovery. Appetite loss during infection and failure to feed up afterwards is a major driver of wasting.

Not giving iron during the acute phase of severe malnutrition.

Ready-to-use therapeutic food made locally. The specification is public, the ingredients are peanut, milk powder, oil, sugar and a micronutrient premix, and local production in Niger, Ethiopia, India and elsewhere has brought cost down and supply closer.

**Gaps.** Wasting prevalence is a point-in-time snapshot and underestimates annual burden by a factor of roughly two to three, as the Joint Child Malnutrition Estimates report itself states, and incidence data are sparse. WHO's 2022 fact sheet figures and the 2025 Joint Child Malnutrition Estimates are different reference years and are not interchangeable; another dossier in this project prints the 2022 figures alone and unflagged, so the superseded numbers are in circulation. Both stand, unresolved. The cause of kwashiorkor is unknown after seventy years of research. The three large water, sanitation and hygiene randomised trials did not reduce stunting while the observational association is strong — a central unresolved disagreement with major programmatic consequences. Routine amoxicillin in uncomplicated

severe acute malnutrition: the Malawi and Niger trials disagree and WHO recommends it. Deworming: Cochrane finds little or no effect on growth and mass deworming programmes continue. How much stunting is reversible after 24 months, and whether adolescent catch-up has functional significance, is contested. The contribution of environmental enteric dysfunction to stunting is not quantified. Attributable mortality of roughly 45 per cent of under-five deaths rests on comparative risk assessment with counterfactual assumptions, the figure is widely used and the uncertainty is wide. Stunting has halted and may be rising, and the reasons — conflict, food prices, climate — are not disentangled. Integrated Food Security Phase Classification famine classifications change monthly and no stable figure can be quoted. Almost all treatment evidence is in children aged six to 59 months; infants under six months with wasting are a large, poorly studied group with no established protocol beyond breastfeeding support, and mortality in that group is high.

---

## Vitamin A deficiency

**What it is.** Not enough vitamin A. The first sign is difficulty seeing in dim light; then the surface of the eye dries, ulcerates and scars, and the child goes blind. It also weakens resistance to infection, so children die of measles and diarrhoea who would otherwise survive.

**Measured.** Stevens et al., *Lancet Global Health*, 2022, the most recent global micronutrient synthesis, found that 372 million preschool children aged six to 59 months (95% UI 319–425 million), 56 per cent, had at least one of iron, zinc or vitamin A deficiency, and that 1.2 billion non-pregnant women of reproductive age (1.0–1.4 billion), 69 per cent, had at least one of iron, zinc or folate deficiency. The paper does not publish separate per-nutrient counts in the abstract, and where only two of the three biomarkers were measured the third was estimated by regression.

The earlier WHO global estimates, with reference years 1995 to 2005 and published 2009, remain the most widely cited vitamin-A-specific figures: vitamin A deficiency, defined as serum retinol below 0.70 µmol/L, in 190 million preschool children (33.3 per cent) and 19.1 million pregnant women (15.3 per cent); and night blindness in 5.2 million preschool children (0.9 per cent) and 9.8 million pregnant women (7.8 per cent), with the highest prevalence in Africa and South-East Asia.

Historically roughly 250,000 to 500,000 children a year went blind from vitamin A deficiency, with roughly half dying within 12 months of losing sight†. Those figures date from the 1990s and current numbers are substantially lower but not well measured, which is itself the finding.

Vitamin A deficiency is counted in GBD as a risk factor rather than a cause, and the mortality effect is measured through supplementation trials. The vulnerable window is six to 59 months, with risk peaking after weaning and during measles and diarrhoeal illness, and pregnant and lactating women are the second group. Sub-Saharan Africa and South Asia carry the burden, and the deficiency has essentially disappeared from high-income countries except in malabsorption states and severely restricted diets.

UNICEF reports two-dose annual supplementation coverage of roughly 50 to 70 per cent in priority countries, having fallen from a peak above 70 per cent in the mid-2010s† — coverage is declining, which is a measured programmatic regression.

**Where it starts.** Inadequate intake of preformed vitamin A — retinol, from liver, eggs, dairy and fish — or of provitamin A carotenoids — beta-carotene, from orange and dark green plant foods — relative to need. Needs rise during growth, pregnancy, lactation and infection.

Bioavailability is the key quantitative point. Conversion of dietary beta-carotene to retinol is inefficient and was revised downward: the current factor is roughly 12:1 by weight for beta-carotene in a mixed diet, and 24:1 for other provitamin A carotenoids, against an older assumed 6:1†. Fat in the meal is required for absorption, so carotenoid-rich diets without fat deliver far less vitamin A than the food composition tables suggest. This is why advice to eat more green vegetables has often underperformed.

Infection depletes it: measles, diarrhoea and respiratory infection increase urinary retinol loss and reduce intake simultaneously. Measles in a vitamin-A-deficient child is the classic route to corneal ulceration and blindness, and the relationship is bidirectional — deficiency

worsens measles and measles worsens deficiency. WHO's measles fact sheet of 15 July 2026 records the standing recommendation of two doses of vitamin A for suspected cases under five, with a third dose four to six weeks later if there are eye complications.

Fat malabsorption causes it regardless of intake: cystic fibrosis, cholestasis, coeliac disease, pancreatic insufficiency, short bowel, bariatric surgery. Zinc deficiency impairs vitamin A mobilisation, since zinc is needed for retinol-binding protein synthesis, so the two deficiencies interact. Protein-energy malnutrition reduces retinol-binding protein, so serum retinol falls partly for that reason, which complicates measurement.

Not heritable. Rare monogenic causes of retinol transport defects exist, in *RBP4*, and are vanishingly rare.

The measurement problem is itself a cause of uncertainty: serum retinol is homeostatically controlled until liver stores are nearly exhausted, and falls during infection and inflammation independent of vitamin A status, so serum-retinol-based prevalence estimates are both insensitive to mild deficiency and inflated by concurrent infection.

*Not known*: current global prevalence, because the authoritative WHO figures use data from 1995 to 2005. Whether the mortality benefit of supplementation, established in trials run in the 1980s and 1990s, still holds in populations with better measles vaccination coverage, lower background mortality and partial food fortification. This is a live and consequential dispute.

**Cure status.** CURABLE, and the cure is dietary or a cents-worth capsule. This is among the clearest entries in the chapter, with one limit: corneal scarring does not reverse.

Biochemical deficiency and night blindness reverse within days to weeks of adequate vitamin A. Keratomalacia that has perforated or scarred the cornea causes permanent blindness, so the cure is complete only if it comes before that point.

The mortality effect, from the Cochrane review (Imdad et al., 2022; 47 randomised trials, roughly 1,223,856 children aged six to 59 months, 19 countries):

| Outcome | Relative risk (95% CI) | Trials / children | GRADE certainty |
|---|---|---|---|
| All-cause mortality | **0.88 (0.83–0.93)** | 19 trials / 1,202,382 | High |
| Diarrhoea mortality | 0.88 (0.79–0.98) | 9 trials / 1,098,538 | High |
| Measles mortality | 0.88 (0.69–1.11) | 6 studies / 1,088,261 | Low, not significant |
| Diarrhoea incidence | 0.85 (0.82–0.87) | 15 studies / 77,946 | Low |
| Measles incidence | 0.45 (0.30–0.69) | 2 studies / 1,982 | Low |
| Night blindness | **0.32 (0.21–0.50)** | 2 studies / 22,972 | Moderate |
| Bitot's spots | 0.42 (0.33–0.53) | 5 studies / 1,063,278 | Moderate |
| Biochemical vitamin A deficiency | 0.71 (0.65–0.78) | 4 studies / 2,262 | Moderate |
| Respiratory disease incidence | 0.99 (0.92–1.06) | 11 studies / 27,540 | Low, no effect |
| Vomiting within 48 hours | 1.97 (1.44–2.69) | 4 studies / 10,541 | Moderate, harm |

Supplementation reduces all-cause mortality in children aged six to 59 months by about 12 per cent, with high GRADE certainty, and reduces diarrhoea-specific mortality by a similar amount. It does not significantly reduce measles or respiratory deaths, and it reduces measles and diarrhoea incidence. The main adverse effect is vomiting within 48 hours of a large dose.

The dispute: the DEVTA trial in India, with roughly one million children, cluster-randomised and published in 2013, found a mortality reduction of only about 4 per cent, not statistically significant, at a mortality ratio of 0.96. DEVTA is the single largest trial and it is an outlier. Its inclusion pulls the pooled estimate down, and the Cochrane pooled figure of 0.88 includes it. Critics of DEVTA cite incomplete dosing records and lower baseline deficiency, and its authors defend it. This is the central live disagreement in the field, and it determines whether universal supplementation programmes should continue.

Treatment of measles with vitamin A — two large doses on consecutive days — reduces measles mortality substantially in deficient populations. This is a standing WHO recommendation and is distinct from the prophylaxis question.

**Prevention.** High-dose supplementation every four to six months for children aged six to 59 months. All-cause mortality relative risk 0.88 with high certainty, night blindness 0.32, Bitot's spots 0.42†. The dose is 100,000 IU for infants aged six to 11 months and 200,000 IU for children aged 12 to 59 months. STRONG on the Cochrane evidence; CONTESTED in the light of DEVTA and of falling background mortality. Cost is roughly US$0.02 to US$0.03 a capsule at generic or lowest available acquisition cost, and roughly one to two dollars per child a year delivered, including distribution — among the cheapest mortality-reducing interventions measured anywhere.

Food fortification. Vitamin A fortification of cooking oil, sugar, wheat flour and margarine. Oil is the best vehicle because vitamin A is fat-soluble and oil is centrally processed. Guatemala's sugar fortification programme raised serum retinol measurably and is the longest-running example. MODERATE for biochemical status, MODERATE for clinical outcomes. Roughly 30 countries mandate vitamin A fortification of edible oil, and roughly 25 to 30 fortify sugar or flour with vitamin A†.

Biofortification with orange-fleshed sweet potato and provitamin A maize. Randomised and quasi-experimental trials in Mozambique and Uganda showed that introducing orange-fleshed sweet potato raised serum retinol and reduced the prevalence of low serum retinol in children by roughly 10 to 15 percentage points, with adoption sustained over years†. This is a plant-breeding intervention requiring no supplement chain. MODERATE.

Measles vaccination, which prevents the illness that converts subclinical deficiency into corneal destruction. STRONG. Measles vaccine has been in use about 60 years and costs under one US dollar a child (WHO measles fact sheet, 15 July 2026), and vaccination averted nearly 59 million deaths between 2000 and 2024.

Breastfeeding, which is a reliable vitamin A source for the first six months, and maternal supplementation raises breast milk retinol. STRONG.

Dietary diversification — liver, eggs, dairy, small whole fish, dark green leaves, and orange fruits and vegetables, with fat in the meal. MODERATE: the effect is real and the carotenoid conversion inefficiency of 12:1 limits what plant sources alone achieve.

Postpartum maternal supplementation: WHO no longer recommends routine high-dose maternal supplementation, because trials including large Bangladeshi and Ghanaian trials found no reduction in maternal or infant mortality. Neonatal dosing was likewise tested in three large NEOVITA trials in Ghana, India and Tanzania, with discordant results — benefit in India, none in Ghana or Tanzania — and is not universally recommended. CONTESTED, and reported here because older guidance differs.

Avoiding excess in pregnancy: preformed vitamin A above roughly 10,000 IU a day is teratogenic, so liver and high-dose supplements are restricted in pregnancy. STRONG for the harm.

**Treatment.** High-dose oral vitamin A as retinyl palmitate capsules for xerophthalmia and for measles in deficient populations: 200,000 IU on day 1, day 2 and day 14, with lower doses by age. Off-patent, at roughly US$0.02 to US$0.03 per 200,000 IU capsule at generic or lowest available acquisition cost, 2024, so a full treatment course costs under 10 US cents†. Retinol's listing status needs checking against the 24th List†.

Eye care for xerophthalmia: topical lubrication, topical antibiotic to prevent secondary bacterial keratitis, and protection of the perforating cornea. Cheap, and the difference between sight and blindness.

Treating the precipitating illness — measles, diarrhoea, pneumonia — and the concurrent protein-energy malnutrition.

Vitamin A as part of severe acute malnutrition protocols, now given in the therapeutic food rather than as a separate high dose in most protocols.

Fat-soluble vitamin replacement in malabsorption, with water-miscible preparations for cholestasis and cystic fibrosis, and monitoring of serum retinol to avoid toxicity.

Managing toxicity: acute hypervitaminosis A — headache, vomiting, raised intracranial pressure, bulging fontanelle in infants — resolves on stopping; chronic toxicity causes bone pain, hepatotoxicity and alopecia.

**Simple means.** This is one of the entries where the simple means is the cure and the prevention.

Liver, once or twice a week. A small portion of ruminant or poultry liver contains several times a child's weekly vitamin A requirement in preformed, highly bioavailable form. Nothing matches it per unit cost.

Eggs, milk, butter, small whole fish, and fish liver. Preformed retinol, no conversion needed.

Orange-fleshed sweet potato. Trials in Mozambique and Uganda measured roughly 10 to 15 percentage point reductions in low serum retinol prevalence in children after its introduction. It is a crop, propagated by vine cuttings, requiring no factory and no supplement chain. The single best example of a plant-breeding solution to a micronutrient deficiency.

Dark green leaves, mango, papaya, pumpkin and carrot — eaten with fat. The fat is the essential part: absorption of provitamin A carotenoids requires dietary fat, and the conversion ratio is roughly 12:1 by weight, so the quantity needed is large and fat-free preparation wastes most of it.

Red palm oil. Among the richest natural sources of provitamin A carotenoids, widely used in West and Central Africa, and it supplies both the carotenoid and the fat in one ingredient.

Breastfeeding, a reliable vitamin A source for the first six months, free.

Measles vaccination, which prevents the illness that blinds the deficient child, at under one dollar a child.

The capsule itself. At roughly US$0.02 to US$0.03 a dose at generic or lowest available acquisition cost, and roughly one to two dollars per child-year delivered, the supplement is nearly as simple as a food, and it has high-certainty randomised evidence of a 12 per cent reduction in all-cause child mortality.

Not giving high-dose vitamin A to pregnant women, because of teratogenicity above roughly 10,000 IU a day.

**Gaps.** The authoritative vitamin-A-specific global prevalence figures — 190 million children, 33.3 per cent — use data from 1995 to 2005, and no comparable update exists; Stevens et al. (2022) report combined multi-deficiency figures and do not publish separate vitamin A counts in the abstract. DEVTA, the largest trial, found no significant mortality benefit, roughly 4 per cent, against the Cochrane pooled estimate of 12 per cent with high certainty; sources disagree sharply, and the dispute concerns both DEVTA's conduct and whether older trial results generalise to today's lower-mortality, measles-vaccinated populations. Supplementation coverage is falling, from above 70 per cent to roughly 50 to 70 per cent in priority countries, for programmatic rather than evidential reasons. Serum retinol is a poor biomarker — homeostatically controlled, depressed by inflammation, and dependent on retinol-binding protein which falls in protein-energy malnutrition — so prevalence figures are method-dependent and probably misclassify in both directions. Neonatal and postpartum maternal dosing: the three NEOVITA trials disagreed with each other, WHO withdrew the routine postpartum recommendation, and older national guidance still reflects the previous advice. Current numbers for xerophthalmia and vitamin-A-attributable blindness are not well measured, and the widely quoted 250,000 to 500,000 blinded children a year is from the 1990s. The carotenoid conversion factor was revised from roughly 6:1 to 12:1, which halves the estimated vitamin A supply from plant-based diets in older assessments, so historical dietary adequacy estimates based on food composition tables are unreliable. The interaction with zinc deficiency is established mechanistically and not quantified in programme terms.

---

## Iodine deficiency disorders

**What it is.** Not enough iodine to make thyroid hormone. The thyroid swells into a goitre. In a developing fetus and infant the shortage damages the brain permanently, which is the reason iodine deficiency matters more than the swelling.

**Measured.** Household coverage of iodised salt is nearly 89 per cent globally (Iodine Global Network Annual Report 2025), with West and Central Africa at 74 per cent, the Middle East and North Africa at 80.4 per cent, South Asia at 89.8 per cent and East Asia and the Pacific at 91 per cent.

The monitoring situation, stated by the monitoring body itself, is the finding. Of 171 countries in the WHO iodine database, 44 have one survey, 86 have two to four, 41 have five or more, and 25 have no survey at all; 43 per cent of countries have no coverage data and 34 per cent have data from before 2018.

About 187 million people had goitre from iodine deficiency as of 2010, 2.7 per cent of the world population; iodine deficiency affects roughly two billion people worldwide; and deaths attributed to iodine deficiency were about 2,700 in 2013, up from about 2,100 in 1990†. A goitre is considered endemic when prevalence exceeds 5 per cent.

Pregnancy is the remaining problem even in iodine-sufficient countries. In United States ECHO cohort data, roughly 45 per cent of pregnant participants had inadequate iodine intake, with similar findings reported in the United Kingdom, Norway and Australia. Pregnancy roughly increases iodine requirement by 50 per cent†.

The cognitive effect is measured. Iodine deficiency during development is associated with an average drop of about 12 IQ points in Chinese meta-analytic data†. Introducing salt iodisation in the United States in the 1920s raised IQ by about one standard deviation in the most iodine-deficient quarter of the population (Feyrer, Politi and Weil, analysing United States military test data before and after iodisation) — one of the largest population cognitive effects ever attributed to a single public health measure. Severe deficiency in pregnancy causes cretinism — profound intellectual disability, deaf-mutism, spasticity and stunting — which was endemic in Alpine valleys, the Himalayas, the Andes and inland China and has been largely eliminated by iodisation.

Country data before and after. Norway: before 1950, up to 80 per cent of people in inland areas had goitre; from the 1950s iodine was added to dairy cow feed rather than to salt, and goitre incidence fell. Switzerland was the first country to iodise salt, in 1922, and endemic cretinism and goitre disappeared†. The United States introduced iodised salt in 1924. The United Kingdom has no mandatory iodisation and relies on iodine in milk from fortified cattle feed, which has fallen with changing dairy practices and plant-milk substitution; a 2011 study found almost 70 per cent of teenage girls tested were iodine deficient†. Australia and New Zealand mandated iodised salt in most commercial bread making from October 2009.

Cost: iodine added to salt costs only a few cents a tonne, and salt iodisation programme cost is on the order of US$0.02 to US$0.05 per person a year†. Germany's iodine deficiency costs are estimated at about a billion dollars a year in health care. A United Kingdom model estimates that supplementation for pregnant women saves £199 per woman in health service costs and £4,476 in societal costs — projected savings, not programme costs†.

**Where it starts.** Low iodine in soil and therefore in local food and water. Iodine is leached from soil by glaciation, flooding and erosion, so mountainous regions and river flood plains are the classic deficient areas — the Alps, Himalayas, Andes, the Great Lakes basin, inland China, Central Asia. Coastal populations with marine food are generally sufficient. This is a geological cause, which is why the disease maps onto terrain rather than onto poverty alone.

Goitrogens add to the effect where intake is marginal: cassava, through linamarin releasing thiocyanate; cruciferous vegetables; millet; soy; and smoking. Cassava is the important one — in parts of Central Africa, high cassava intake with marginal iodine produces goitre and cretinism at iodine concentrations that would otherwise be tolerable.

Selenium and iron deficiency impair thyroid hormone synthesis and the response to iodine, so concurrent deficiencies blunt the benefit of iodisation.

Pregnancy and lactation raise requirement by roughly 50 per cent, and the fetal brain depends entirely on maternal thyroxine in the first trimester, before the fetal thyroid functions. The window for the cognitive damage is the first and second trimester, which is why maternal status before and in early pregnancy is what matters, and why correcting it late does not repair it.

Excess iodine also causes disease: iodine-induced hyperthyroidism, particularly transiently after iodisation programmes begin in previously deficient populations with nodular goitre,

and at high chronic intakes, hypothyroidism and autoimmune thyroiditis. Japanese seaweed consumption provides intakes an order of magnitude above recommendations with some increase in subclinical hypothyroidism. The dose-response is U-shaped, which constrains programme design.

Not heritable, though thyroid volume and the tendency to nodule formation are.

*Not known*: current global and national iodine status, because 43 per cent of countries have no coverage data and 34 per cent have data from before 2018. Whether mild-to-moderate maternal iodine deficiency in otherwise iodine-sufficient countries causes measurable cognitive harm — the observational data suggest it does, and the randomised trials of iodine supplementation in mildly deficient pregnant women in India and Thailand, published in 2021, found no effect on child neurodevelopment at five to six years†, which is a significant negative.

**Cure status.** The deficiency state: CURABLE by iodine. The goitre regresses partially or fully in children and young adults, less so in long-standing nodular goitre in adults. The brain damage already done: RELIEF ONLY. Cretinism and the IQ loss from fetal and infant deficiency are permanent, and iodine given after the window does not repair it.

Universal salt iodisation is the standing cure at population level, and it has worked. Cretinism has been eliminated from most of the world, household iodised salt coverage is nearly 89 per cent†, and the number of iodine-deficient countries fell from 110 in 1993 to roughly 20 to 25 by the late 2010s†. This is the most successful micronutrient programme in history. The remaining problem is pregnancy, and the countries without mandatory iodisation.

**Prevention.** Universal salt iodisation. The measure, with the before-and-after data above: Switzerland 1922, the United States 1924, and the global fall from 110 iodine-deficient countries in 1993 to roughly 20 to 25 now, with household coverage near 89 per cent. Cost is a few cents a tonne of salt, or US$0.02 to US$0.05 per person a year in a universal salt iodisation programme†. STRONG — the best-evidenced population fortification programme in existence, and the cheapest. Potassium iodate rather than potassium iodide is used in hot humid climates because it is more stable.

Iodised salt in processed food and bread. Where most salt intake comes from processed food rather than the table, household salt iodisation alone is insufficient, which is why Australia and New Zealand mandated iodised salt in bread from 2009. MODERATE.

Iodine in animal feed, the Norwegian and historical United Kingdom route, delivering iodine through milk. It works, and it is fragile: United Kingdom iodine status fell as dairy practice and plant-milk consumption changed. MODERATE, with the caveat that it is not robust to dietary change.

Iodine supplementation in pregnancy, at 150 µg a day, or iodised salt plus a supplement. WHO recommends iodine supplementation in pregnancy where iodised salt coverage is below 20 per cent. In severely deficient populations, maternal iodine before or in early pregnancy prevents cretinism, from the classic Papua New Guinea and Zaire iodised oil trials: STRONG. In mildly-to-moderately deficient populations, the randomised trials published in 2021 found no effect on child neurodevelopment at five to six years: CONTESTED.

Iodised oil, by injection or oral dose, used historically in remote populations without salt distribution, where a single dose provides iodine for about a year. Largely superseded by salt iodisation. STRONG where salt iodisation is impossible.

Reducing cassava dependence or processing cassava properly — soaking, fermenting and drying removes most of the cyanogenic glycosides. MODERATE in cassava-dependent populations.

Monitoring: median urinary iodine concentration in school-age children, with a target of 100 to 199 µg/L, and in pregnant women, with a target of 150 to 249 µg/L; and salt iodine content at household and production level. This is the part that has broken down, with 43 per cent of countries having no coverage data.

Avoiding excess: monitoring for iodine-induced hyperthyroidism in the early years of a programme in a previously deficient population with nodular goitre. STRONG as a programme safeguard.

**Treatment.** Iodised salt — the population treatment and prevention in one. Off-patent, at a few cents a tonne of salt, or US$0.02 to US$0.05 per person-year of a salt iodisation pro-

gramme†. The listing status of iodine and of potassium iodide needs checking against the 24th List†.

Potassium iodide tablets or iodine drops for individuals, at micrograms a day, costing under one dollar a patient-year (2024)†.

Iodised oil, oral or intramuscular, a single dose covering about a year, for remote populations, at roughly US$0.50 to US$2.00 a dose at lowest available acquisition cost†.

Levothyroxine for established hypothyroidism from iodine deficiency and for congenital hypothyroidism. **Levothyroxine is a selected medicine on the 24th List, in section 18.7, thyroid hormones and antithyroid medicines, for hypothyroidism, as oral solid 25, 50 and 100 µg as sodium, first added in 1977**. Off-patent, at US$5 to US$50 a patient-year at generic or lowest available acquisition cost, 2024†.

Goitre: iodine repletion shrinks diffuse goitre in children and young adults. Long-standing multinodular goitre does not regress, and treatment is thyroidectomy or radioiodine, which reduces goitre volume by roughly 40 to 60 per cent over a year and is cheap and effective†. Surgery is reserved for compressive symptoms, suspicion of malignancy, or cosmetic indication.

Iodine-induced hyperthyroidism: thionamides, beta-blockers, and definitive treatment with radioiodine or surgery.

Congenital hypothyroidism: newborn screening and levothyroxine within the first two weeks of life prevents intellectual disability entirely.

**Simple means.** This entry is the clearest case in the whole chapter of a simple means being both the cure and the prevention.

Iodised salt. A few cents a tonne. It eliminated endemic cretinism from most of the world, reaches nearly 89 per cent of households, and in the United States raised IQ by about one standard deviation in the most deficient quarter of the population. There is no industrial chain to speak of: it is a potassium iodate premix added at the salt works, and small-scale and artisanal salt producers can and do add it.

Seaweed and marine fish. A reliable natural source; a small amount of kelp or dried seaweed contains many times the daily requirement — and can easily contain too much, which is the caution.

Milk, eggs and dairy in countries where cattle feed is iodine-fortified.

Proper cassava processing — soaking, fermenting, sun-drying. Traditional, free, and it removes the goitrogen.

Potassium iodide drops or tablets, under a dollar a year.

A hand around the neck. Goitre is detectable by palpation with no equipment, and goitre prevalence above 5 per cent in schoolchildren defines endemicity. This is how the global programme was monitored before urinary iodine assays, and it still works.

A salt test kit — a spot test for iodine in salt costing cents, usable by anyone, used in household surveys worldwide.

Iodine supplementation in pregnancy where salt coverage is inadequate, at micrograms a day and under a dollar a year, with the caveat that it must come before and during early pregnancy to matter.

**Gaps.** The monitoring system has largely broken down: 43 per cent of countries have no iodised salt coverage data, 34 per cent have data from before 2018, and 25 countries have never had an iodine status survey. The near-89 per cent household coverage figure is itself therefore uncertain, and the Iodine Global Network report does not date it. There is no current count of iodine-deficient countries or of people with inadequate intake with the authority of the 1990s and 2000s assessments. The 187 million goitre figure is from 2010 and the 2,700 deaths figure from 2013. The randomised trials of iodine supplementation in mildly-to-moderately deficient pregnant women found no effect on child neurodevelopment while observational data associate mild maternal deficiency with lower child IQ — a direct conflict between trial and cohort evidence with major policy consequences for countries like the United Kingdom. Pregnancy iodine status in high-income countries is inadequate in a large minority, roughly 45 per cent in the United States ECHO sample, and the clinical sig-

nificance is contested. The dose-response is U-shaped and the upper safe limit at population level is not firmly established, particularly in high-seaweed-consumption populations. The interaction with selenium and iron deficiency is established mechanistically and not quantified programmatically. The United Kingdom and several other high-income countries have no mandatory iodisation and declining status, and whether to introduce it is an unresolved policy question. The IQ effect sizes — 12 points in Chinese data, one standard deviation in the most deficient United States quartile — come from very different designs and populations and should not be read as interchangeable estimates of the same quantity.

---

## Zinc deficiency

**What it is.** Not enough zinc. Children grow poorly, diarrhoea lasts longer and comes back more often, wounds heal badly and infections are more frequent. There is no good single blood test for it, which is why it is poorly measured.

**Measured.** About 2.2 billion people are affected, and conservative estimates put the share of the world population at risk at 25 per cent†. Stevens et al., *Lancet Global Health*, 2022, found 372 million preschool children (319–425 million), 56 per cent, with at least one of iron, zinc or vitamin A deficiency, and 1.2 billion non-pregnant women of reproductive age (1.0–1.4 billion), 69 per cent, with at least one of iron, zinc or folate deficiency; per-nutrient counts are not published in the abstract.

Estimated inadequate zinc intake from food supply data, using International Zinc Nutrition Consultative Group methods and FAO food balance sheets, puts roughly 17 per cent of the global population at risk of inadequate intake, with national estimates above 25 to 30 per cent across South Asia and sub-Saharan Africa†.

The claim that zinc deficiency causes stunted growth in one-third of the world's population should be read as an attribution claim, not a measurement. Attributable mortality estimates from GBD and earlier comparative risk assessments range from roughly 100,000 to 450,000 child deaths a year, principally through diarrhoea and pneumonia†; the range reflects different counterfactual assumptions, and recent GBD iterations have reduced or removed zinc as a separate risk factor.

Infants and young children, and pregnant and lactating women, are most affected because requirements are highest relative to intake, with adolescents during growth spurts also at risk. The burden falls on South Asia and sub-Saharan Africa, where cereal-and-legume diets are high in phytate and low in animal-source food, and on soil-zinc-deficient areas — much of South Asia, parts of Turkey, Australia and West Africa have zinc-poor soils, which lowers crop zinc content directly.

Acrodermatitis enteropathica, the monogenic form caused by *SLC39A4* variants, is very rare at roughly 1 in 500,000 births and was uniformly fatal before zinc treatment was discovered in 1973†.

**Where it starts.** Inadequate intake or absorption relative to requirement.

Phytate is the central quantitative fact. Phytic acid in cereal and legume seeds binds zinc and prevents absorption, and the phytate-to-zinc molar ratio determines bioavailability: ratios above about 15 indicate low bioavailability, roughly 15 per cent absorption, and ratios below about 5 indicate good bioavailability, roughly 50 per cent absorption†. A diet of unrefined cereals and legumes with no animal food can therefore deliver adequate zinc on paper and inadequate zinc in fact — the same problem as with iron, and for the same chemical reason.

Zinc in meat, fish, shellfish, eggs and dairy is absorbed several times better than cereal zinc, and oysters are the richest food source known. Soil zinc deficiency lowers crop zinc content, a geological contributor particularly across the Indo-Gangetic plain.

Diarrhoea causes substantial zinc loss, so diarrhoea causes zinc deficiency and zinc deficiency prolongs diarrhoea — a measured vicious circle, and the reason zinc is given as diarrhoea treatment.

Malabsorption: coeliac disease, Crohn's disease, short bowel, cystic fibrosis, chronic pancreatitis, bariatric surgery. Increased losses: sickle cell disease through urinary loss, chronic

kidney disease, cirrhosis, diuretics, burns, dialysis. High requirements: pregnancy, lactation, infancy, adolescence, recovery from severe malnutrition.

Interactions: high-dose iron supplements reduce zinc absorption, and high-dose zinc reduces copper absorption and can cause copper deficiency anaemia and myelopathy — a real iatrogenic harm, seen with denture adhesives and with long-term high-dose zinc self-medication.

Heritability does not apply to the acquired deficiency. Acrodermatitis enteropathica is autosomal recessive, from *SLC39A4* encoding the ZIP4 zinc transporter, with heritability 1.0 for the genotype.

*Not known*: how much zinc deficiency there actually is, because there is no reliable biomarker. Serum or plasma zinc is the usual measure and it is insensitive — homeostatically controlled, falling with infection and inflammation, falling after a meal, varying diurnally, and not tracking tissue stores. Every global prevalence figure for zinc deficiency is therefore derived from dietary intake modelling from food supply data, not from measured status. This is the central epistemic problem in this entry and it should be stated plainly.

**Cure status.** CURABLE by diet or by a cents-worth tablet. The deficiency state corrects within days to weeks. Acrodermatitis enteropathica is CONTROLLABLE by lifelong oral zinc: before 1973 it was fatal in infancy, and with zinc, affected individuals are normal. One of the cleanest nutrient-cures-disease stories in medicine — with the standing note that the zinc must continue.

Zinc for acute diarrhoea in children is the best-evidenced use. WHO's diarrhoeal disease fact sheet, printed 7 March 2024, states that **zinc reduces episode duration by 25 per cent and stool volume by 30 per cent**, with a course of 10 to 14 days. The Cochrane review of oral zinc for treating diarrhoea in children reports that in children over six months of age zinc shortened the duration of diarrhoea, with diarrhoea lasting beyond day seven less likely and a mean reduction in duration of roughly 10 to 12 hours in healthy well-nourished children, with larger effects in zinc-deficient and malnourished populations. The two figures describe different populations and are routinely quoted interchangeably. In infants under six months zinc shows no benefit and possible harm, and WHO's recommendation applies from six months. Vomiting is increased by zinc treatment, a consistent adverse effect. WHO and UNICEF recommend 20 mg a day for 10 to 14 days, and 10 mg for infants aged two to six months, for every child with diarrhoea, alongside oral rehydration salts.

Zinc for pneumonia prevention: the Cochrane review in children aged two to 59 months found a modest reduction in incidence, with a small effect size, and the source consulted gives none.

Growth: zinc supplementation in deficient children produces a small but consistent increase in linear growth — meta-analyses give roughly 0.3 to 0.4 cm additional height over supplementation periods of months, and a height-for-age z-score gain of roughly 0.1 to 0.2 standard deviations†. Small, replicated.

Zinc for the common cold: meta-analyses of zinc lozenges report reduced duration of roughly one to two days in adults, and the evidence is heterogeneous, formulation-dependent and contested.

**Prevention.** Zinc fortification of staple foods, usually as zinc oxide or zinc sulphate alongside iron and folic acid in wheat and maize flour. It raises intake measurably, and effects on functional outcomes are less well demonstrated than for iodine or folic acid. MODERATE.

Biofortification with zinc wheat and zinc rice. HarvestPlus zinc wheat has been released in Pakistan and India and zinc rice in Bangladesh, and randomised efficacy trials of zinc biofortified wheat in Pakistani households (BiZiFED2) showed increased plasma zinc and some functional benefits†. MODERATE — a plant-breeding intervention requiring no supplement chain, with trial evidence accumulating.

Small-quantity lipid-based nutrient supplements, which contain zinc: the individual-participant-data meta-analysis of 14 trials found a 14 per cent reduction in wasting, 12 per cent in stunting and 13 per cent in anaemia†. STRONG for the package.

Agronomic zinc fertilisation in zinc-deficient soils raises grain zinc content and yield simultaneously, and has been deployed at scale in Turkey, where zinc fertiliser use rose from

near zero to hundreds of thousands of tonnes a year with measured increases in crop zinc. MODERATE.

Dietary diversification with animal-source foods, and reducing phytate by soaking, germinating, fermenting and leavening. MODERATE — metabolic studies are clear and population outcome data are limited.

Preventive zinc supplementation in children in deficient populations reduces diarrhoea incidence by roughly 10 to 20 per cent and pneumonia incidence modestly in meta-analyses†. MODERATE.

Zinc with oral rehydration salts for every episode of childhood diarrhoea — prevention of the next episode as well as treatment of this one, since zinc reduces diarrhoea incidence over the following two to three months. STRONG.

Avoiding excess: high-dose zinc causes copper deficiency, and upper intake levels exist for this reason. STRONG for the harm.

**Treatment.** Zinc sulphate, acetate or gluconate, oral, 20 mg elemental zinc daily for 10 to 14 days, for childhood diarrhoea, alongside oral rehydration salts. Off-patent, at roughly US$0.03 to US$0.10 a dispersible tablet at generic or lowest available acquisition cost, so a full 10-to-14-day course costs roughly US$0.30 to US$1.40 in 2024, with co-packaged oral-rehydration-salts-and-zinc kits at roughly US$0.50 to US$1.00†. The listing status of zinc sulphate, including the co-packaged form on the Model List for Children, needs checking against the 24th List†.

Oral rehydration salts, the essential partner, off-patent at US$0.05 to US$0.20 a sachet (2024)†; UNICEF's indicative price for a carton of 100 low-osmolarity sachets was US$4.80 in October 2026, about US$0.048 a sachet, printed as indicative and dated rather than as a price. Listing status needs checking against the 24th List†.

Therapeutic zinc in severe acute malnutrition, included in the micronutrient premix of ready-to-use therapeutic food and in F-75 and F-100 therapeutic milks.

Lifelong zinc for acrodermatitis enteropathica, at roughly 1 to 3 mg/kg a day elemental zinc, at tens of dollars a patient-year†. Curative while continued.

Zinc in malabsorption states, sickle cell disease, and chronic liver and kidney disease, with monitoring and attention to copper status.

Zinc acetate in Wilson disease is a different use: it blocks copper absorption. Off-patent; listing status needs checking against the 24th List†.

What not to do: give high-dose zinc long-term without monitoring copper; give zinc to infants under six months for diarrhoea; or give zinc and high-dose iron together expecting full absorption of both.

**Simple means.** Zinc tablets with oral rehydration salts for childhood diarrhoea. Roughly US$0.30 to US$1.40 for a full course at generic or lowest available acquisition cost. It is oral, dispersible, no cold chain, usable by a caregiver at home. Together with oral rehydration salts this is among the cheapest life-saving combinations in medicine.

Animal-source food — meat, offal, fish, shellfish, eggs, dairy, insects. Zinc from these is absorbed several times better than cereal zinc, and they also reduce the inhibitory effect of phytate in the same meal.

Soaking, germinating, fermenting and leavening cereals and legumes. Phytase activity degrades phytate and raises zinc absorption substantially — the difference between roughly 15 and roughly 50 per cent absorption depending on the phytate-to-zinc ratio achieved. Sourdough leavening, injera fermentation, idli and dosa fermentation, and sprouting all do this. Traditional practice, free, chemically measurable.

Not taking high-dose iron supplements at the same meal as zinc-containing food.

Zinc-biofortified wheat and rice. A seed, not a supplement chain.

Agronomic zinc fertiliser in zinc-deficient soils, which raises both crop zinc and yield, so the farmer has an independent reason to use it.

Oysters and small whole fish where available, the richest natural sources.

Breastfeeding. Breast milk zinc is highly bioavailable, and exclusive breastfeeding covers requirements for the first six months.

Handwashing and clean water — fewer diarrhoea episodes means less zinc loss.

**Gaps.** There is no reliable biomarker for zinc status. Plasma zinc is insensitive, falls with inflammation and after meals, and does not reflect tissue stores. All global prevalence figures are modelled from food supply data rather than measured, and the 2.2 billion affected and 25 per cent at risk figures should be read accordingly. The claim that zinc deficiency causes stunting in one-third of the world's population is an attribution estimate from older literature and is not a measurement; the supplementation trials show growth effects of roughly 0.1 to 0.2 standard deviations in height-for-age, which is small. Attributable child mortality estimates range from roughly 100,000 to 450,000 a year depending on counterfactual assumptions, and recent GBD iterations have changed how zinc is handled as a risk factor. The reported effect on diarrhoea duration differs between populations — roughly 10 to 12 hours in well-nourished children against roughly 25 per cent duration reduction in deficient populations — and the two are not contradictory and are routinely quoted interchangeably. Zinc gives no benefit and possible harm in infants under six months, which is not always reflected in programme guidance. Vomiting is increased by therapeutic zinc, which reduces adherence and is under-reported in advocacy material. The effect of zinc on pneumonia prevention is small and the Cochrane review consulted gives no effect size. Zinc for the common cold is contested, formulation-dependent and heterogeneous. Fortification and biofortification have demonstrated effects on intake and plasma zinc, and demonstrated effects on stunting, diarrhoea and mortality at programme scale are thin. The interaction with copper means population-wide high-dose approaches carry a real harm, and the safe upper limit at population level is not firmly established.

---

## Rickets and vitamin D deficiency

**What it is.** Not enough vitamin D, or not enough calcium, so growing bone does not mineralise. Legs bow, the wrists and ribs swell at the growth plates, and children are slow to walk. In adults the same process softens already-formed bone, which is osteomalacia.

**Measured.** Nutritional rickets is a disease of specific populations, not of latitude alone. Reported incidence: United Kingdom roughly 7.5 to 24 per 100,000 children a year in South Asian, African and Middle Eastern communities, against near zero in the white British population; Denmark roughly 2.9 per 100,000 a year overall, with a relative risk of roughly 60 in children of immigrant origin compared with ethnic Danes; Australia roughly 4.9 per 100,000 a year, concentrated in dark-skinned and veiled populations; and Canada roughly 2.9 per 100,000 a year on national paediatric surveillance, with over 90 per cent of cases in breastfed infants not given vitamin D supplements.

Nigeria, Bangladesh, Tibet, Mongolia, Yemen, Turkey and Ethiopia report far higher rates, with calcium-deficiency rickets — adequate vitamin D and very low dietary calcium — the dominant form in Nigeria and The Gambia, and vitamin D deficiency rickets dominant in Mongolia, Tibet and parts of the Middle East and South Asia, where prevalence in some surveys has exceeded 30 to 70 per cent of young children.

Vitamin D deficiency, defined as serum 25-hydroxyvitamin D below 30 nmol/L, the threshold used in the 2016 Global Consensus on nutritional rickets, affects roughly 5 to 20 per cent of the general population in high-income countries, with much higher figures in specific groups — up to 50 to 80 per cent in veiled women, dark-skinned populations at high latitude, nursing-home residents and people with limited outdoor exposure. Insufficiency, below 50 nmol/L, affects roughly 30 to 60 per cent of populations in Europe and North America in winter, depending on the threshold chosen.

Rickets presents from about three months to two years in the vitamin D deficiency form, and later — 18 months to four years, and again in adolescence — in the calcium deficiency form. Osteomalacia is an adult and elderly disease.

The geographic paradox is that rickets is common at high latitude and in sunny countries where clothing, indoor living, air pollution and skin pigmentation limit UVB exposure: Mon-

golia, Tibet, the Gulf, and parts of North Africa and South Asia have among the highest reported rates.

Rickets itself rarely kills, and hypocalcaemic seizures, dilated cardiomyopathy and cardiac arrest from vitamin D deficiency in infancy are documented causes of infant death and are entirely preventable. Rickets admissions in England rose several-fold between the 1990s and the 2010s, and the condition is now described as re-emerging in several high-income countries.

**Where it starts.** Two distinct causes, and distinguishing them matters for treatment. Vitamin D deficiency — inadequate cutaneous synthesis plus inadequate intake. Dietary calcium deficiency — adequate vitamin D but calcium intake far below requirement, typical of maize- and cassava-based diets with little dairy, and the dominant form in Nigeria and The Gambia. Giving vitamin D alone does not cure the calcium form.

Cutaneous synthesis is the main source and it is highly constrained. UVB wavelengths of 290 to 315 nm are required, and above roughly 35 to 37 degrees of latitude there is effectively no cutaneous synthesis in winter — the vitamin D winter lasts roughly November to March in northern Europe. Melanin absorbs UVB, and deeply pigmented skin requires roughly three to ten times the exposure of pale skin for the same synthesis. Clothing and veiling block synthesis entirely in covered areas. Sunscreen at correct application thickness blocks most synthesis, though real-world application reduces it less than laboratory studies suggest. Glass blocks UVB, so indoor sunlight does not work. Cutaneous synthetic capacity falls by roughly 50 to 75 per cent between young adulthood and old age†. Air pollution attenuates UVB measurably and is a documented contributor in South Asian cities. Synthesis occurs around solar noon, and morning and evening sun at temperate latitudes produces little.

Dietary sources are few: oily fish, cod liver oil, egg yolk, UV-exposed mushrooms, liver and fortified foods. Unfortified diets essentially cannot supply adequate vitamin D, which is why fortification and supplementation exist.

Breast milk is low in vitamin D, roughly 20 to 80 IU/L, so exclusively breastfed infants require supplementation unless the mother is on high-dose supplementation. This is the single commonest cause of nutritional rickets in high-income countries — over 90 per cent of Canadian surveillance cases were breastfed infants without supplements — and it is one of the few places in this chapter where breastfeeding alone is insufficient and a supplement is required.

Maternal vitamin D deficiency produces deficient neonates, because fetal stores depend on maternal status. Malabsorption — coeliac disease, Crohn's disease, cystic fibrosis, cholestasis, bariatric surgery — causes it. Drugs accelerate vitamin D catabolism: anticonvulsants (phenytoin, phenobarbital, carbamazepine), rifampicin, glucocorticoids, antiretrovirals. Chronic kidney disease impairs 1-alpha-hydroxylation and causes renal rickets and osteodystrophy, which requires active vitamin D analogues rather than cholecalciferol.

Genetic forms must be distinguished because they do not respond to ordinary doses. X-linked hypophosphataemic rickets, from *PHEX*, at roughly 1 in 20,000, is now treated with burosumab, an anti-FGF23 antibody far more effective than phosphate and active vitamin D and costing on the order of US$200,000 to US$400,000 a patient-year at lowest available acquisition cost†. Vitamin D-dependent rickets type 1, from *CYP27B1* 1-alpha-hydroxylase deficiency, is treated with calcitriol. Type 2, from a *VDR* receptor defect, needs very high-dose calcium and calcitriol. Hereditary hypophosphatasia, from *ALPL*, is treated with asfotase alfa.

Serum 25-hydroxyvitamin D concentration is heritable at roughly 0.2 to 0.5 in twin studies, with *GC*, *CYP2R1*, *DHCR7* and *CYP24A1* as the main loci†. Nutritional rickets itself is environmental.

*Not known*: what serum 25-hydroxyvitamin D concentration people actually need. The thresholds differ between authorities — the United States Institute of Medicine set 50 nmol/L as sufficient for bone health in 97.5 per cent of the population, the Endocrine Society prefers above 75 nmol/L, and the 2016 Global Consensus on nutritional rickets uses below 30 nmol/L as deficiency, 30 to 50 as insufficiency and above 50 as sufficiency. These are not reconciled, and the entire vitamin D deficiency prevalence literature depends on which is chosen.

**Cure status.** Nutritional rickets and adult osteomalacia: CURABLE. Genetic forms, X-linked hypophosphataemia and vitamin D-dependent rickets: CONTROLLABLE. Established fixed deformity: RELIEF ONLY, with corrective osteotomy.

Nutritional rickets heals completely with vitamin D and calcium. Biochemical healing — alkaline phosphatase, calcium, phosphate, parathyroid hormone — occurs over weeks; radiographic healing over one to three months; and bone deformity in young children remodels and usually corrects fully without surgery if treated before the deformity becomes fixed. Established severe deformity in older children may require corrective osteotomy, so the cure is complete only if it comes early enough.

Hypocalcaemic seizures and cardiomyopathy reverse with calcium and vitamin D.

Calcium-deficiency rickets requires calcium, and vitamin D alone will not cure it. This is the commonest treatment error in the African literature.

The genetic forms are controllable rather than curable: X-linked hypophosphataemia responds well to burosumab and requires it indefinitely, and vitamin D-dependent rickets requires lifelong calcitriol.

Adult osteomalacia heals with repletion, with resolution of bone pain and proximal myopathy, over months.

**Prevention.** Universal infant vitamin D supplementation. The measure that works, and the near-universal recommendation: 400 IU (10 µg) daily from birth for all breastfed infants, and for formula-fed infants taking less than roughly one litre of fortified formula a day. Where implemented and adhered to, nutritional rickets becomes rare: Finland had very high rickets rates in the early twentieth century and has had near-universal infant supplementation plus food fortification since, and rickets is now almost absent. Adherence is the problem — supplementation rates among breastfed infants are roughly 20 to 60 per cent in surveys in Canada, the United States and the United Kingdom, and over 90 per cent of Canadian rickets surveillance cases were unsupplemented breastfed infants. Cost is roughly one to five US dollars per infant-year for vitamin D drops (2024)†. STRONG.

Pregnancy supplementation at 400 to 1,000 IU a day, higher in deficient women, raises neonatal 25-hydroxyvitamin D and reduces neonatal hypocalcaemia. The MAVIDOS trial found no effect on neonatal bone mineral content overall and a benefit in winter-born infants. MODERATE.

Food fortification. Mandatory or widespread vitamin D fortification of milk, in the United States and Canada from the 1930s and 1940s; of margarine, mandatory in the United Kingdom from the 1940s until deregulation; and more recently of a wider range of foods in Finland, from 2003 onward, for fluid milks and fat spreads. **The Finnish fortification policy produced a measured population rise in mean serum 25-hydroxyvitamin D of roughly 20 nmol/L, and reduced the prevalence of concentrations below 50 nmol/L from roughly 55 per cent to roughly 9 per cent between the 2000 and 2011 national health surveys**†. This is the clearest before-and-after fortification dataset for vitamin D. STRONG. United States and Canadian milk fortification effectively eliminated classical nutritional rickets in the mid-twentieth century: STRONG, from historical before-and-after data. Overall: STRONG for biochemical status and for classical rickets; CONTESTED for the wider non-skeletal claims.

Calcium adequacy, the other half, and the limiting nutrient in much of sub-Saharan Africa. STRONG for calcium-deficiency rickets.

Sunlight exposure. Effective and free, and constrained by latitude, season, pigmentation, clothing, air pollution and skin cancer risk. The 2016 Global Consensus declined to give a quantitative sun exposure recommendation because the required dose varies so widely and because of skin cancer risk. MODERATE — mechanistically certain, not quantifiable as a prescription.

Targeted supplementation of high-risk groups: dark-skinned and veiled individuals at high latitude, nursing-home and housebound people, people on anticonvulsants, those with malabsorption, and people with obesity, in whom vitamin D is sequestered in adipose tissue and serum concentrations are lower for the same intake. STRONG.

What vitamin D does not prevent, by randomised trial — stated because it determines how much to spend. VITAL, with 25,871 participants on 2,000 IU a day for 5.3 years, found no reduction in cancer incidence or major cardiovascular events. D2d, with 2,423 participants with prediabetes on 4,000 IU a day, found no significant reduction in progression to type 2 diabetes overall†. Multiple trials and meta-analyses find no reduction in fracture risk from vitamin D alone in community-dwelling adults; the fracture benefit is seen with vitamin D plus calcium in institutionalised and deficient populations. On falls the effect is inconsistent, and high intermittent doses — 500,000 IU annually, 60,000 IU monthly — increased falls and fractures in two randomised trials†, an important harm. On respiratory infection, meta-analyses show a small reduction concentrated in deficient individuals receiving daily rather than bolus dosing, the largest trials have been null, and the effect is CONTESTED. So vitamin D prevents rickets and osteomalacia, which is a large and certain benefit in the deficient; the wider claims have mostly not survived randomised testing.

**Treatment.** Cholecalciferol (vitamin D3) or ergocalciferol (vitamin D2), with calcium. The 2016 Global Consensus on the Prevention and Management of Nutritional Rickets recommends, for treatment: infants under three months, 2,000 IU a day for at least three months; three to 12 months, 2,000 IU a day; 12 months to 12 years, 3,000 to 6,000 IU a day; and over 12 years, 6,000 IU a day — for a minimum of three months, followed by maintenance of 400 to 600 IU a day, together with oral calcium 500 mg a day in all cases, because the healing bone takes up calcium rapidly and hypocalcaemia can otherwise be precipitated. Single high-dose therapy of 50,000 to 600,000 IU is an alternative where adherence is a problem, and doses above 300,000 IU risk hypercalcaemia. Off-patent, at roughly one to ten US dollars a patient-year for cholecalciferol at preventive doses, and roughly US$2 to US$20 for a full treatment course at generic or lowest available acquisition cost, 2024† — among the cheapest cures in medicine. The listing status of ergocalciferol, cholecalciferol and calcium needs checking against the 24th List†.

Calcium — carbonate, lactate, gluconate, or dietary. Off-patent, at US$5 to US$30 a patient-year at generic or lowest available acquisition cost, 2024†. For calcium-deficiency rickets, calcium is the treatment and vitamin D is adjunctive. Listing status needs checking against the 24th List†.

Intravenous calcium for hypocalcaemic seizures or cardiomyopathy, an emergency, at cents an ampoule; UNICEF's indicative price for calcium gluconate was printed at 10.66 and at US$5.01 on different catalogue pages in October 2026, which is why these are given as indicative and dated rather than as a price. Listing status needs checking against the 24th List†.

Active vitamin D analogues — alfacalcidol or calcitriol — for renal rickets, 1-alpha-hydroxylase deficiency and vitamin D receptor defects. Not for nutritional rickets. Off-patent, at US$50 to US$400 a patient-year at generic or lowest available acquisition cost, 2024†. Calcitriol's listing status needs checking against the 24th List†.

Phosphate and active vitamin D, or burosumab, for X-linked hypophosphataemia. Burosumab is patented at roughly US$200,000 to US$400,000 a patient-year at lowest available acquisition cost, 2024†; its listing status needs checking against the 24th List†. The price-to-effect contrast with nutritional rickets — cured for under US$20 at generic or lowest available acquisition cost, 2024 — is one of the widest in this chapter.

Orthopaedic correction for fixed deformity after biochemical healing. Treatment of the underlying malabsorption or drug cause, with higher doses and water-miscible preparations in malabsorption.

Monitoring: alkaline phosphatase, calcium, phosphate, parathyroid hormone, 25-hydroxyvitamin D, and wrist or knee radiographs for healing. A falling alkaline phosphatase is the cheapest marker of response.

**Simple means.** This entry, with iodine deficiency and vitamin A deficiency, is one where the simple means is the cure.

Sunlight. Free, and the evolved source. The constraints are quantitative and must be stated: UVB at 290 to 315 nm, around solar noon, on uncovered skin, outdoors because glass blocks it, with roughly three to ten times longer exposure needed for deeply pigmented skin, and effectively no synthesis above roughly 35 to 37 degrees of latitude in winter. The 2016 Global Consensus declined to give a numerical sun prescription for those reasons and because of

skin cancer risk, so sunlight is reported here as an effective means, not as a dosing instruction.

Vitamin D drops for infants, 400 IU a day, at roughly one to five dollars per infant-year. This single measure, where adhered to, makes nutritional rickets rare. Over 90 per cent of Canadian surveillance cases were unsupplemented breastfed infants, so the gap is adherence, not cost or technology.

Cod liver oil. The historical cure, identified in the 1920s, and still among the cheapest and most concentrated natural sources. A teaspoon supplies several times the daily requirement.

Oily fish — sardines, mackerel, herring, salmon — including small fish eaten whole with bones, which supply vitamin D and calcium together.

Egg yolk, liver, and UV-exposed mushrooms. Mushrooms exposed to sunlight generate substantial vitamin D2, a free household intervention.

Dietary calcium: dairy, small whole fish with bones, ground eggshell — used as a calcium source in several low-income settings and measurably effective — dark green leaves, calcium-set tofu, and traditionally nixtamalised maize, lime-treated, which raises the calcium content of the staple substantially. Nixtamalisation is an ancient Mesoamerican process using wood ash or lime, and it is one of the best examples of a traditional food technology solving a nutritional deficiency.

Fortified milk and margarine. The cost per person per year of fortification is cents, and Finland's programme moved mean population 25-hydroxyvitamin D by roughly 20 nmol/L and cut the proportion below 50 nmol/L from roughly 55 per cent to roughly 9 per cent.

Measuring alkaline phosphatase — a cheap, widely available blood test that is the most useful single marker of active rickets where 25-hydroxyvitamin D assays are unavailable.

Not using high intermittent bolus doses. Two randomised trials found that annual 500,000 IU and monthly 60,000 IU regimens increased falls and fractures. A simple means of avoiding harm.

**Gaps.** The threshold for vitamin D deficiency is unresolved: the United States Institute of Medicine sets 50 nmol/L as sufficient, the Endocrine Society prefers above 75 nmol/L, and the Global Consensus on nutritional rickets sets below 30 nmol/L as deficiency. Every prevalence figure is threshold-dependent and the literature routinely quotes figures from one framework against another. 25-hydroxyvitamin D assays are poorly standardised between laboratories, with inter-assay differences of 10 to 30 per cent†, which further undermines comparison. No global prevalence estimate for nutritional rickets exists; the incidence figures here are from national surveillance systems in a handful of high-income countries plus scattered surveys elsewhere. Calcium-deficiency rickets and vitamin D deficiency rickets are frequently not distinguished in the literature, and the treatment differs; Nigerian and Gambian data show the calcium form dominating there, and vitamin D alone does not cure it. The non-skeletal claims have largely failed randomised testing — VITAL negative for cancer and cardiovascular outcomes, D2d negative for diabetes prevention, no fracture benefit from vitamin D alone, inconsistent falls data, and a contested respiratory infection effect — and much published and popular material predates or ignores these trials. High intermittent bolus dosing increased falls and fractures in two trials and remains in widespread use. Infant supplementation adherence is 20 to 60 per cent where recommended, for behavioural and system-level rather than evidential reasons. Obesity lowers serum 25-hydroxyvitamin D for the same intake through adipose sequestration, so thresholds derived in lean populations may misclassify. Burosumab at roughly US$200,000 to US$400,000 a patient-year at lowest available acquisition cost treats a condition affecting roughly 1 in 20,000, while nutritional rickets — far commoner — is cured for under US$20 at generic or lowest available acquisition cost, and no source reconciles that allocation.

---

## Hypothyroidism

**What it is.** The thyroid makes too little thyroid hormone, and everything slows: heart rate, bowels, thought, metabolism. People feel cold, tired, constipated and low, and gain weight. A daily tablet replaces what is missing.

**Measured.** A meta-analysis of 17 European studies from 1975 to 2012 (Garmendia Madariaga et al., *Journal of Clinical Endocrinology and Metabolism*) found that nearly 11 per cent of Europeans have thyroid dysfunction and only about half of them know it. Known dysfunction has a mean prevalence of 3.82 per cent, of which known hypothyroidism is 3.05 per cent and known hyperthyroidism 0.75 per cent; about 85.2 per cent of known cases were subclinical. Undiagnosed dysfunction has a mean prevalence of 6.71 per cent, of which undiagnosed hypothyroidism is 4.94 per cent and undiagnosed hyperthyroidism 1.72 per cent; about 80.1 per cent of undiagnosed cases were subclinical†.

Incidence is 259.12 per 100,000 a year for all thyroid dysfunction, of which 226.2 is hypothyroidism and 51 hyperthyroidism†. Subclinical hypothyroidism, a raised thyroid-stimulating hormone (TSH) with normal free thyroxine, is the leading form. Overt hypothyroidism affects roughly 0.3 to 2 per cent of people in iodine-sufficient populations. Subclinical disease affects roughly 4 to 10 per cent, rising to 15 to 20 per cent of women over 60†. Women outnumber men by roughly 5 to 8 to 1, and prevalence rises steeply with age†.

Congenital hypothyroidism occurs in roughly 1 in 2,000 to 1 in 4,000 births. It is the commonest treatable cause of intellectual disability and is found by newborn screening. In iodine-sufficient countries the dominant cause is autoimmune thyroiditis (Hashimoto). In iodine-deficient areas iodine deficiency is the dominant cause, so the world distribution of hypothyroidism follows the iodine map.

The disease is rarely recorded as a cause of death. Myxoedema coma, the decompensated extreme, is now rare and carries a mortality of roughly 20 to 40 per cent even with treatment†. Levothyroxine is consistently among the three most prescribed drugs by volume in the United States and the United Kingdom, with over 100 million prescriptions a year in the United States alone†. Set against the prevalence of overt disease, that volume shows substantial prescribing for subclinical disease and for symptoms without biochemical disease.

**Where it starts.** Autoimmune thyroiditis is the dominant cause where iodine is sufficient. Lymphocytes infiltrate and destroy the gland. Antibodies to thyroid peroxidase (anti-TPO) are present in roughly 90 to 95 per cent of cases and antibodies to thyroglobulin in roughly 60 to 80 per cent†. Anti-TPO antibodies are found in roughly 10 to 15 per cent of the general population, most of whom have normal thyroid function, so the antibody predicts risk and not disease. Progression from antibody-positive normal function to overt hypothyroidism runs at roughly 2 to 4 per cent a year, and faster if TSH is already high-normal†.

Iodine deficiency is the dominant cause worldwide. Iodine excess also causes hypothyroidism, particularly in people with underlying autoimmune thyroiditis: amiodarone, radiographic contrast, kelp supplements and povidone-iodine are the sources. The dose-response is U-shaped, as for iodine generally.

Treatment of other conditions accounts for a large share of cases in high-income countries. Thyroidectomy, radioiodine for hyperthyroidism and external radiotherapy to the neck remove or damage the gland. Lithium, amiodarone, interferon-alpha, tyrosine kinase inhibitors such as sunitinib and sorafenib, and immune checkpoint inhibitors cause it as a drug effect. Thyroid dysfunction occurs in roughly 5 to 20 per cent of patients on checkpoint inhibitors and is now a common cause of new hypothyroidism in oncology.

Postpartum thyroiditis affects roughly 5 to 10 per cent of women after delivery, and roughly 20 to 40 per cent of those go on to permanent hypothyroidism†.

Central hypothyroidism, from pituitary or hypothalamic disease, is roughly 1 in 1,000 of all cases†. The causes are tumour, surgery, radiotherapy, Sheehan syndrome, haemochromatosis and hypophysitis, including that caused by checkpoint inhibitors. TSH is low or normal in this form, so TSH-based screening misses it. Thyroid hormone must also not be started before glucocorticoid replacement if adrenal insufficiency coexists.

Heritability of autoimmune thyroid disease is roughly 0.6 to 0.8 in twin studies, among the highest of any autoimmune disease, and sibling relative risk is roughly 9 to 17†. Associated loci include HLA-DR3, *CTLA4*, *PTPN22*, *CD40*, *TSHR*, *FOXP3* and thyroglobulin. No clinically useful genetic test exists.

Smoking protects against hypothyroidism and is a risk factor for Graves disease. The inversion is consistent and unexplained. Selenium deficiency worsens autoimmune thyroiditis, and supplementation lowers anti-TPO titres in trials without changing clinical outcomes. Vitamin

D deficiency is associated, with causality unresolved. Pregnancy and the postpartum period unmask autoimmune thyroid disease.

Congenital causes are thyroid dysgenesis (agenesis, ectopia or hypoplasia), roughly 85 per cent of congenital hypothyroidism, and dyshormonogenesis, roughly 15 per cent†. The latter is autosomal recessive and involves *TPO*, *TG*, *SLC5A5* and *DUOX2*.

*Not known*: what triggers autoimmune thyroiditis. Why so many people with normal thyroid function attribute symptoms to the thyroid. Whether combined thyroxine and triiodothyronine helps the roughly 10 to 15 per cent of treated patients who stay symptomatic with a normal TSH†.

**Cure status.** Overt hypothyroidism from autoimmune disease, surgery, radioiodine or radiotherapy: CONTROLLABLE. Iodine-deficiency hypothyroidism: CURABLE, by iodine. Drug-induced hypothyroidism: CURABLE where withdrawal is possible, as it often reverses. The hypothyroid phase of postpartum, subacute (de Quervain) and silent thyroiditis: SELF-LIMITING, with roughly 60 to 80 per cent recovering thyroid function†.

Levothyroxine restores normal function in essentially all patients. Taken once daily and titrated to TSH, it normalises symptoms, lipids and metabolic rate, and life expectancy is normal. It is replacement for life, because the thyroid does not recover. That is control, not cure.

**Prevention.** Universal salt iodisation prevents the globally dominant cause, at a few cents a tonne of salt. See iodine deficiency disorders. STRONG.

Newborn screening for congenital hypothyroidism. Levothyroxine started within the first two weeks prevents the intellectual disability entirely. This is one of the highest-value screening programmes in existence. STRONG.

Monitoring thyroid function in patients on lithium, amiodarone, interferon, tyrosine kinase inhibitors and checkpoint inhibitors, and after thyroid surgery, radioiodine or neck radiotherapy. STRONG.

Avoiding iodine excess: amiodarone where alternatives exist, kelp supplements, and unnecessary iodinated contrast in people with autoimmune thyroid disease. MODERATE.

Thyroid function testing in pregnancy for high-risk women: previous thyroid disease, positive antibodies, type 1 diabetes, prior postpartum thyroiditis, recurrent miscarriage. Overt maternal hypothyroidism harms fetal neurodevelopment and is corrected cheaply. STRONG for high-risk screening. Universal screening in pregnancy is CONTESTED: the CATS trial found no improvement in child IQ at 3 years from screening and treating, and the United States and United Kingdom do not recommend universal screening, while some endocrine societies do.

Selenium supplementation lowers anti-TPO titres in trials. No effect on progression to hypothyroidism or on symptoms has been shown. WEAK.

Smoking cessation is recommended for every other reason and not for this one, because smoking is protective against hypothyroidism. Not graded, and reported for accuracy.

No established prevention of autoimmune thyroiditis itself exists.

**Treatment.** Levothyroxine, oral, once daily on an empty stomach, titrated to a TSH within the reference range, and to the lower half of it in pregnancy. It is on the WHO Essential Medicines List 24th List (2025), section 18.7, for hypothyroidism, as 25, 50 and 100 µg oral solid, first added in 1977. It has been off-patent for decades. The generic international price is a few dollars to a few tens of dollars a patient-year, and retail prices in the United States run higher; it is among the cheapest complete treatments for any chronic disease.

Full replacement in overt disease is roughly 1.6 µg/kg a day, with lower starting doses in the elderly and in ischaemic heart disease. The therapeutic index is narrow and formulations are not perfectly interchangeable, so a change of brand requires a repeat TSH. Calcium, iron, proton pump inhibitors, bile acid sequestrants, soy, coffee and food impair absorption, and this explains much apparent treatment failure.

Subclinical hypothyroidism is where the evidence says not to treat most people. The TRUST trial (Stott et al., *New England Journal of Medicine*, 2017) gave levothyroxine or placebo for a median of 12 months to 737 adults aged 65 and over with subclinical hypothyroidism

and found no improvement in hypothyroid symptoms or tiredness scores. The IEMO 80-plus trial, in adults aged 80 and over, found no benefit†. A meta-analysis of 21 trials (Feller et al., *JAMA*, 2018) found no association of levothyroxine with improved quality of life or thyroid-related symptoms. A 2019 *BMJ* Rapid Recommendation advises strongly against routine levothyroxine for adults with subclinical hypothyroidism.

Treatment is still generally advised at a TSH above roughly 10 mIU/L, in pregnancy or planned pregnancy, and in young symptomatic patients with positive antibodies. Subclinical disease is roughly ten times commoner than overt disease and accounts for a large share of prescribing.

Liothyronine (triiodothyronine), shorter-acting, is used in combination regimens and in myxoedema coma. Its listing status needs checking against the 24th List†. It is off-patent, yet UK prices rose roughly sixty-fold between 2007 and 2017 because of a single-supplier market†. That led to a Competition and Markets Authority investigation and a substantial fine. Prices have since fallen. This is a molecule that became unaffordable through market structure and not through patents.

Combined thyroxine and triiodothyronine has shown no consistent superiority over thyroxine alone for symptoms or quality of life in randomised trials and meta-analyses. A subgroup, possibly defined by a *DIO2* polymorphism, may benefit. CONTESTED. Desiccated porcine thyroid extract, fixed in ratio and variable in content, is not recommended by major guidelines; some patients prefer it. CONTESTED.

Myxoedema coma needs intravenous levothyroxine or liothyronine, intravenous hydrocortisone until adrenal insufficiency is excluded, passive rewarming, and ventilatory and circulatory support. Hydrocortisone's listing status needs checking against the 24th List†.

In central hypothyroidism with possible adrenal insufficiency, glucocorticoid goes first. Thyroid hormone given first can precipitate adrenal crisis, which is a lethal failure mode. In pregnancy the levothyroxine dose typically rises by roughly 25 to 50 per cent from early pregnancy, with TSH checked every 4 to 6 weeks†. Untreated overt maternal hypothyroidism is associated with miscarriage, pre-eclampsia, low birthweight and impaired child neurodevelopment.

Not to be done: treating most subclinical hypothyroidism, treating symptoms in a biochemically normal patient with levothyroxine, and combining thyroxine and triiodothyronine by default.

**Simple means.** Where iodine deficiency is the cause, which is most of the world's hypothyroidism, the simple means is the cure and the prevention: iodised salt, at a few cents a tonne.

Levothyroxine is not a no-chain intervention, but it is as close as a chronic-disease treatment gets. It is a single daily tablet, off-patent, on the Essential Medicines List, at a few dollars a patient-year, and it gives normal life expectancy. The binding constraint worldwide is not the drug but the TSH assay needed to titrate it.

Taking the tablet on an empty stomach, away from calcium, iron, coffee and antacids, is free and is the commonest reason a dose appears not to work. Not treating subclinical hypothyroidism avoids cost, monitoring and overtreatment, because the trials are negative. Palpation of the neck costs nothing and finds goitre. The newborn heel-prick, a dried blood spot and a TSH assay, prevents intellectual disability entirely. Seaweed and marine fish supply dietary iodine, with the caution that excess also causes hypothyroidism. Fibre and fluids ease constipation in the weeks before replacement takes full effect.

Where no laboratory exists, hypothyroidism can be treated on clinical grounds with a standard levothyroxine dose and clinical follow-up, and this is done. The TSH assay, at a few dollars, is what makes treatment safe, and it is the real access gap.

**Gaps.** The European meta-analysis spans 1975 to 2012, a period in which iodine status, assay sensitivity and diagnostic thresholds all changed, so its pooled figures mix eras. Subclinical disease is 80 to 85 per cent of detected thyroid dysfunction†, and whether it is a disease at all is unresolved. Figures that combine overt and subclinical disease, such as the 11 per cent figure, describe a mixture of a treatable condition and a laboratory finding.

The TSH reference range is contested. The upper limit in use, commonly 4.0 to 4.5 mIU/L, is a population statistic that rises with age and differs between assays. Narrowing it would reclassify millions of people as diseased.

Levothyroxine prescribing greatly exceeds the prevalence of overt disease, and no reconciliation exists in the literature. TRUST, IEMO 80-plus and the *JAMA* meta-analysis are negative for treating subclinical hypothyroidism, and prescribing continues to rise. Trial and practice disagree.

Combined thyroxine and triiodothyronine is negative overall in trials while patient groups report benefit. Universal pregnancy screening is negative for child IQ in CATS, and endocrine societies and national bodies disagree. The mechanism of the protective effect of smoking is unknown. Central hypothyroidism is missed by TSH screening and its true prevalence is unknown. No global prevalence estimate with GBD-level method exists; the figures here are from European and North American surveys.

The sixty-fold liothyronine price rise shows that off-patent status does not guarantee affordability. No systematic data exist on how often this occurs.

---

## Hyperthyroidism and Graves disease

**What it is.** The thyroid makes too much hormone. The heart races, weight falls despite eating, hands shake, and the person is hot, anxious and sleepless. In Graves disease an antibody switches the thyroid on, and in some people the eyes become inflamed and protrude.

**Measured.** The European meta-analysis of 1975 to 2012 (Garmendia Madariaga et al., described under hypothyroidism) gives known hyperthyroidism at 0.75 per cent and undiagnosed hyperthyroidism at 1.72 per cent, of which about 80 per cent is subclinical. Incidence is 51 per 100,000 a year.

Overt hyperthyroidism affects roughly 0.2 to 1.3 per cent of people in iodine-sufficient populations and subclinical hyperthyroidism roughly 0.7 to 3 per cent†. Graves disease accounts for roughly 60 to 80 per cent of hyperthyroidism in iodine-sufficient countries†. Toxic multinodular goitre and toxic adenoma account for most of the rest and predominate in iodine-deficient and older populations. The ratio of Graves to nodular disease shifts with iodine status, and this is a measured effect of iodisation programmes.

Graves disease is 5 to 10 times commoner in women, with onset mostly between 30 and 50 years†. Toxic nodular disease comes later, typically after 60.

Graves orbitopathy, the eye disease, is clinically apparent in roughly 25 to 30 per cent of Graves patients, moderate to severe in roughly 5 to 6 per cent, and sight-threatening in roughly 0.3 to 0.5 per cent†. Thyroid storm accounts for roughly 1 to 2 per cent of hospitalised thyrotoxic patients and kills roughly 10 to 30 per cent of them even with treatment†.

Untreated or undertreated disease has measured consequences. Atrial fibrillation occurs in roughly 10 to 15 per cent of overt hyperthyroid patients over 60†. Individual-participant-data meta-analyses associate subclinical hyperthyroidism with atrial fibrillation (hazard ratio roughly 1.7 to 1.9), hip fracture (roughly 1.3 to 1.4) and total and cardiovascular mortality (roughly 1.2 to 1.3)†. The risk is concentrated in those with TSH below 0.1 mIU/L. Thyrotoxicosis also accelerates bone loss.

Graves disease is commoner in iodine-sufficient populations. Iodine-induced hyperthyroidism occurs transiently when iodisation is introduced into a previously deficient population with nodular goitre. It has been measured in Zimbabwe, the Democratic Republic of Congo and elsewhere.

**Where it starts.** In Graves disease the mechanism is established and unusual in autoimmunity, because the antibody stimulates instead of destroying. Antibodies to the TSH receptor (TRAb) act as agonists and drive continuous hormone synthesis and thyroid growth. TRAb is present in roughly 95 to 99 per cent of untreated Graves patients and is diagnostic and prognostic: high titres predict relapse after antithyroid drugs are withdrawn. The same antibody acts on orbital fibroblasts, which carry the TSH receptor and the IGF-1 receptor, and causes the orbitopathy. Eye and thyroid disease share a cause.

Heritability of Graves disease is roughly 0.6 to 0.8 in twin studies. Concordance is roughly 20 to 35 per cent in identical twins and 2 to 5 per cent in non-identical twins, and sibling relative risk is roughly 10†. The loci are HLA-DR3 (*DRB1*03*), *CTLA4*, *PTPN22*, *CD40*, *TSHR*, *FCRL3* and *IL2RA*. No clinically useful genetic test exists.

Smoking is the strongest modifiable risk factor. It roughly doubles the risk of Graves disease (odds ratio roughly 1.9 to 3.3)†. For orbitopathy the effect is far larger, with an odds ratio of roughly 7 to 8 in current smokers, dose-related†. Smoking also worsens the response to orbitopathy treatment and raises the risk of orbitopathy worsening after radioiodine. Stopping improves orbitopathy outcomes.

Iodine excess precipitates hyperthyroidism in nodular goitre: amiodarone (type 1), radiographic contrast, kelp, and the rise seen when iodisation begins. Other drugs act as well. Amiodarone causes two types of thyrotoxicosis that need different treatment. Interferon-alpha, and rarely lithium, can cause it. Checkpoint inhibitors cause thyroiditis with a thyrotoxic phase in roughly 5 to 10 per cent†. Alemtuzumab causes Graves disease in roughly 20 to 30 per cent of treated multiple sclerosis patients, one of the largest drug-induced autoimmunity effects known.

Graves disease commonly presents or relapses in the first postpartum year, and pregnancy itself, being immunosuppressive, often improves it. Selenium deficiency is associated with orbitopathy severity. Stress and infection are proposed triggers and are not established.

Thyroiditis causes a transient thyrotoxic phase that is not hyperthyroidism in the synthetic sense. Subacute (de Quervain, post-viral, painful), silent and postpartum thyroiditis release stored hormone and then become hypothyroid. Telling these from Graves disease is the central diagnostic task, because thyroiditis needs no antithyroid drug and resolves by itself.

*Not known*: what triggers the TSH receptor antibody. Why orbitopathy affects only a quarter of Graves patients. Why smoking raises orbitopathy risk roughly eight-fold. Which patients will remit after antithyroid drugs. TRAb titre and goitre size help but do not predict individually, and roughly half relapse.

**Cure status.** Graves disease treated by radioiodine or thyroidectomy: CONTROLLABLE — the hyperthyroidism is removed and permanent hypothyroidism follows in nearly all, held by lifelong levothyroxine. Graves disease treated by a thionamide course: CURABLE in roughly 40 to 50 per cent who enter lasting remission†, and CONTROLLABLE for as long as the drug is taken in the rest. Toxic nodular disease: CURABLE by radioiodine or surgery; thionamides give CONTROLLABLE only. Thyroiditis-associated thyrotoxicosis: SELF-LIMITING. Graves orbitopathy: CONTROLLABLE, and this is where the serious residual disability lies.

Radioiodine (iodine-131) ablates the thyroid. A single dose cures roughly 80 to 90 per cent of Graves disease, and a second dose cures most of the remainder. The cure converts a costly, fluctuating disease into a cheap, stable one. A therapeutic dose costs hundreds to low thousands of dollars, plus the handling infrastructure.

Total thyroidectomy cures immediately and with near certainty, at the cost of permanent hypothyroidism and surgical risk. Permanent recurrent laryngeal nerve injury is roughly 1 to 2 per cent and permanent hypoparathyroidism roughly 1 to 3 per cent in high-volume centres, and both are considerably higher in low-volume settings.

A 12 to 18 month course of carbimazole or methimazole induces lasting remission in roughly 40 to 50 per cent of Graves patients, and the rest relapse, usually within a year of stopping. Longer treatment, five years or more, raises remission to roughly 60 to 70 per cent in randomised and cohort data, and practice has shifted toward longer courses. Antithyroid drugs do not work for toxic nodular disease, because nodular autonomy does not remit. Definitive treatment is required there.

In thyroiditis the thyrotoxic phase resolves over weeks to months. Treatment is a beta-blocker and, if painful, an anti-inflammatory drug or corticosteroid. Antithyroid drugs do not work and should not be given, because there is no excess synthesis to block.

Teprotumumab, an anti-IGF-1 receptor antibody approved in the United States in January 2020, is the first drug to reverse proptosis. In its phase 3 trial 83 per cent of treated patients had a proptosis response of at least 2 mm against 10 per cent on placebo, with improvement in diplopia and quality of life. A course of 8 infusions costs hundreds of thousands of dollars. Hearing impairment occurs in roughly 10 per cent and can be permanent†.

Intravenous methylprednisolone remains first-line for moderate-to-severe active orbitopathy. It is off-patent and costs tens to hundreds of dollars a course. Roughly 50 to 80 per cent respond in inflammatory signs, with little effect on proptosis. The cost of treating the eye disease thus spans from tens of dollars to hundreds of thousands, for different endpoints.

**Prevention.** Smoking cessation. The most effective preventive measure here: smoking roughly doubles Graves disease risk and raises orbitopathy risk roughly 7 to 8-fold†, dose-dependently, and stopping improves orbitopathy outcomes. STRONG.

Avoiding iodine excess in nodular goitre: unnecessary iodinated contrast, kelp, and amiodarone where alternatives exist. MODERATE.

Corticosteroid cover with radioiodine in patients with existing orbitopathy or who smoke reduces the risk of post-radioiodine orbitopathy worsening. MODERATE.

Selenium in mild Graves orbitopathy. The EUGOGO randomised trial found improved eye outcomes and quality of life and slowed progression to more severe disease. MODERATE.

Treating overt and high-risk subclinical hyperthyroidism, to prevent cardiovascular and skeletal consequences. Subclinical hyperthyroidism with TSH below 0.1 mIU/L is associated with atrial fibrillation (hazard ratio roughly 1.7 to 1.9), hip fracture (roughly 1.3 to 1.4) and mortality (roughly 1.2 to 1.3), and guidelines recommend treating that group, particularly over 65†. MODERATE: the association is firm and trial evidence that treatment removes the risk is lacking.

Monitoring thyroid function on amiodarone, interferon, lithium, checkpoint inhibitors and alemtuzumab. STRONG.

Antithyroid drug choice in pregnancy. Propylthiouracil is used in the first trimester, because methimazole and carbimazole are associated with aplasia cutis and choanal and oesophageal atresia, the methimazole embryopathy, at an absolute risk of roughly 2 to 4 per cent†. Treatment switches to methimazole afterwards, because propylthiouracil carries a hepatotoxicity risk of roughly 1 in 10,000†. TSH receptor antibodies cross the placenta and can cause fetal and neonatal thyrotoxicosis, so TRAb measurement in pregnancy guides fetal surveillance. STRONG.

Monitoring for agranulocytosis on thionamides. STRONG.

No prevention of Graves disease itself exists beyond smoking cessation.

**Treatment.** Thionamides are first-line: carbimazole or methimazole, and propylthiouracil in the first trimester, in thyroid storm and in thionamide intolerance. All three are off-patent, and a year of treatment costs tens of dollars. Their status on the WHO Essential Medicines List 24th List needs checking†.

Agranulocytosis occurs in roughly 0.2 to 0.5 per cent, usually in the first three months, and can be fatal†. Patients must be told to stop the drug and obtain a white cell count for fever or sore throat. A written warning costs nothing and is the main safety measure. Propylthiouracil carries a boxed warning for severe liver injury, roughly 1 in 10,000, which is why it is second-line outside the first trimester. Block-and-replace and titration regimens are equally effective, with more drug exposure on block-and-replace.

Beta-blockers, propranolol or atenolol, control tremor, palpitations, anxiety and heat intolerance while the thionamide takes 4 to 8 weeks to work. They are off-patent and cost a few dollars to tens of dollars a patient-year, and they give the fastest relief available. Their listing status needs checking against the 24th List†.

Radioiodine is not a medicine in the Essential Medicines List sense. It needs nuclear medicine facilities, which is the access barrier. It is contraindicated in pregnancy and breastfeeding, and pregnancy must be deferred roughly 6 months†. Thyroidectomy is for large goitres, compressive symptoms, suspected malignancy, severe orbitopathy, pregnancy where drugs fail, and patient preference. It needs preoperative control with thionamides and potassium iodide (Lugol's iodine) to reduce vascularity. Cost varies enormously, from thousands to tens of thousands of dollars.

Potassium iodide blocks hormone release acutely (the Wolff-Chaikoff effect) and is used in thyroid storm and before surgery. It is off-patent and costs cents a dose. Its listing status needs checking against the 24th List†.

Thyroid storm is treated with a thionamide, propylthiouracil preferred because it also blocks conversion of T4 to T3, then iodide at least an hour later, plus a beta-blocker, hydrocortisone, cooling, fluids and treatment of the precipitant. All the drugs are off-patent and cost dollars. Hydrocortisone's listing status needs checking against the 24th List†.

Orbitopathy is treated, first, by stopping smoking, which is free. Selenium is used for mild disease. Intravenous methylprednisolone, cumulatively roughly 4.5 g over 12 weeks, is used for moderate-to-severe active disease, and its listing status needs checking against the 24th List†. Teprotumumab is patented, and its listing status needs checking against the 24th List†. Mycophenolate added to steroids improved outcomes in a European trial. Tocilizumab, rituximab (conflicting trial results) and orbital radiotherapy are also used. Orbital decompression is for optic neuropathy, and strabismus and lid surgery follow once the disease is inactive. Artificial tears, taping the lids at night, prisms for diplopia and sunglasses are symptomatic, cheap and genuinely useful.

Levothyroxine afterwards, because the definitive treatments cause hypothyroidism; see hypothyroidism.

Not to be done: thionamides for thyroiditis, radioiodine for a smoker with active orbitopathy without steroid cover, and iodide before the thionamide in thyroid storm.

**Simple means.** Stopping smoking. It halves the risk of developing Graves disease, reduces orbitopathy risk roughly eight-fold, improves response to orbitopathy treatment, and costs nothing. In this disease it is not general health advice. It is the principal modifiable determinant of whether a person loses vision.

A beta-blocker gives symptomatic relief within hours while definitive treatment is arranged, at a few dollars to tens of dollars a patient-year. Carbimazole or methimazole, at tens of dollars a patient-year, cures roughly half of Graves patients after a 12 to 18 month course and roughly 60 to 70 per cent after a longer one.

A written warning about sore throat and fever. Agranulocytosis occurs in 0.2 to 0.5 per cent and can kill, and the countermeasure is a sentence on paper and a full blood count. Potassium iodide drops, at cents, block hormone release within hours in a crisis. Selenium for mild orbitopathy costs cents a day and has a positive randomised trial.

Artificial tears, taping the eyelids shut at night and sunglasses prevent corneal exposure damage and cost almost nothing. Sleeping with the head elevated reduces periorbital oedema. Distinguishing thyroiditis from Graves disease clinically, by a painful thyroid and a preceding viral illness, avoids unnecessary treatment for free. Nodular goitre calls for avoiding iodine excess: kelp supplements and unnecessary contrast.

**Gaps.** The European prevalence figures mix studies from 1975 to 2012 across changing iodine status and assay generations. About 80 per cent of undiagnosed hyperthyroidism is subclinical, so the headline figures combine a treatable disease with a laboratory finding.

Whether treating subclinical hyperthyroidism removes the measured excess risk of atrial fibrillation, fracture and death has never been tested in a randomised trial. The associations are firm and the intervention evidence is absent.

Which Graves patients will remit after antithyroid drugs cannot be predicted individually, so the choice between a drug course and definitive treatment is made without being able to give the patient their own odds beyond roughly 50 per cent†. Optimal drug duration is unsettled: longer courses give higher remission in cohort and some randomised data, and guidelines have only partly adopted this.

Teprotumumab costs hundreds of thousands of dollars a course and intravenous methylprednisolone tens to hundreds. The endpoints differ, proptosis against inflammatory activity. There is no head-to-head trial on equal footing and no cost-effectiveness consensus. Hearing loss in roughly 10 per cent is a real and incompletely characterised harm. Rituximab trials in orbitopathy conflict, a positive United States trial against a negative European one. Why smoking raises orbitopathy risk roughly eight-fold is unknown.

Radioiodine availability, not cost, is the binding constraint in much of the world, and no systematic data exist on global nuclear medicine coverage for benign thyroid disease. The iodine-induced hyperthyroidism that follows the introduction of iodisation is documented, but its magnitude and duration have not been systematically quantified across programmes.

## Thyroid nodules and goitre

**What it is.** A lump in the thyroid, or a generally enlarged thyroid. Most lumps are benign and cause no trouble. The difficulty is that looking for the few that are cancer finds very large numbers that never would have mattered.

**Measured.** Prevalence depends entirely on the method of looking. Nodules are palpable in roughly 4 to 7 per cent of adults in iodine-sufficient populations†. Ultrasound finds them in roughly 20 to 70 per cent of adults, rising with age and reaching roughly 50 to 60 per cent in women over 60†. Autopsy finds them in roughly 50 per cent of thyroids†. Ultrasound therefore finds roughly ten times as many nodules as palpation, and most of what it finds would never have been known.

The malignancy rate in a nodule under investigation is roughly 5 to 10 per cent, and lower in small nodules found by chance†. Goitre is endemic where prevalence exceeds 5 per cent. About 187 million people had goitre from iodine deficiency in 2010, 2.7 per cent of the world population†. In iodine-sufficient countries sporadic multinodular goitre affects roughly 3 to 5 per cent of adults, rising with age and female sex†.

The central measured fact is the overdiagnosis of thyroid cancer. In South Korea, ultrasound was offered opportunistically alongside a national screening programme from 1999. Thyroid cancer incidence rose roughly fifteen-fold by 2011 and became the country's most commonly diagnosed cancer. Thyroid cancer mortality did not change.

An analysis by the International Agency for Research on Cancer (Vaccarella et al., *New England Journal of Medicine*, 2016) estimated that 470,000 women and 90,000 men were overdiagnosed with thyroid cancer in 12 countries over roughly two decades. In South Korea an estimated 90 per cent of thyroid cancers diagnosed in women were overdiagnosis, and in Italy, France and the United States roughly 70 to 80 per cent. In the United States incidence roughly tripled from 1975 to 2009, almost entirely papillary carcinoma under 2 cm, with mortality essentially flat†. Autopsy series find occult papillary carcinoma in roughly 5 to 35 per cent of thyroids of people who died of other causes, a reservoir of subclinical disease far larger than clinical incidence.

The United States Preventive Services Task Force recommends against screening for thyroid cancer in asymptomatic adults, grade D, an explicit recommendation against a test on the ground of net harm.

Nodules and thyroid cancer diagnosis are roughly 3 to 4 times commoner in women, but thyroid cancer mortality is roughly equal between the sexes. That discrepancy is itself evidence of differential detection. Thyroid cancer mortality is roughly 0.3 to 0.5 per 100,000 a year and has been flat or slowly falling for decades in high-income countries despite the rise in incidence.

**Where it starts.** Iodine deficiency is the dominant global cause of goitre and nodular disease. Chronic TSH stimulation causes hyperplasia, then nodule formation, then autonomy. Iodisation lowers goitre prevalence and shifts the pattern of thyroid disease: less nodular goitre and less follicular carcinoma, more Graves disease and more papillary carcinoma. The papillary-to-follicular ratio rises after iodisation, a consistently measured effect.

Ionising radiation to the neck in childhood is the one firmly established cause of thyroid cancer, with a clear dose-response. After Chernobyl, Belarus, Ukraine and western Russia saw a large excess of childhood papillary carcinoma attributable to iodine-131 in milk, roughly 6,000 to 7,000 excess cases by the 2000s†. The risk was concentrated in those exposed under age 5 and was amplified by background iodine deficiency. Childhood radiotherapy, for benign conditions in the past and for cancer, carries the same risk. The adult thyroid is relatively radioresistant.

Female sex, parity and age are consistently associated with nodules and goitre. Obesity is associated with thyroid cancer incidence in cohort studies, with modest relative risks. A first-degree relative with thyroid cancer raises the risk of papillary carcinoma roughly 4 to 8-fold, a high relative risk on a low base†. Thyroid cancer has one of the highest familial relative risks of any cancer, and the heritability of nodular goitre in twin studies is roughly 0.5 to 0.8†. Loci include *FOXE1*, *NKX2-1*, *DIRC3* and *MBIP*.

Genetic syndromes matter. MEN2 (*RET*) causes medullary thyroid carcinoma, and prophylactic thyroidectomy in *RET* carriers is genuinely preventive. Familial adenomatous polyposis, Cowden syndrome (*PTEN*), DICER1 syndrome and Carney complex also carry thyroid risk. Somatic drivers are *BRAF* V600E in roughly 60 per cent of papillary carcinoma, *RAS* in follicular, *RET/PTC* rearrangements in radiation-associated and paediatric tumours, and *TERT* promoter mutations marking aggressive behaviour.

The incidence rise is detection, not biology. The rise is confined to small papillary tumours, mortality is flat, autopsy prevalence greatly exceeds clinical incidence, and incidence tracks ultrasound and screening intensity across countries. This is as close to a settled conclusion as cancer epidemiology produces.

*Not known*: which small papillary carcinomas will progress. No molecular or imaging marker reliably separates the indolent majority from the few that matter, which is why active surveillance has become the practical answer. Also not known: whether the modest rise in large thyroid tumours in some datasets is a small real increase on top of the overdiagnosis.

**Cure status.** Benign nodules and non-compressive goitre: CONTROLLABLE by observation. Most never cause disease and need no treatment. Compressive goitre: CURABLE, by surgery or radioiodine. Toxic nodular goitre: CURABLE, by radioiodine or surgery. Differentiated thyroid cancer: CURABLE, with 10-year survival above roughly 95 per cent for papillary carcinoma†. Low-risk papillary microcarcinoma, 1 cm or under: CURABLE by surgery, and active surveillance gives the same survival. Confined medullary thyroid carcinoma: CURABLE, by complete surgery. Advanced medullary carcinoma and radioiodine-refractory differentiated cancer: CONTROLLABLE, with targeted drugs. Anaplastic thyroid carcinoma: RELIEF ONLY.

For benign disease, observation is the evidence-based management. Radioiodine reduces goitre volume by roughly 40 to 60 per cent over a year and is cheap, and surgery is immediate and definitive. Antithyroid drugs do not induce remission in nodular autonomy; see hyperthyroidism and Graves disease.

For differentiated cancer, treatment is lobectomy or total thyroidectomy, with radioiodine for higher-risk disease. Disease-specific survival is roughly 99 per cent for tumours under 1 cm†. For small papillary carcinoma, doing nothing is as good as operating. The Kuma Hospital (Japan) active-surveillance cohorts (Ito, Miyauchi et al.) followed over 1,200 patients with papillary microcarcinoma of 1 cm or less. Tumour enlargement of 3 mm or more occurred in roughly 8 per cent at 10 years, new nodal metastases in roughly 3.8 per cent, and no patient died of thyroid cancer†. Patients who later had surgery did as well as those operated on immediately. Memorial Sloan Kettering and other Western cohorts have replicated this, and active surveillance is an accepted option in American Thyroid Association and other guidelines. This is one of the few entries where the correct course is often to withhold the curative treatment.

Anaplastic carcinoma has a median survival of roughly 4 to 6 months†. Dabrafenib plus trametinib in *BRAF*-mutant anaplastic carcinoma produces response rates of roughly 56 to 69 per cent and has changed the outlook for that subgroup†. Selpercatinib and pralsetinib, *RET* inhibitors, produce high response rates in advanced medullary disease and cost hundreds of thousands of dollars a patient-year.

**Prevention.** Universal salt iodisation prevents endemic goitre and nodular disease and reduces follicular carcinoma, at a few cents a tonne of salt. STRONG. See iodine deficiency disorders.

Stable iodine prophylaxis after a nuclear accident. Potassium iodide tablets taken promptly block thyroid uptake of radioiodine. Poland distributed iodide after Chernobyl and saw no excess childhood thyroid cancer, in contrast to Belarus and Ukraine. It is off-patent and costs cents. STRONG. Its listing status on the WHO Essential Medicines List 24th List needs checking†.

Avoiding unnecessary radiation to the neck in childhood, particularly CT. STRONG. Prophylactic thyroidectomy in *RET* mutation carriers prevents medullary thyroid carcinoma and is one of the clearest cases of preventive surgery in medicine. STRONG.

Not screening for thyroid cancer is a prevention in its own right. The United States Preventive Services Task Force recommends against screening asymptomatic adults, grade D.

South Korea's fifteen-fold rise in incidence with unchanged mortality is the evidence. What not screening prevents is the overdiagnosis of roughly 70 to 90 per cent of diagnoses in the countries measured, with its lifelong levothyroxine, surgical complications, and insurance and employment consequences. STRONG.

Not aspirating small, sonographically low-risk nodules. Risk-stratified ultrasound systems (ACR TI-RADS, EU-TIRADS, ATA) set size thresholds below which biopsy is not recommended. Applying them reduces biopsies by roughly 20 to 50 per cent without missing clinically significant cancers in validation studies. MODERATE. Not measuring calcitonin or doing ultrasound in asymptomatic people. MODERATE.

Not treating nodular disease with suppressive levothyroxine. TSH suppression reduces nodule volume modestly and causes bone loss and atrial fibrillation, and it is no longer recommended. STRONG, as a recommendation against.

**Treatment.** Observation, for benign, asymptomatic, non-compressive nodules and goitre and for low-risk papillary microcarcinoma under active surveillance. It is evidence-based and free. Monitoring is clinical plus periodic ultrasound.

Fine-needle aspiration cytology, where risk stratification indicates it, is cheap, outpatient and the single decisive test, at tens to hundreds of dollars. The Bethesda classification reports it. Indeterminate categories, Bethesda III and IV, are roughly 20 to 30 per cent of aspirates and are the practical problem, with malignancy rates of roughly 10 to 40 per cent†. Molecular testing (Afirma, ThyroSeq) of indeterminate aspirates reduces unnecessary diagnostic surgery by roughly 50 per cent in validation studies†, at several thousand dollars a test, which is more than the surgery costs in many countries.

Levothyroxine is given only where there is hypothyroidism or after thyroidectomy, and not to shrink a benign nodule. It is on the WHO Essential Medicines List 24th List, section 18.7, for hypothyroidism, and costs a few dollars to a few tens of dollars a patient-year.

Radioiodine treats toxic nodular goitre and large non-toxic goitre, at hundreds to low thousands of dollars. Recombinant human TSH-stimulated radioiodine increases volume reduction further and costs thousands of dollars a course, a large price difference for an incremental gain. Surgery, lobectomy or total thyroidectomy, is for compressive goitre, suspected or confirmed malignancy, cosmetic indication or toxic nodular disease. Permanent recurrent laryngeal nerve injury runs roughly 1 to 2 per cent and permanent hypoparathyroidism roughly 1 to 3 per cent in high-volume centres, and both are substantially higher in low-volume settings. That is an argument for surveillance of low-risk disease wherever surgical volume is low. Surgery costs thousands to tens of thousands of dollars.

Thermal ablation, by radiofrequency, microwave, laser or high-intensity focused ultrasound, treats benign symptomatic nodules with volume reduction of roughly 50 to 80 per cent at one year, preserving thyroid function and avoiding a scar. It is increasingly used in Korea, Italy and China, at thousands of dollars.

For differentiated cancer: surgery; radioiodine ablation for intermediate- and high-risk disease and not for low-risk disease; TSH suppression in higher-risk disease. The ESTIMABL2 and IoN randomised trials both found no benefit from radioiodine ablation in low-risk papillary carcinoma, which has changed practice. Lenvatinib and sorafenib treat radioiodine-refractory disease at roughly a hundred thousand dollars or more a patient-year. Selpercatinib and pralsetinib treat *RET*-altered tumours, and larotrectinib and entrectinib treat *NTRK*-fusion tumours. Anaplastic carcinoma is treated with dabrafenib plus trametinib where *BRAF*-mutant, and otherwise with palliative radiotherapy and airway management. Where iodine deficiency is the cause, iodine treats it.

**Simple means.** Iodised salt prevents the endemic goitre that still affected roughly 187 million people in 2010, at a few cents a tonne.

Doing nothing is the best-evidenced management for most thyroid nodules and for low-risk papillary microcarcinoma. The Kuma Hospital cohorts recorded 8 per cent growth at 10 years, 3.8 per cent new nodal metastases and no thyroid cancer deaths under observation. Not operating is free and avoids a permanent hypoparathyroidism rate of 1 to 3 per cent and lifelong levothyroxine.

Not screening is the measured case: South Korea's fifteen-fold rise with flat mortality, and the IARC estimate of roughly 560,000 overdiagnoses in 12 countries†. The Task Force's grade D is the formal statement of it.

Palpation of the neck costs nothing and detects the goitre and the nodules large enough to matter. It does not detect the subclinical reservoir that ultrasound finds. In this entry the cruder test is the safer one.

Potassium iodide tablets held in stock near nuclear installations cost cents a dose. Avoiding unnecessary neck CT in children costs nothing. A voice check and a serum calcium after thyroid surgery are cheap and cover the two complications that matter. Levothyroxine follows where the thyroid has been removed.

**Gaps.** Nodule prevalence spans 4 to 70 per cent depending on the detection method†. No single prevalence figure is meaningful without stating the method, and the literature often does not.

No marker separates the indolent small papillary carcinoma from the one that will progress. This is the central unsolved problem, and active surveillance is the workaround and not the answer.

The overdiagnosis estimates, 70 to 90 per cent of diagnoses in some countries, are modelled from the discordance of incidence and mortality. They are not observed in individuals, and the exact fraction is contested even though the phenomenon is not. Whether a real small increase in incidence lies under the overdiagnosis is unresolved, since some datasets show a modest rise in larger tumours.

Molecular testing of indeterminate aspirates costs several thousand dollars a test, more than diagnostic surgery in many health systems, and its cost-effectiveness outside the United States is not established. ESTIMABL2 and IoN found no benefit from radioiodine in low-risk disease, and practice in many countries has not fully changed. Thermal ablation is in widespread use in some countries with limited randomised comparison against surgery or observation.

Active surveillance data come overwhelmingly from two Japanese centres plus smaller Western cohorts, and outcomes beyond 20 years are not available. The goitre burden figure of 187 million is from 2010, and iodine status monitoring has since deteriorated, so current endemic goitre prevalence is not well known. Surgical complication rates differ severalfold between high- and low-volume settings. That changes the risk-benefit calculation for operating on low-risk disease and is rarely incorporated into guidelines written in high-volume centres.

---

## Adrenal insufficiency

**What it is.** The adrenal glands make too little cortisol, and in the primary form too little aldosterone as well. Fatigue, weight loss, low blood pressure and salt craving build up over months. An infection or injury can then tip the person into shock and kill within hours.

**Measured.** Prevalence of Addison disease, primary adrenal insufficiency, runs from 5 to 221 per million across countries. European studies in Norway, Italy and the United Kingdom give roughly 100 to 220 per million, about 1 in 5,000 to 1 in 10,000, and incidence of roughly 4 to 6 per million a year†. Secondary (pituitary) adrenal insufficiency runs at roughly 150 to 280 per million, so it is commoner than primary†.

The commonest form is tertiary, from exogenous glucocorticoids, and it is poorly counted. A systematic review and meta-analysis (Broersen et al., 2015) found adrenal insufficiency after glucocorticoid withdrawal in roughly 48.7 per cent overall. By route the rates were roughly 4.2 per cent for nasal, 7.8 per cent for topical, 8 to 10 per cent for inhaled, 48.7 per cent for oral and 52.2 per cent for intra-articular glucocorticoids. Given how widely corticosteroids are prescribed, this is the largest group of people with adrenal insufficiency in the world, and no population prevalence figure exists for it.

Congenital adrenal hyperplasia is the commonest cause in children. Incidence of the classical form, 21-hydroxylase deficiency, is 1 in 14,200 live births from newborn screening data†.

Autoimmune adrenalitis accounts for 80 to 90 per cent of primary cases in industrialised countries since 1950†. Roughly half occur within autoimmune polyendocrine syndrome type

2, with autoimmune thyroid disease or type 1 diabetes, and a smaller share in type 1 (*AIRE* mutations, with hypoparathyroidism and candidiasis). Tuberculosis was historically the dominant cause worldwide and is still the leading cause where tuberculosis burden is high. Older series from India and Africa report 40 to 70 per cent†. Other causes are HIV and its opportunistic infections, histoplasmosis, paracoccidioidomycosis, metastatic disease, bilateral adrenal haemorrhage (anticoagulation, antiphospholipid syndrome, meningococcal sepsis), adrenoleukodystrophy, which is a leading cause in boys, drugs (ketoconazole, etomidate, mitotane, abiraterone, checkpoint inhibitors) and bilateral adrenalectomy.

Autoimmune Addison disease peaks at 30 to 50 years, with women outnumbering men by roughly 1.5 to 2.5 to 1†. Congenital adrenal hyperplasia presents in the neonatal period.

The measured harm is mortality. In diagnosed patients adrenal crisis occurs roughly 5 to 8 times per 100 patient-years, about a 1 in 15 chance each year†. Crisis mortality is roughly 0.5 per 100 patient-years, and case fatality of a crisis roughly 6 per cent†. The standardised mortality ratio is roughly 2 in Swedish and Norwegian registry studies, with excess deaths from infection, cardiovascular disease and adrenal crisis. Untreated primary adrenal insufficiency is fatal. Before cortisone, in 1949, median survival from diagnosis was roughly 2 years†.

Diagnosis is late. Roughly 50 to 70 per cent of patients in registry surveys saw three or more doctors before diagnosis, the median delay is 1 to 2 years, and a substantial minority are diagnosed only at crisis†.

**Where it starts.** Autoimmune adrenalitis destroys the adrenal cortex through autoantibodies and T cells directed at 21-hydroxylase (*CYP21A2*). Anti-21-hydroxylase antibodies are present in roughly 85 to 90 per cent of autoimmune cases and precede clinical disease by months to years. As in type 1 diabetes, there is a measurable preclinical phase. Roughly 20 to 30 per cent of antibody-positive individuals progress to overt insufficiency over a decade.

The HLA association is strong: *HLA-DR3-DQ2*, *DR4-DQ8* and the *MICA5.1* allele. Non-HLA loci are *CTLA4*, *PTPN22*, *CYP27B1*, *NLRP1*, *AIRE*, *BACH2* and *CLEC16A*. Sibling relative risk is high but the disease is rare, so absolute risks stay low. Heritability is not well established for Addison disease specifically, and the polyendocrine syndromes are more clearly familial.

The monogenic causes are congenital adrenal hyperplasia (*CYP21A2* in roughly 95 per cent, also *CYP11B1*, *HSD3B2*, *CYP17A1*, *StAR*)†, familial glucocorticoid deficiency (*MC2R*, *MRAP*), triple A syndrome (*AAAS*) and autoimmune polyendocrine syndrome type 1 (*AIRE*). Adrenoleukodystrophy (*ABCD1*, X-linked) is another. Adrenal insufficiency is often its first manifestation in boys and can precede neurological disease by years, making it a treatable sentinel.

Tuberculosis destroys the glands by caseating granulomatous replacement, and calcification is visible on CT. Adrenal insufficiency occurs in roughly 5 per cent of patients with active tuberculosis†.

Exogenous glucocorticoids suppress the hypothalamic-pituitary-adrenal axis. Risk rises with dose, duration and potency. It occurs with inhaled, topical, intranasal and intra-articular routes and not only oral, which is widely underappreciated and is the commonest reason a patient has unrecognised adrenal insufficiency. Checkpoint inhibitor hypophysitis causes secondary adrenal insufficiency in roughly 1 to 6 per cent of treated patients and is usually permanent†. Chronic opioid therapy suppresses the axis in a measurable minority.

Crisis precipitants are, in order of frequency, gastrointestinal infection with vomiting, because the oral dose cannot be absorbed; fever; surgery; trauma; and failure to increase the dose during illness, the single commonest preventable precipitant.

*Not known*: what triggers autoimmune adrenalitis. The true population prevalence of glucocorticoid-induced adrenal insufficiency. Which antibody-positive individuals will progress. Whether any preclinical intervention preserves adrenal function, since immunomodulation trials have been small and inconclusive. The optimal replacement dose and schedule, which is why mortality stays roughly twice expected after seventy-five years of treatment.

**Cure status.** Primary adrenal insufficiency, autoimmune: CONTROLLABLE. Tuberculous adrenalitis: CONTROLLABLE, because the tuberculosis is cured but the destroyed adrenal tissue does not return and replacement is lifelong. Secondary adrenal insufficiency

from pituitary disease: CONTROLLABLE. Congenital adrenal hyperplasia: CONTROLLABLE. Glucocorticoid-induced insufficiency: CURABLE, by tapering and withdrawing the glucocorticoid. Drug-induced insufficiency from ketoconazole, mitotane or abiraterone: CURABLE, as it reverses on withdrawal. Bilateral adrenal haemorrhage: CONTROLLABLE, with function sometimes partly recovering.

Hydrocortisone and fludrocortisone restore survival from a median of 2 years to decades, and with proper diagnosis, monitoring and treatment people can live normally. That is substantially true. But the standardised mortality ratio remains roughly 2, with excess deaths from infection and adrenal crisis†. Replacement does not reproduce the physiological cortisol rhythm or the stress response. Oral hydrocortisone two or three times a day produces peaks and troughs that do not match the circadian profile, and no preparation reproduces the stress-induced rise. Quality-of-life scores in Addison disease stay below population norms in every published cohort.

Glucocorticoid-induced insufficiency recovers over weeks to roughly a year after withdrawal, though recovery can be incomplete.

In congenital adrenal hyperplasia the balance between under-replacement (virilisation, poor growth) and over-replacement (growth suppression, obesity, bone loss) is the central difficulty. Crinecerfont, a CRF1 receptor antagonist approved in the United States in December 2024, reduced androgen levels and allowed glucocorticoid dose reduction in phase 3 trials†. It is the first mechanistically new treatment in decades and costs high tens of thousands of dollars a patient-year. Adrenal transplantation and stem-cell-derived adrenal tissue are experimental.

**Prevention.** No primary prevention of autoimmune adrenalitis exists. Tuberculosis prevention and treatment prevents the second-largest cause worldwide. STRONG.

Glucocorticoid stewardship prevents the commonest form. It means the lowest effective dose and duration, and tapering rather than stopping abruptly after courses longer than roughly 2 to 3 weeks. It also means recognising that inhaled, topical, intranasal and intra-articular routes suppress the axis. Meta-analysis found adrenal insufficiency in roughly 8 to 10 per cent after inhaled and 52 per cent after intra-articular glucocorticoids†. STRONG.

Prevention of adrenal crisis is where essentially all the preventable mortality sits. Sick-day rules, doubling or tripling the glucocorticoid dose during febrile illness and giving parenteral hydrocortisone when vomiting or unable to take tablets: STRONG. No trial exists, the practice is universally accepted, and crisis precipitants are dominated by failure to do it. An emergency hydrocortisone injection kit at home, with patient and family trained to use it: MODERATE, as studies of patient education programmes show reduced crisis rates. A steroid emergency card and a medical alert bracelet: MODERATE, at zero cost. The United Kingdom introduced a national NHS Steroid Emergency Card in 2020 after repeated deaths from unrecognised adrenal crisis in hospital†. Parenteral hydrocortisone cover for surgery, labour and major procedures: STRONG. Structured patient education, repeated, because crisis rates fall after education programmes in cohort studies: MODERATE.

Newborn screening for congenital adrenal hyperplasia prevents salt-wasting crisis and death in the neonatal period and prevents incorrect sex assignment in virilised female infants. It is included in newborn panels in the United States, Japan and much of Europe. STRONG. Screening for adrenal insufficiency in boys with adrenoleukodystrophy, and in patients on checkpoint inhibitors or long-term opioids: MODERATE.

Screening relatives of people with other autoimmune endocrine disease for 21-hydroxylase antibodies identifies the preclinical phase. No intervention is known to prevent progression, so the benefit is earlier diagnosis and avoidance of crisis at presentation. MODERATE.

**Treatment.** The proportion of glucocorticoid-induced insufficiency that recovers is not given. Recovery is over weeks to roughly a year after withdrawal and can be incomplete. Hydrocortisone, oral, in two or three divided doses, typically 15 to 25 mg a day in adults weighted to the morning†. It is off-patent, and a year costs tens to low hundreds of dollars at generic prices. In the United Kingdom hydrocortisone tablet prices rose sharply in the 2010s under a single-supplier market, the Competition and Markets Authority found abusive pricing and imposed fines, and prices have since fallen. Prednisolone is an acceptable alternative at a few dollars to tens of dollars a patient-year, and in much of the world it is what is used

because of price and availability. The listing status of hydrocortisone, oral and injectable, and of prednisolone, on the WHO Essential Medicines List 24th List needs checking†.

Modified-release hydrocortisone (Plenadren, Chronocort or Efmody) better approximates the circadian profile, and small trials show improved quality of life and metabolic measures. It is patented, at thousands of dollars a patient-year. Whether the improvement justifies a price 30 to 100 times higher is unresolved†.

Fludrocortisone, a mineralocorticoid, 0.05 to 0.2 mg once daily, is for primary adrenal insufficiency only. It is not needed in secondary insufficiency, where aldosterone production is intact. It is off-patent, costs tens to hundreds of dollars a patient-year, and prices have been volatile in some markets because of few suppliers. Liberal salt intake is the free adjunct. Its listing status needs checking against the 24th List†.

Adrenal crisis is treated with 100 mg hydrocortisone intravenously or intramuscularly, immediately, plus intravenous saline. An ampoule costs dollars. This is one of the cheapest life-saving drugs in medicine, and it is the whole treatment of a condition with roughly 6 per cent case fatality. Given in time it is almost always effective, and the deaths come from not giving it. An emergency injection kit for home use is a vial, a syringe and training, for a few dollars.

Dehydroepiandrosterone (DHEA), for women with impaired wellbeing and low androgens, shows small and inconsistent benefits on mood and sexual function in randomised trials. CONTESTED. Its listing status needs checking against the 24th List†.

In congenital adrenal hyperplasia, treatment is hydrocortisone (in adults sometimes prednisolone or dexamethasone), fludrocortisone, salt supplementation in infancy, and crinecerfont or tildacerfont, CRF1 antagonists, to reduce ACTH drive and allow lower glucocorticoid doses. Crinecerfont is patented at high tens of thousands of dollars a patient-year.

The cause is treated where it can be: antituberculous therapy, tapering the exogenous glucocorticoid, stopping the implicated drug. For adrenoleukodystrophy, Lorenzo's oil and haematopoietic stem cell transplant or gene therapy (elivaldogene autotemcel) treat the neurological disease and not the adrenal failure.

In pregnancy the hydrocortisone dose is increased in the third trimester, with parenteral cover in labour. Dexamethasone is not used, because it crosses the placenta.

Not to be done: giving levothyroxine before glucocorticoid in combined pituitary failure, which precipitates crisis; using dexamethasone for routine replacement, which has no mineralocorticoid activity and is hard to titrate; and withholding hydrocortisone while awaiting a cortisol result in a suspected crisis.

**Simple means.** Hydrocortisone tablets and fludrocortisone together cost tens to hundreds of dollars a patient-year at generic prices, both off-patent, and convert a disease with a 2-year median survival into a near-normal life. Prednisolone, at a few dollars to tens of dollars a patient-year, is an acceptable substitute where hydrocortisone is unavailable or unaffordable.

Salt. Liberal salt intake supports blood pressure in primary adrenal insufficiency and is free. Salt craving is a presenting symptom.

An ampoule of hydrocortisone and a syringe in the house, and someone trained to use it, cost a few dollars. Adrenal crisis has roughly 6 per cent case fatality and roughly 5 to 8 crises occur per 100 patient-years, and the drug that stops it costs about a dollar†.

Sick-day rules written on a card: double the dose during fever and inject when vomiting. Failure to do this is the commonest precipitant of crisis, and the countermeasure is a card and a conversation. A steroid emergency card or bracelet is free. Oral rehydration salts go alongside the increased steroid dose during gastrointestinal illness. Not stopping a long corticosteroid course abruptly is free and prevents the commonest form of the disease from becoming a crisis.

Recognition is clinical: weight loss, fatigue, postural dizziness, salt craving, abdominal pain, and hyperpigmentation of scars, buccal mucosa and palmar creases in primary disease. Hyperpigmentation is visible without any test and is specific. Low sodium and high potassium on a basic electrolyte panel, which costs a few dollars, point straight at it. Asking about previous corticosteroid courses in anyone with unexplained collapse costs nothing.

**Gaps.** Prevalence spans 5 to 221 per million, a 44-fold range. It reflects differences in ascertainment and in the balance of autoimmune and infectious causes, not variation of that size.

Glucocorticoid-induced adrenal insufficiency is the commonest form and has no population prevalence estimate. The Broersen meta-analysis gives rates after withdrawal by route, 4 to 52 per cent, in selected study populations, and these cannot be converted into a population figure. The source consulted gives no percentage for tuberculosis as a cause, and the global split between autoimmune and infectious causes is not systematically measured. The 80 to 90 per cent autoimmune figure applies to industrialised countries only.

Standardised mortality remains roughly 2 after seventy-five years of replacement therapy. The reason, non-physiological replacement, is accepted and not fixed. The optimal replacement dose and schedule is not established by trial, and doses have fallen over decades on observational grounds. Modified-release hydrocortisone costs 30 to 100 times more than conventional hydrocortisone for improvements measured mainly on quality-of-life and metabolic surrogates in small trials, with no cost-effectiveness consensus. DHEA replacement is contested.

No intervention is known to prevent progression from antibody-positive preclinical disease to overt insufficiency, so screening relatives yields earlier diagnosis and nothing more. Diagnostic delay of 1 to 2 years, with many patients diagnosed at crisis, is consistently reported, and the reasons are system-level.

Hydrocortisone and fludrocortisone prices have been volatile in single-supplier markets despite being off-patent, and the United Kingdom hydrocortisone case ended in competition enforcement. It is a second instance where off-patent status did not guarantee affordability. Almost no outcome data exist from low-income countries, where tuberculous Addison disease is commonest and hydrocortisone supply is least reliable.

---

## Cushing syndrome

**What it is.** Too much cortisol for too long. Fat gathers on the trunk, face and neck while the limbs thin, the skin bruises and splits, and blood pressure, glucose and bone all move the wrong way. Most cases are caused by prescribed steroids and not by a gland.

**Measured.** Endogenous Cushing syndrome, caused by a tumour, occurs at about 2 to 3 cases per million people a year†. For Cushing disease, the pituitary ACTH-secreting adenoma, a Danish study found fewer than 1 case per million a year, and most European registries give 1.2 to 2.4 per million a year†. Prevalence of endogenous disease is roughly 40 to 80 per million†.

Iatrogenic (exogenous) Cushing syndrome is far commoner and is not counted. The source consulted states that the most common cause is prescribed glucocorticoids and gives no percentage split, so iatrogenic cases are the majority. Oral glucocorticoid use at any one time is roughly 1 to 3 per cent of the population in high-income countries, and roughly 0.5 to 1 per cent long-term†. That is a population two to three orders of magnitude larger than the one with endogenous disease.

Among endogenous cases, pituitary Cushing disease is about 70 per cent. Adrenal adenoma or carcinoma is roughly 15 to 20 per cent. Ectopic ACTH secretion, from small cell lung cancer, bronchial and thymic carcinoid, medullary thyroid carcinoma and pancreatic neuroendocrine tumours, is roughly 10 to 15 per cent†. ACTH-independent adrenal hyperplasias and genetic syndromes are a small remainder. Endogenous disease is roughly 3 to 8 times commoner in women, with onset at 25 to 45 years†. Ectopic ACTH syndrome is commoner in older men, tracking lung cancer.

Untreated endogenous Cushing syndrome had a 5-year mortality of roughly 50 per cent in series from before effective treatment, from cardiovascular disease, infection, thromboembolism and suicide. The standardised mortality ratio in treated Cushing disease is roughly 1.5 to 3.0 overall. It is roughly 1.0 in sustained remission and roughly 3.7 to 5.0 in persistent disease†. Remission normalises mortality, and persistence does not.

Venous thromboembolism risk is raised roughly 10 to 18-fold and is highest around surgery, which is why thromboprophylaxis is now standard around pituitary surgery for Cushing dis-

ease. Cardiovascular events, diabetes, osteoporotic fracture, infection and psychiatric morbidity remain elevated for years after biochemical cure, a consistent and important finding.

Diagnosis takes a median of roughly 2 to 3 years, with patients seeing several specialists for individual features before the syndrome is recognised. At diagnosis hypertension is present in roughly 70 to 85 per cent, glucose intolerance or diabetes in 20 to 50, osteoporosis or osteopenia in 50 to 80, depression in 50 to 80 and vertebral fracture in 30 to 70 per cent†.

**Where it starts.** Exogenous glucocorticoids are the dominant cause, dose- and duration-dependent. All routes can do it: oral, injected, intra-articular, inhaled (particularly high-dose fluticasone), topical (especially potent steroids on large areas, in children or under occlusion) and intranasal. Interactions matter. Ritonavir, cobicistat, itraconazole and clarithromycin inhibit CYP3A4 and can turn a modest inhaled or intra-articular steroid dose into florid Cushing syndrome. The interaction is well documented and avoidable.

Somatic *USP8* mutations occur in roughly 35 to 60 per cent of pituitary corticotroph adenomas, with *USP48* and *BRAF* in smaller fractions†. Somatic *PRKACA* mutations occur in roughly 35 to 65 per cent of cortisol-producing adrenal adenomas, with *GNAS* and *CTNNB1*†. These are acquired and not inherited.

Rare genetic syndromes change management: Carney complex (*PRKAR1A*), McCune-Albright syndrome (somatic *GNAS*), multiple endocrine neoplasia type 1 (*MEN1*), familial isolated pituitary adenoma (*AIP*), primary bilateral macronodular adrenal hyperplasia (*ARMC5*, in roughly 20 to 25 per cent†) and Li-Fraumeni syndrome (*TP53*). In southern Brazil a founder *TP53* R337H variant gives a markedly raised incidence of adrenocortical carcinoma, particularly in children. Ectopic ACTH is driven by the underlying neuroendocrine tumour, and smoking is the main risk factor through small cell lung cancer.

Cortisol excess does its damage through glucocorticoid receptor activation in liver, muscle, adipose tissue, bone, vessel wall and brain. The results are gluconeogenesis and insulin resistance, proteolysis and myopathy, central fat redistribution, osteoblast apoptosis and reduced bone formation, hypertension and hypokalaemia from mineralocorticoid receptor activation at high cortisol concentrations, and immune suppression. The mechanisms are established, which is why the features are so predictable.

Pseudo-Cushing states must be excluded: severe obesity, poorly controlled diabetes, depression, chronic alcohol use, polycystic ovary syndrome, and the physiological hypercortisolism of pregnancy and severe stress. They produce overlapping biochemistry, which is why diagnosis needs more than one abnormal test.

*Not known*: the true population burden of iatrogenic Cushing syndrome. Why cardiovascular, skeletal and psychiatric morbidity persist for years after biochemical cure. Whether to treat mild autonomous cortisol secretion surgically. It is found in roughly 5 to 30 per cent of the growing number of incidentally found adrenal nodules and is associated with hypertension, diabetes, fracture and mortality.

**Cure status.** Iatrogenic Cushing syndrome: CURABLE, by withdrawing the glucocorticoid. Cushing disease: CURABLE by transsphenoidal adenomectomy, with recurrence in roughly 10 to 25 per cent at 10 years; where bilateral adrenalectomy is needed, the hypercortisolism is cured and lifelong adrenal insufficiency is CONTROLLABLE. Adrenal adenoma: CURABLE, by unilateral adrenalectomy. Adrenocortical carcinoma, stage I to II, completely resected: CURABLE. Adrenocortical carcinoma, stage IV: RELIEF ONLY. Ectopic ACTH syndrome, source tumour resectable: CURABLE. Ectopic ACTH syndrome, otherwise: RELIEF ONLY, with medical control of cortisol while the tumour is treated.

Withdrawal of the glucocorticoid must be gradual, because the axis is suppressed, and adrenal insufficiency follows withdrawal in roughly half of patients after oral courses; see adrenal insufficiency. The cure is free and the hazard lies in how it is done.

Initial remission after pituitary surgery is roughly 70 to 90 per cent for microadenomas in experienced hands and roughly 50 to 65 per cent for macroadenomas†. Recurrence is roughly 10 to 25 per cent at 10 years and roughly 20 to 35 per cent at longer follow-up, so lifelong surveillance is needed†. Surgeon volume matters substantially for remission and complication rates, and this is the main argument for centralising the operation. Second-line options are repeat surgery, stereotactic radiosurgery or fractionated radiotherapy (remission in roughly 50 to 60 per cent over 2 to 5 years, hypopituitarism in roughly 20 to 40 per cent),

medical therapy, and bilateral adrenalectomy†. Bilateral adrenalectomy cures the hypercortisolism with certainty and carries a roughly 10 to 30 per cent risk of Nelson syndrome, progressive corticotroph tumour growth.

Unilateral adrenalectomy for adenoma has cure rates approaching 100 per cent†. The operation is laparoscopic, and the contralateral gland recovers over months, during which glucocorticoid replacement is needed. Adrenocortical carcinoma has 5-year survival of roughly 60 to 80 per cent at stage I to II and under 15 per cent at stage IV†. Mitotane plus etoposide, doxorubicin and cisplatin (the FIRM-ACT regimen) is standard for advanced disease, with modest benefit.

After cure, life expectancy is usually normal, and standardised mortality in sustained remission approaches 1.0. Patients whose surgery cannot remove the entire tumour have increased risk of death. Glucocorticoid withdrawal syndrome after cure causes months of profound fatigue, joint pain and low mood, and is routinely mistaken for treatment failure.

**Prevention.** Glucocorticoid stewardship is the prevention of the commonest form and the only prevention available at scale. It means the lowest effective dose for the shortest time, and topical and inhaled routes preferred while recognising that these also cause it. It means avoiding potent topical steroids on large areas and under occlusion, particularly in children. It means checking for CYP3A4-inhibitor interactions with ritonavir, cobicistat, itraconazole and clarithromycin before prescribing any steroid. STRONG.

Avoiding unlicensed and adulterated products. Skin-lightening creams, herbal remedies and unregulated injections containing undeclared potent corticosteroids are a documented cause of iatrogenic Cushing syndrome in several countries. MODERATE, and it is a regulatory matter. No prevention of endogenous Cushing syndrome exists.

Prevention of complications and deaths. Perioperative thromboprophylaxis against a 10 to 18-fold raised risk: STRONG. Treating hypertension, hyperglycaemia and hypokalaemia from diagnosis and not after cure: STRONG. Bone protection and fracture assessment, with osteoporosis or osteopenia present in 50 to 80 per cent at diagnosis and vertebral fracture in 30 to 70 per cent: STRONG. *Pneumocystis* prophylaxis in severe hypercortisolism, which is profoundly immunosuppressive, since opportunistic infection is a leading cause of death in florid disease: MODERATE. Psychiatric assessment, with depression in 50 to 80 per cent and suicide a recognised cause of death: MODERATE. Centralising pituitary surgery in high-volume centres: MODERATE. Lifelong surveillance for recurrence, with 10 to 25 per cent recurring by 10 years: STRONG.

Earlier diagnosis. The median delay is 2 to 3 years, and the preventable harm accrues during it. Testing for Cushing syndrome in people with a specific combination of features is cheap: resistant hypertension with hypokalaemia, early osteoporosis with fracture, new diabetes with weight gain and proximal myopathy, easy bruising with purple striae. The tests are an overnight dexamethasone suppression test, a late-night salivary cortisol, or a 24-hour urine free cortisol. MODERATE.

**Treatment.** Withdraw the glucocorticoid where the cause is exogenous, gradually, with replacement-dose cover and monitoring for adrenal insufficiency. It is free and curative.

Transsphenoidal pituitary surgery is first-line for Cushing disease. It is not a medicine, and costs tens of thousands of dollars in high-income systems. Transient diabetes insipidus occurs in roughly 10 to 25 per cent and is permanent in roughly 1 to 3 per cent; hypopituitarism occurs in roughly 5 to 15 per cent; cerebrospinal fluid leak in roughly 1 to 4 per cent†. Unilateral adrenalectomy for adenoma is curative and laparoscopic, at thousands to tens of thousands of dollars.

Medical therapy is used while awaiting surgery, after failed surgery, while radiotherapy takes effect, and in ectopic ACTH syndrome. Steroidogenesis inhibitors come first.

Ketoconazole is off-label in many countries and licensed as Ketoconazole HRA in Europe for Cushing syndrome. It controls cortisol in roughly 50 to 75 per cent†. Generic ketoconazole costs hundreds of dollars a patient-year and the licensed European product tens of thousands. Hepatotoxicity requires monitoring. Its listing on the WHO Essential Medicines List 24th List is for fungal infection, not Cushing syndrome, and its status needs checking.

Metyrapone controls cortisol in roughly 50 to 75 per cent†. It is off-patent in principle but supplied by few manufacturers, and has risen steeply to tens of thousands of dollars a patient-year. Its listing status needs checking against the 24th List†.

Osilodrostat, an 11-beta-hydroxylase inhibitor approved in 2020, was tested in the LINC-3 randomised withdrawal trial. At week 34, 86 per cent of osilodrostat patients maintained normal urinary free cortisol against 29 per cent on placebo†. It is patented and costs hundreds of thousands of dollars a patient-year at United States list price. Levoketoconazole was approved in 2021. Etomidate, intravenous and a cheap generic, gives rapid emergency control of severe hypercortisolism in intensive care. Mitotane is adrenolytic, used in adrenocortical carcinoma and occasionally for cortisol control, with a narrow therapeutic index and off-patent; its listing status needs checking against the 24th List†.

Pituitary-directed drugs: pasireotide, a somatostatin analogue, normalises cortisol in roughly 15 to 26 per cent and causes hyperglycaemia in roughly 70 per cent†. Cabergoline is off-patent, costs hundreds of dollars a patient-year, and is effective in roughly 25 to 40 per cent†. Mifepristone, a glucocorticoid receptor antagonist, improves glucose and clinical features, but cortisol cannot be used to monitor it. It is patented in the United States for this indication at hundreds of thousands of dollars a patient-year.

Radiotherapy or stereotactic radiosurgery treats persistent Cushing disease, with remission in 50 to 60 per cent over 2 to 5 years and hypopituitarism in 20 to 40 per cent. Bilateral adrenalectomy gives definitive control at the price of lifelong adrenal insufficiency and a 10 to 30 per cent risk of Nelson syndrome†. It is cheap and permanent, and is used where other options fail and in severe ectopic ACTH syndrome.

Complications are treated directly: antihypertensives, with mineralocorticoid receptor antagonists such as spironolactone particularly appropriate given the mechanism; antidiabetic drugs; potassium replacement; bisphosphonates for bone; anticoagulant prophylaxis; antidepressants; and *Pneumocystis* prophylaxis in severe disease. Spironolactone is on the 24th List, but for oedema, ascites and heart failure, and its record does not carry hypertension as an indication. After cure, glucocorticoid replacement covers the months of axis recovery, and the patient is warned about glucocorticoid withdrawal syndrome.

**Simple means.** Stopping the steroid. The commonest cause of this syndrome is a prescription, and the cure is to stop it, tapered. It costs nothing and is the single most effective intervention in this entry.

A medication review, asking what creams, inhalers, injections, joint injections, nasal sprays and unlicensed or imported products a person uses. Topical and inhaled steroids, and adulterated skin-lightening creams and herbal products, cause florid Cushing syndrome, and the history is free. A check for a CYP3A4 interaction before prescribing any corticosteroid to someone on ritonavir, cobicistat, itraconazole or clarithromycin takes thirty seconds and prevents an iatrogenic disease.

A blood pressure cuff and a potassium level. Resistant hypertension with unexplained hypokalaemia is one of the cheapest pointers to cortisol excess. Looking at the patient. Purple striae wider than 1 cm, proximal myopathy (difficulty rising from a chair without using the arms), easy bruising and facial plethora have the highest discriminating value, and all are free to assess. With a median diagnostic delay of 2 to 3 years, examination is the intervention.

A late-night salivary cortisol is collected at home with no venepuncture. It is among the cheapest and most specific screening tests in endocrinology, at tens of dollars a test where the assay is available.

Spironolactone for the hypertension and hypokalaemia is off-patent, costs tens of dollars a patient-year, and is mechanistically the right drug. Generic ketoconazole, at hundreds of dollars a patient-year, serves where osilodrostat at hundreds of thousands is unavailable. It works in 50 to 75 per cent of patients and requires liver monitoring. Low-molecular-weight heparin around surgery is cheap, against a 10 to 18-fold raised thrombosis risk. Glucocorticoid withdrawal syndrome after cure should not be mistaken for treatment failure.

**Gaps.** The split between iatrogenic and endogenous Cushing syndrome is not quantified. The source consulted gives no percentage. Iatrogenic disease is stated to be the commonest cause and has no population prevalence estimate, so the single most common form of this disease is essentially uncounted.

Surgical remission rates of 70 to 90 per cent for microadenomas come from high-volume specialist centres and are not representative of outcomes where pituitary surgery is done occasionally. No source consulted gives a pooled remission figure across all settings. Recurrence rises with length of follow-up, 10 to 25 per cent at 10 years and higher later, so cure is provisional and published cure rates depend on follow-up duration.

Cardiovascular, skeletal and psychiatric morbidity persist for years after biochemical cure and the mechanism is unexplained. Mild autonomous cortisol secretion from adrenal incidentalomas is increasingly detected and associated with hypertension, diabetes, fracture and mortality. Whether to operate is unresolved, and no adequately powered randomised trial exists.

Osilodrostat at hundreds of thousands of dollars a patient-year stands against generic ketoconazole at hundreds, with no head-to-head trial. Metyrapone, nominally off-patent, costs tens of thousands of dollars a patient-year because of supplier concentration, which is another case where off-patent status did not deliver affordability.

Pseudo-Cushing states overlap biochemically and no single test separates them, so diagnostic accuracy in practice is lower than published test characteristics suggest. Diagnostic delay of 2 to 3 years is consistently reported, because the features present to different specialties separately. Almost no epidemiological or outcome data exist from low- and middle-income countries. The *TP53* R337H founder effect in southern Brazil shows that adrenocortical carcinoma incidence can vary enormously by population, and comparable founder effects elsewhere are unstudied.

---

## Acromegaly

**What it is.** A pituitary tumour makes too much growth hormone in an adult. Hands, feet, jaw and brow grow slowly larger over years, the tongue and soft tissues thicken, and the heart, joints and metabolism suffer. The change is gradual, so recognition is usually late.

**Measured.** Prevalence is about 6 per 100,000 people, roughly 60 per million. Published estimates range from roughly 28 to 137 per million, with higher figures from systematic case-finding. A German primary care screening study found a prevalence roughly 10 times the registry figure, which suggests substantial under-diagnosis. Incidence is roughly 3 to 5 per million a year in European registries†. Diagnosis is typically in middle age, mean roughly 40 to 45 years, and the sexes are about equal, with women diagnosed slightly later.

Diagnostic delay is the defining epidemiological feature: roughly 5 to 10 years from first symptom, among the longest for any endocrine disease. The facial and acral changes are slow and go unnoticed by the patient and by people who see them daily. Patients commonly present first to dentists (jaw and bite change), rheumatologists (joint pain, carpal tunnel), cardiologists, sleep clinics and ophthalmologists. Roughly 60 to 80 per cent of tumours are macroadenomas of 10 mm or more at diagnosis, a direct consequence of the delay, and tumour size is the main determinant of surgical cure.

The change in mortality is the central measured finding. Untreated, life expectancy is reduced by roughly 10 years†. Historical cohorts gave standardised mortality ratios of roughly 1.7 to 3.0, from cardiovascular disease, respiratory disease and cancer. A meta-analysis of modern cohorts gives a pooled ratio of roughly 1.3 to 1.7, and with biochemical control, normalised IGF-1 and growth hormone, mortality approaches that of the general population, with a ratio of roughly 1.1 or lower†. The source consulted states that early, successfully treated patients have life expectancy equal to the general population. Biochemical control demonstrably restores normal survival, and the whole therapeutic objective is defined by that.

Comorbidity at diagnosis: hypertension roughly 35 to 60 per cent, diabetes or impaired glucose tolerance 30 to 55, obstructive sleep apnoea 50 to 80, arthropathy 60 to 75, cardiomyopathy and left ventricular hypertrophy 30 to 60, carpal tunnel syndrome 20 to 60, and colonic polyps 25 to 45 per cent†. Gigantism is the same disease before the growth plates fuse and produces extreme height. It is rare. X-linked acrogigantism (*GPR101* microduplication) and *AIP* mutations account for a substantial share of childhood-onset cases.

**Where it starts.** In over 95 per cent of cases the cause is a somatotroph adenoma of the anterior pituitary. It secretes growth hormone, which drives hepatic IGF-1 production, and IGF-1 produces most of the peripheral effects†. Activating *GNAS* mutations (the *gsp* oncogene) occur in roughly 30 to 40 per cent of sporadic adenomas†. These tumours tend to be smaller, more granulated and more responsive to somatostatin analogues, a genotype-treatment link.

Germline and syndromic causes are roughly 5 per cent of cases and change surveillance. *AIP* mutations, in familial isolated pituitary adenoma, cause young-onset, large, aggressive, somatostatin-resistant tumours, and are found in roughly 15 to 20 per cent of patients diagnosed under 30 and in roughly 50 per cent of familial isolated pituitary adenoma families†. *GPR101* microduplication (Xq26.3) causes infant-onset gigantism. Others are multiple endocrine neoplasia type 1 (*MEN1*) and type 4 (*CDKN1B*), Carney complex (*PRKAR1A*), McCune-Albright syndrome (somatic *GNAS* mosaicism) and the phaeochromocytoma and paraganglioma syndromes (*SDHx*). Ectopic secretion of growth hormone-releasing hormone from a bronchial or pancreatic neuroendocrine tumour accounts for under 1 per cent of cases† and is cured by removing the tumour.

The great majority are not heritable. Familial forms are Mendelian, with high penetrance for *GPR101* and incomplete penetrance, roughly 15 to 30 per cent, for *AIP*†. No environmental cause is established: no dietary, occupational or infectious risk factor has been demonstrated.

The comorbidities follow from established mechanisms. Growth hormone and IGF-1 drive soft tissue and skeletal growth, sodium retention and volume expansion (hypertension), insulin resistance (diabetes), cardiomyocyte hypertrophy and fibrosis (cardiomyopathy), pharyngeal soft tissue growth (sleep apnoea), cartilage hypertrophy then degeneration (arthropathy) and colonic mucosal proliferation (polyps). The mechanisms explain why some comorbidities reverse with treatment and others, particularly the arthropathy and skeletal changes, do not.

*Not known*: why diagnostic delay remains 5 to 10 years when the condition is recognisable on sight once considered. Why arthropathy progresses after biochemical cure. Whether colorectal cancer risk is genuinely raised. What determines somatostatin analogue responsiveness beyond *GNAS* status and tumour granulation pattern.

**Cure status.** Microadenoma: CURABLE, by transsphenoidal surgery, in roughly 75 to 90 per cent†. Macroadenoma: CURABLE by surgery in roughly 40 to 60 per cent†, and CONTROLLABLE, by medical therapy that is indefinite, in the rest. Large invasive tumour with cavernous sinus extension: CONTROLLABLE, with surgical cure in under 30 per cent†. Ectopic growth hormone-releasing hormone tumour: CURABLE, by resection. Established arthropathy and the bony facial and acral changes: RELIEF ONLY.

Surgery is most successful when blood growth hormone is below 40 ng/ml and the tumour is 10 mm or smaller, and success depends on the surgeon’s skill, according to the source consulted. Surgeon and centre volume are major determinants, as in Cushing disease. Recurrence after initial remission is roughly 2 to 8 per cent over 10 years†.

Medical therapy controls and does not cure. Somatostatin receptor ligands (octreotide LAR, lanreotide autogel) normalise IGF-1 in roughly 25 to 45 per cent in unselected first-line use, higher, roughly 50 to 60 per cent, in older or selected series, and reduce tumour size in roughly 50 to 75 per cent†. Pasireotide LAR normalises IGF-1 in roughly 35 to 40 per cent, more than octreotide in head-to-head trials, at the cost of hyperglycaemia in roughly 55 to 70 per cent†.

Pegvisomant, a growth hormone receptor antagonist, controls disease activity in virtually everyone according to the source consulted. IGF-1 normalisation is roughly 90 to 97 per cent in the original trials with adequate dose titration and roughly 60 to 75 per cent in real-world registry use, where doses are often lower†. It blocks the receptor and not the tumour, so growth hormone levels rise and cannot be used for monitoring, and the tumour is not treated.

Cabergoline, a dopamine agonist, normalises IGF-1 in roughly 30 to 35 per cent of patients with modest elevation and is more effective in mixed growth-hormone-and-prolactin tumours. The source consulted notes that oral cabergoline costs considerably less than injectable treatments. Combination therapy, a somatostatin ligand with pegvisomant or cabergoline, raises control rates further. Radiotherapy or stereotactic radiosurgery gives biochemical remission

in roughly 40 to 60 per cent over 5 to 10 years, with hypopituitarism in roughly 20 to 50 per cent at 10 years and a long latency, so it is third-line†.

After control, sleep apnoea, hypertension, glucose intolerance, headache, sweating and soft tissue swelling improve substantially. The bony facial and acral changes, established arthropathy and some cardiac fibrosis do not reverse.

**Prevention.** No primary prevention exists. The tumour is sporadic in over 95 per cent of cases† and no environmental cause is known.

Genetic testing and family screening in young-onset disease, gigantism, familial cases and syndromic presentations (*AIP*, *GPR101*, *MEN1*, *CDKN1B*, *PRKAR1A*). In *AIP* carriers, prospective screening of relatives detects tumours at a smaller size, with higher surgical cure rates than clinical presentation. MODERATE.

Earlier diagnosis is the main avenue, and it is a recognition problem. Acromegaly is to be considered in patients with new diabetes and acral enlargement, bilateral carpal tunnel syndrome, resistant hypertension with sleep apnoea, worsening dental occlusion, or increasing ring and shoe size. A single serum IGF-1 measurement is the screening test, at tens of dollars. Case-finding in primary care, sleep apnoea clinics and diabetes clinics detects undiagnosed acromegaly at several-fold the registry prevalence. Comparing old photographs is free and often decisive. MODERATE: case-finding yield is demonstrated, and the effect on long-term outcome is inferred from the relationship between tumour size and cure rate.

Prevention of complications and excess mortality. Achieving biochemical control, normal age-adjusted IGF-1 and random growth hormone, restores standardised mortality to roughly 1.0. STRONG. Screening and treating sleep apnoea, hypertension, diabetes, cardiomyopathy by echocardiography, and vertebral fracture. Vertebral fracture is common in acromegaly despite normal or high bone density, so bone density alone misleads and vertebral imaging is needed. STRONG.

Colonoscopy at diagnosis and periodically is recommended because of the 25 to 45 per cent polyp prevalence. Whether colorectal cancer risk is raised is CONTESTED: some cohorts show a modest increase, meta-analyses are inconsistent, and the polyp finding is firm while the cancer finding is not. Thyroid nodule surveillance carries the same dispute, and the overdiagnosis caution under thyroid nodules and goitre applies. Anticipating the airway in perioperative and peripartum care prevents a documented anaesthetic hazard, since pharyngeal soft tissue growth makes intubation difficult. STRONG.

**Treatment.** Transsphenoidal surgery is first-line for almost all patients, including as debulking in large tumours to improve the later medical response. It is not a medicine, costs tens of thousands of dollars in high-income systems, and outcomes depend substantially on centre volume.

Somatostatin receptor ligands: octreotide LAR, monthly intramuscular, and lanreotide autogel, monthly deep subcutaneous. They are off-patent in part: generic octreotide LAR is available in several markets, and lanreotide has biosimilar competition in Europe. Originator prices in the United States and Europe are tens of thousands of dollars a patient-year, generic octreotide LAR thousands to low tens of thousands, and in India and some other markets generic octreotide is a few thousand dollars a patient-year. Their listing status on the WHO Essential Medicines List 24th List needs checking†. Oral octreotide (Mycapssa, approved 2020) removes the injection and is priced comparably to or above the injectables. Pasireotide LAR gives higher control rates with hyperglycaemia in 55 to 70 per cent, is patented, and costs tens of thousands of dollars a patient-year.

Pegvisomant is a daily subcutaneous injection. It is patented, costs from over a hundred thousand to hundreds of thousands of dollars a patient-year depending on dose, and is among the most expensive endocrine treatments in routine use. It needs liver function monitoring, causes lipohypertrophy at injection sites and does not treat the tumour. Its listing status needs checking against the 24th List†.

Cabergoline is oral, twice weekly and off-patent, at hundreds of dollars a patient-year. Its listing status needs checking against the 24th List†. Against pegvisomant it costs two to three orders of magnitude less and controls a real minority of patients, particularly those with modest IGF-1 elevation†. In most of the world it is the only affordable medical option, and it is under-used relative to its effect size. Added to a somatostatin ligand it is a cheap

addition that raises control by roughly 15 to 30 percentage points in the partially controlled†. A somatostatin ligand plus pegvisomant is expensive and highly effective.

Radiotherapy or radiosurgery is third-line. Temozolomide, off-patent, is for aggressive and malignant pituitary tumours. Comorbidities are treated directly: CPAP for sleep apnoea, at hundreds of dollars one-off plus consumables; generic antihypertensive and antidiabetic drugs; analgesia and joint replacement for arthropathy; carpal tunnel decompression; and heart failure treatment. Pituitary hormone replacement is needed where surgery or radiotherapy causes hypopituitarism: levothyroxine, hydrocortisone, sex steroids and occasionally growth hormone. Levothyroxine is on the 24th List; the others need checking against it†.

**Simple means.** Looking at old photographs is free and is frequently the step that makes the diagnosis after years of delay. The patient and the people who see them daily cannot see a change that takes a decade, and a photograph from fifteen years earlier makes it obvious.

Asking about ring size, shoe size, hat size and dental bite. Rings that no longer fit, shoes a size or two larger, and teeth that have separated or a bite that has changed are specific and cost nothing to ask about. Dentists detect a meaningful share of cases.

A single IGF-1 blood test, at tens of dollars, is the screening test for a disease with a 5 to 10 year diagnostic delay in which tumour size at diagnosis determines whether surgery cures. A blood pressure cuff, a fasting glucose and a question about snoring and daytime sleepiness find the three commonest comorbidities.

Cabergoline, oral and off-patent at hundreds of dollars a patient-year, normalises IGF-1 in roughly a third of patients with modest elevation and adds 15 to 30 percentage points of control when added to a somatostatin ligand. Against pegvisomant at hundreds of thousands of dollars a patient-year, this is the most consequential price fact in the entry, and it is noted even in general reference sources.

Telling the anaesthetist. Pharyngeal and laryngeal soft tissue growth makes intubation difficult and is a documented cause of anaesthetic death, and a sentence prevents it. Weight and sleep position measures help sleep apnoea while definitive treatment is arranged. Testing relatives in young-onset or familial disease finds *AIP* carriers who present with smaller tumours and higher cure rates. Simple analgesia and joint protection serve the arthropathy, the main residual disability, which does not respond to biochemical cure.

**Gaps.** Prevalence estimates range from roughly 28 to 137 per million, and systematic case-finding finds rates up to 10 times the registry figures. The true prevalence is unknown, and the commonly quoted figure of about 60 per million is probably an underestimate. Diagnostic delay of 5 to 10 years is consistently reported and has not shortened despite decades of awareness campaigns.

The source consulted gives no annual incidence figure, no median age at diagnosis, no quantified diagnostic delay, no standardised mortality ratio, no surgical cure percentage, and no somatostatin analogue or pegvisomant control rate. The figures in this entry for those quantities come from the wider registry and trial literature. Pegvisomant’s real-world IGF-1 normalisation, roughly 60 to 75 per cent, is substantially lower than in trials, roughly 90 to 97 per cent, apparently because of under-dosing. The phrase “controls disease activity in virtually everyone” reflects the trial figure and not practice.

Surgical cure rates come from high-volume centres. Outcomes in low-volume settings are not systematically reported, and the source consulted states only that success depends on the surgeon’s skill. Whether colorectal cancer risk is raised is contested, since polyps are clearly more common and cancer findings are inconsistent, yet colonoscopy surveillance is recommended on the basis of it. Thyroid cancer risk in acromegaly is similarly contested, and surveillance risks the overdiagnosis documented under thyroid nodules.

Arthropathy progresses after biochemical cure and is the main residual disability. No treatment prevents it and the mechanism is unexplained. Vertebral fractures occur despite normal or high bone mineral density, so standard osteoporosis assessment misleads and the right surveillance strategy is not established. Essentially all epidemiology and outcome data come from European and North American registries. Almost nothing comes from low- and middle-income countries, where somatostatin analogues are unaffordable and cabergoline and surgery are the only options.

## Osteoporosis

**What it is.** Bone loses mass and internal structure, so it breaks under forces it should withstand. There are no symptoms until a fracture happens. A hip fracture in an older person often ends independent living and kills roughly one in four within a year.

**Measured.** By the World Health Organization definition, a bone mineral density T-score of -2.5 or below at the femoral neck, osteoporosis affects roughly 20 to 25 per cent of women and 5 to 8 per cent of men aged 50 and over in European and North American surveys†. International Osteoporosis Foundation analyses of the European Union put roughly 32 million people aged 50 and over with osteoporosis in 2019, 25.5 million women and 6.5 million men, about 5.6 per cent of the EU population over 50†.

Roughly 9 million osteoporotic fractures occur a year worldwide, the standing estimate, derived from hip fracture incidence and extrapolation. Hip fractures number roughly 1.3 to 1.6 million a year globally and are projected to reach 4.5 to 6.3 million by 2050 on demographic grounds alone†. Lifetime risk of an osteoporotic fracture from age 50 is roughly 40 to 50 per cent in women and 13 to 22 per cent in men in high-income countries†. In the EU-27 plus the United Kingdom and Switzerland in 2019 there were roughly 4.3 million new fragility fractures, at a cost of roughly €56 billion, projected to rise by roughly 25 per cent by 2034†.

Hip fracture outcomes are the hard numbers. Excess mortality in the first year is roughly 20 to 30 per cent, with the standing figure that about one in four older patients dies within 12 months†. Roughly 40 per cent cannot walk independently afterwards, roughly 60 per cent need help a year later, and roughly 10 to 20 per cent move permanently into institutional care†. Mortality after hip fracture is consistently higher in men than in women.

Roughly two-thirds of vertebral fractures are clinically silent and found only on imaging. A prevalent vertebral fracture raises the risk of a further vertebral fracture roughly 4 to 5-fold and of hip fracture roughly 2-fold†. Risk of a second fracture is highest immediately after the first, roughly 2.7 to 5-fold in the first year or two, declining thereafter†. This underpins fracture liaison services.

Hip fracture rates vary more than 10-fold between countries. They are highest in Scandinavia, Austria and parts of northern Europe and lowest in parts of Africa, Latin America and East Asia, and the gradient does not track vitamin D status, calcium intake or latitude straightforwardly.

The treatment gap is the central measured failure. Roughly 70 to 80 per cent of people at high fracture risk receive no osteoporosis treatment in European, United States and Australian audits. Treatment initiation after a fragility fracture is roughly 20 to 30 per cent†. In the United States bisphosphonate use fell by roughly 50 per cent between the mid-2000s and mid-2010s, largely attributed to publicity about atypical femoral fracture and osteonecrosis of the jaw. Those risks run at roughly 1 in 10,000 to 1 in 100,000 patient-years, against a fracture risk reduction of the order of 1 in 20 to 1 in 100†. Persistence with oral bisphosphonates at 12 months is roughly 40 to 50 per cent†.

**Where it starts.** The mechanism is an imbalance in bone remodelling, with resorption by osteoclasts exceeding formation by osteoblasts, driven chiefly by the RANK, RANKL and osteoprotegerin and the Wnt and sclerostin pathways. Loss of trabecular connectivity and cortical thinning and porosity reduce strength out of proportion to the loss of mass, which is why bone mineral density explains only part of fracture risk.

Peak bone mass, reached by roughly age 20 to 30, is the starting point and is roughly 60 to 80 per cent heritable†. Oestrogen deficiency is the dominant cause in women. Bone loss accelerates to roughly 2 to 3 per cent a year at the spine in the first 5 to 10 years after menopause, against roughly 0.5 to 1 per cent a year thereafter†. Early menopause, surgical oophorectomy and prolonged amenorrhoea (athletic, anorexia nervosa, hyperprolactinaemia) all cause it. Age is the strongest single risk factor, independent of bone density.

Established risk factors, with the effect sizes used in FRAX and similar tools:

- Previous fragility fracture: roughly 2-fold; a recent fracture roughly 2.7 to 5-fold in the first years.
- Parental hip fracture: roughly 1.5 to 2-fold.
- Glucocorticoids, prednisolone 5 mg a day or more: vertebral fracture risk roughly 2 to 5-fold, with most of the loss in the first 3 to 6 months. Fracture risk rises before bone

density falls much, so glucocorticoid-induced osteoporosis is treated on the exposure and not the scan.
- Current smoking: roughly 1.3 to 1.8-fold for hip fracture.
- Alcohol, 3 units a day or more: roughly 1.4 to 2-fold.
- Low body weight, body mass index under 20: roughly 2-fold for hip fracture.
- Rheumatoid arthritis: roughly 1.5 to 2-fold, independent of steroids.
- Type 1 diabetes: hip fracture risk raised roughly 6 to 7-fold. Type 2 diabetes: roughly 1.3 to 1.7-fold despite higher bone density, so density underestimates risk in diabetes.

Falls are the proximate cause of roughly 90 per cent of hip fractures†. Fall risk and bone fragility are separate and multiplicative, so fall prevention is a distinct intervention. Other secondary causes are hyperthyroidism and over-replacement with levothyroxine, hyperparathyroidism, hypogonadism, coeliac disease and other malabsorption, chronic kidney and liver disease, myeloma, mastocytosis, anorexia nervosa and HIV. Drugs include aromatase inhibitors, androgen deprivation therapy, proton pump inhibitors (modestly), SSRIs, thiazolidinediones, antiepileptics, heparin, calcineurin inhibitors and injectable medroxyprogesterone acetate.

Heritability of bone mineral density in twin studies is roughly 0.5 to 0.8, and of fracture roughly 0.25 to 0.35, lower because falls and trauma intervene†. Genome-wide studies have found over 500 loci for bone density, among them *WNT16*, *LRP5*, *SOST*, *ESR1*, *RANKL* and *OPG*, which together explain roughly 20 per cent of density variance†. Monogenic bone fragility includes osteogenesis imperfecta (*COL1A1*, *COL1A2* and others, roughly 1 in 15,000 to 20,000 births), osteoporosis-pseudoglioma syndrome (*LRP5*) and hypophosphatasia (*ALPL*)†. These present and are treated differently. Bisphosphonates are harmful in hypophosphatasia, which is a trap.

*Not known*: why hip fracture rates vary more than ten-fold between countries, and why they have been falling in several high-income countries since the 1990s after age adjustment. The decline is real, substantial and unexplained. Why bone mineral density explains only part of fracture risk. Whether the long-term balance beyond 10 years favours continuing bisphosphonates, which is why drug holidays exist as a practice without trial support.

**Cure status.** CONTROLLABLE. No treatment restores normal bone architecture, and treatment reduces fracture risk without abolishing it.

Antiresorptive treatment reduces fracture risk substantially, and the effect is lost when treatment stops, rapidly with denosumab and slowly with bisphosphonates, which persist in bone. The pivotal randomised trials measured the following.

Zoledronic acid, HORIZON-PFT: 7,765 postmenopausal women with osteoporosis, 3,889 on zoledronic acid 5 mg intravenously at 0, 12 and 24 months and 3,876 on placebo, 60 centres, 3 years, all receiving calcium and vitamin D†. Vertebral fracture in those not on other osteoporosis drugs was 3.3 per cent against 10.9 per cent, relative risk 0.30 (95% confidence interval 0.24 to 0.38), a roughly 70 per cent relative reduction and 7.6 percentage points absolute†. Hip fracture in all randomised was 1.4 per cent against 2.5 per cent, hazard ratio 0.59 (0.42 to 0.83), a roughly 41 per cent relative reduction and 1.1 percentage points absolute†. Non-vertebral fracture was 8.0 per cent against 10.7 per cent, hazard ratio 0.75†. The safety signals were an acute-phase reaction (fever 16.1 per cent against 2.1), a transient creatinine rise (1.2 against 0.4 per cent) and more serious atrial fibrillation events (1.3 against 0.5 per cent)†. No osteonecrosis of the jaw was reported.

Alendronate, the Fracture Intervention Trial: in women with prevalent vertebral fracture, vertebral fracture fell by roughly 47 per cent, hip fracture by roughly 51 and wrist fracture by roughly 48 per cent†. Risedronate reduced vertebral fracture by roughly 41 to 49 per cent and hip fracture by roughly 30 per cent†.

Denosumab, FREEDOM: 7,868 women over 3 years, vertebral fracture reduced 68 per cent, hip fracture 40 and non-vertebral fracture 20 per cent†. Stopping denosumab causes rapid rebound bone loss and multiple vertebral fractures in a measurable minority, so it cannot simply be discontinued and must be followed by a bisphosphonate.

Teriparatide, an anabolic agent, reduced vertebral fracture 65 per cent and non-vertebral fracture 53 per cent in the pivotal trial†. In the VERO head-to-head trial it reduced new vertebral fractures by roughly 56 per cent compared with risedronate in women with severe osteoporosis. Abaloparatide reduced vertebral fracture roughly 86 per cent against placebo†.

Romosozumab, anti-sclerostin and both anabolic and antiresorptive, was tested in FRAME and ARCH. In ARCH, romosozumab followed by alendronate reduced vertebral fracture by roughly 48 per cent and hip fracture by roughly 38 per cent compared with alendronate alone†. ARCH also showed an excess of serious cardiovascular events, 2.5 against 1.9 per cent, which produced a boxed warning and restricts use in patients with recent myocardial infarction or stroke.

Hormone replacement therapy in the Women's Health Initiative reduced hip fracture by 33 per cent and total fracture by roughly 24 per cent in the oestrogen-plus-progestogen arm†. The fracture benefit was overshadowed by the breast cancer and cardiovascular findings, and the balance differs by age at initiation. Sequence matters: anabolic-first then antiresorptive gives greater bone density gains than the reverse, and this is now reflected in guidelines for severe disease.

Fracture risk can thus be roughly halved, and vertebral fracture risk reduced by up to two-thirds to four-fifths. The number needed to treat over 3 years to prevent one vertebral fracture is roughly 13 to 20 in high-risk women and to prevent one hip fracture roughly 90 to 100†. The HORIZON-PFT absolute differences give the same values: 1 / 0.076 is about 13, and 1 / 0.011 is about 91. This is not a cure, and it is a large effect.

**Prevention.** Fall prevention, because falls cause roughly 90 per cent of hip fractures. A Cochrane review of exercise for falls prevention in older people living in the community covered 59 trials and roughly 13,000 participants. It found a roughly 23 per cent reduction in the rate of falls (rate ratio 0.77) and a roughly 15 per cent reduction in the number of people falling. Balance and functional exercise, and Tai Chi (rate ratio roughly 0.81), were the effective categories†. STRONG. Multifactorial assessment and intervention in high-risk older people reduces falls by roughly 20 to 25 per cent. MODERATE. Medication review and withdrawal of psychotropics: MODERATE. Home hazard modification in those at high risk reduces falls by roughly 25 to 30 per cent†. MODERATE. Cataract surgery and vision correction: MODERATE. Hip protectors in nursing homes reduce hip fracture modestly, roughly 15 to 20 per cent, with poor adherence†. WEAK.

Calcium and vitamin D. Vitamin D alone does not reduce fractures in community-dwelling adults, and multiple randomised trials and meta-analyses are negative, including VITAL. Calcium plus vitamin D reduces fracture in institutionalised and deficient older people, by roughly 15 to 20 per cent for total fracture and roughly 25 to 30 per cent for hip fracture in the French nursing-home trials (Decalyos and Chapuy). High intermittent vitamin D doses, 500,000 IU annually or 60,000 IU monthly, increased falls and fractures in two randomised trials†. STRONG for calcium plus vitamin D in institutionalised and deficient populations. CONTESTED, to negative, for vitamin D alone in community-dwelling replete adults.

Weight-bearing and resistance exercise raises lumbar spine and femoral neck bone density by roughly 1 to 2 per cent over 6 to 12 months in meta-analyses, a small effect on density, and the fracture benefit comes mainly through falls. MODERATE for density, STRONG for the falls pathway. Not smoking and limiting alcohol: MODERATE. Adequate protein and avoiding underweight: MODERATE.

Glucocorticoid-sparing strategies, and bone protection from the start of any course expected to last 3 months or more at prednisolone 5 to 7.5 mg a day or more. Bisphosphonate prophylaxis reduces vertebral fracture in glucocorticoid-treated patients. STRONG. Correcting secondary causes: coeliac disease, hyperparathyroidism, hyperthyroidism, levothyroxine over-replacement, hypogonadism, vitamin D deficiency. STRONG.

Fracture liaison services systematically identify and treat everyone presenting with a fragility fracture. Observational and some controlled data show increased treatment rates and reduced refracture and mortality, and they address the 70 to 80 per cent treatment gap directly. MODERATE.

Screening. The United Kingdom SCOOP trial, 12,483 women aged 70 to 85, found a 28 per cent reduction in hip fractures with FRAX-based screening, and no reduction in all osteoporotic fractures. The Danish ROSE trial was negative for its primary endpoint. MODERATE: screening by fracture-risk tool, and not by bone density scan, has the better evidence.

**Treatment.** No bisphosphonate is on the WHO Essential Medicines List 24th List (2025) for osteoporosis. A live query of the electronic list returns zero recommendations for alendronate, which is not on the list at all. Zoledronic acid is listed only under Supportive

medicines, section 8.2.5, for malignant neoplasm metastasis in bone or bone marrow and for osteogenesis imperfecta. Neither indication is osteoporosis. The most cost-effective fracture-prevention drug class in medicine is absent from the list for its main indication.

Oral bisphosphonates, alendronate weekly and risedronate weekly or monthly, are first-line almost everywhere. They are off-patent and cost tens of dollars a patient-year. Vertebral fracture falls by roughly 40 to 50 per cent and hip fracture by roughly 30 to 50 per cent†. Practical constraints are that the tablet must be taken fasting with water, upright, 30 to 60 minutes before food, with upper gastrointestinal intolerance, and persistence at 12 months is only 40 to 50 per cent.

Zoledronic acid, 5 mg intravenously once yearly, gives the HORIZON-PFT results above. It is off-patent and costs tens to hundreds of dollars a patient-year including the infusion visit. Once-yearly dosing solves the adherence problem that defeats oral bisphosphonates, and that is its main practical advantage. An acute-phase reaction follows the first dose in roughly 16 per cent† and is reduced by paracetamol.

Denosumab, 60 mg subcutaneously every 6 months, gives the FREEDOM results above. Biosimilars launched in Europe and the United States from 2024 to 2025 and prices are falling sharply. The originator costs thousands of dollars a patient-year and biosimilars hundreds. The discontinuation hazard is the key point: stopping causes rebound resorption and multiple vertebral fractures in a measurable minority, so a bisphosphonate must follow. That makes it a poor choice where follow-up cannot be guaranteed. Its listing status needs checking against the 24th List†.

Anabolic agents are for severe osteoporosis, multiple vertebral fractures or failure on antiresorptives. Teriparatide, daily subcutaneous for a maximum of 24 months, has biosimilars; the originator costs tens of thousands of dollars a patient-year and a biosimilar thousands. Its listing status needs checking against the 24th List†. Abaloparatide is patented at about the originator teriparatide price. Romosozumab, monthly for 12 months, costs tens of thousands of dollars a course and carries the cardiovascular boxed warning.

Hormone replacement therapy serves women with menopausal symptoms and fracture risk and premature menopause, at tens to hundreds of dollars a patient-year. Raloxifene, a selective oestrogen receptor modulator, reduces vertebral fracture roughly 30 to 40 per cent, does not reduce hip fracture, reduces invasive breast cancer and increases venous thromboembolism. It is off-patent at hundreds of dollars a patient-year. Calcium and vitamin D are adjuncts in all treated patients and primary prevention in deficient and institutionalised people, at a few dollars to tens of dollars a patient-year. The listing status of oestrogens, calcium and vitamin D on the 24th List needs checking†.

Secondary causes are treated and bone-harmful drugs reviewed. Hip fracture needs early surgery, within 24 to 48 hours, which reduces mortality†. Orthogeriatric care reduces mortality and length of stay, and early mobilisation helps. Vertebroplasty and kyphoplasty did not show benefit over sham in two randomised sham-controlled trials, and remain contested. Drug holidays after 3 to 5 years of bisphosphonate treatment in lower-risk patients are standard practice, based on the FLEX and HORIZON extension trials, and are not supported by fracture-endpoint trials of holiday against continuation.

Not to be done: bisphosphonates in hypophosphatasia, stopping denosumab without follow-on treatment, and treating on bone density alone in diabetes or glucocorticoid exposure, where density underestimates risk.

**Simple means.** Exercise, specifically balance and functional training, and Tai Chi. The Cochrane review of 59 trials found a roughly 23 per cent reduction in the rate of falls, with Tai Chi at a rate ratio of roughly 0.81†. Since falls cause roughly 90 per cent of hip fractures, this is the highest-yield non-pharmacological intervention, and it needs no equipment.

Removing hazards at home, such as loose rugs, poor lighting, clutter, absent stair rails and slippery bathrooms, reduces falls roughly 25 to 30 per cent in high-risk people for the cost of a few fittings. Reviewing medicines, particularly sedatives, antihypertensives causing postural hypotension and anticholinergics, is free. So are getting cataracts operated on and glasses corrected.

Calcium from food: dairy, small whole fish with bones, calcium-set tofu, dark leaves, nixtamalised maize and ground eggshell, used as a calcium supplement in several low-income

settings and measurably bioavailable. Vitamin D from sunlight; see rickets and vitamin D deficiency. In institutionalised and deficient older people, calcium plus vitamin D reduces hip fracture by roughly 25 to 30 per cent.

Alendronate costs tens of dollars a patient-year, is off-patent, and halves vertebral fracture risk. It is not on the WHO Essential Medicines List. It is the cheapest effective fracture-prevention drug in existence, and it is absent from the list. Zoledronic acid once a year costs tens to hundreds of dollars a patient-year including the visit and removes the adherence problem entirely, with a single annual contact. That suits settings with limited follow-up capacity, except that it needs an intravenous infusion.

Not smoking, limiting alcohol, adequate protein and not being underweight. Treating the fracture promptly and getting the person up: early surgery and early mobilisation after hip fracture reduce mortality, and both are organisational and not technological.

Asking about previous fractures. A prior fragility fracture roughly doubles future risk and is the strongest single clinical predictor. Identifying it costs one question, and the 70 to 80 per cent treatment gap exists largely because the question is not asked. FRAX or a similar risk tool is free, paper- or web-based, needs no bone density scan, and SCOOP showed a 28 per cent hip fracture reduction from a FRAX-based screening programme.

**Gaps.** Hip fracture rates vary more than ten-fold between countries and the gradient is unexplained. Age-adjusted rates have been falling in several high-income countries since the 1990s, also unexplained, which means the projection of 4.5 to 6.3 million hip fractures by 2050 may be an overestimate. The 9 million global fractures figure is an extrapolation from hip fracture data in a minority of countries, and there is no direct global fracture surveillance.

Bone mineral density explains only part of fracture risk and in diabetes and glucocorticoid exposure actively underestimates it. The WHO T-score definition remains the diagnostic standard nonetheless.

The treatment gap is 70 to 80 per cent in high-income countries with full access to cheap generic drugs, so the barrier is not price. Bisphosphonate use fell by roughly half in the United States after publicity about rare harms of 1 in 10,000 to 1 in 100,000 patient-years. No source reconciles this failure of risk communication. Separately, the drug class that is cheapest and best evidenced is not on the WHO Essential Medicines List for osteoporosis, so the global procurement reference does not carry it.

Drug holidays are standard practice without fracture-endpoint trial support. Denosumab rebound fractures on discontinuation were not anticipated by the pivotal trials and emerged after marketing, and the optimal transition strategy is not established by trial. Romosozumab's cardiovascular signal, 2.5 against 1.9 per cent in ARCH, is of uncertain mechanism, and the FRAME trial did not show it, so sources disagree on how real it is. Vertebroplasty was not superior to sham in two randomised trials and continues to be performed. Vitamin D alone does not prevent fractures and continues to be prescribed for that purpose, and high intermittent doses increased falls and fractures.

For screening, SCOOP was positive for hip fracture and ROSE negative for its primary endpoint. The sources disagree, and no country has adopted universal osteoporosis screening. Almost all prevalence, cost and outcome data are from Europe, North America, Australia and parts of East Asia. Fracture epidemiology in Africa, South Asia and Latin America is thinly measured, and the apparently low rates may be partly ascertainment. Male osteoporosis is under-studied, under-diagnosed and under-treated despite higher post-fracture mortality than in women.

---

## Gout and hyperuricaemia

**What it is.** Uric acid crystallises in a joint and the body attacks the crystals. The joint becomes excruciatingly painful, red and swollen within hours, classically at the base of the big toe. Attacks stop by themselves. Without lowering the uric acid they come back and eventually destroy the joint.

**Measured.** The Global Burden of Disease 2021 gout analysis (*Lancet Rheumatology*, July 2024) found 55.8 million people with gout globally in 2020, 95 per cent uncertainty interval 44.4 to 69.8 million. Age-standardised prevalence was 659.3 per 100,000 (525.4 to 822.3),

up 22.5 per cent since 1990. The male-to-female prevalence ratio was about 3.26 to 1, and prevalence rises with age. The age-standardised YLD rate was 20.5 per 100,000 (14.4 to 28.2).

The projection to 2050 is about 95.8 million cases (81.1 to 116 million), an increase of over 70 per cent from 2020, with the age-standardised rate forecast at 667 per 100,000†. Population growth and ageing drive most of the rise, and changes in prevalence rates contribute little. High body mass index accounted for 34.3 per cent (27.7 to 40.6) of gout YLDs and kidney dysfunction for 11.8 per cent (9.3 to 14.2)†. The study states that many low- and middle-income countries rely on modelled and not primary data, and that severity and disability data are often missing.

Hyperuricaemia, serum urate above roughly 0.36 to 0.42 mmol/L (6 to 7 mg/dL), is far commoner than gout. It is present in roughly 20 per cent of United States adults in the NHANES survey†. Most people with hyperuricaemia never develop gout. Roughly 10 to 20 per cent do over a decade, rising steeply with urate level: annual incidence is roughly 0.5 per cent at urate below 7 mg/dL and roughly 4 to 5 per cent above 9 mg/dL†.

The highest recorded prevalences are in Māori and Pacific Island populations. Gout affects roughly 8 to 14 per cent of Māori men and over 10 per cent in some Pacific populations, among the highest in the world, and Taiwanese Indigenous populations are similarly high. It is also high in the United States, Australia, New Zealand and parts of Europe. Gout is rare before puberty. In men incidence rises from the third decade, and in women it rises sharply after menopause because oestrogen is uricosuric, so the sex ratio narrows with age.

Among gout patients in United States cohorts, hypertension is present in roughly 70 per cent, chronic kidney disease in 20 to 25, obesity in 50 to 55, type 2 diabetes in 25 and cardiovascular disease in 10 to 15 per cent†. Gout is associated with raised all-cause and cardiovascular mortality, hazard ratios roughly 1.1 to 1.3, persisting after adjustment for comorbidities, though whether this is causal is contested.

The central measured failure is in treatment. In United States and European audits roughly one-third to one-half of gout patients ever receive urate-lowering therapy, and adherence at one year is roughly 20 to 40 per cent, among the worst of any chronic disease†. Serum urate is measured and treated to target in a minority. Gout is a disease whose activity can be abolished under treatment, and largely is not. The reason is implementation.

**Where it starts.** The mechanism is fully established. Humans lack uricase, so urate is the end product of purine metabolism. Above its solubility limit, roughly 0.36 to 0.40 mmol/L (6.0 to 6.8 mg/dL) at body temperature and pH, monosodium urate crystallises, preferentially in cooler, acidic peripheral joints. Crystals activate the NLRP3 inflammasome in macrophages and release IL-1 beta, which drives the acute attack. That is why IL-1 blockade works, and it is the cleanest line from mechanism to drug in rheumatology.

Renal urate handling is the dominant determinant. Roughly 90 per cent of gout is under-excretion and not over-production†. The transporters involved are URAT1 (*SLC22A12*), GLUT9 (*SLC2A9*), ABCG2, OAT1 and OAT3, and NPT1 (*SLC17A1*), and they are both the genetic signal and the drug targets.

Heritability of serum urate is roughly 0.4 to 0.6 in twin and family studies, and of gout roughly 0.3 to 0.4†. *SLC2A9* is the strongest common locus, explaining roughly 3 to 4 per cent of urate variance alone, unusually large for a common variant. *ABCG2* Q141K is the strongest gout risk variant, with odds ratios of roughly 2 to 3, and is particularly frequent in East Asian and Polynesian populations, which partly explains the high prevalence there. Over 180 urate loci are now identified and together explain roughly 7 to 8 per cent of urate variance†. Monogenic causes are familial juvenile hyperuricaemic nephropathy (*UMOD*, *REN*, *HNF1B*), HPRT deficiency (Lesch-Nyhan syndrome), *PRPS1* superactivity and glycogen storage disease type I. They present young and must be recognised.

Diet is real and smaller than commonly assumed. Measured relative risks, from the Health Professionals Follow-up Study and similar cohorts, are roughly 1.2 to 1.4 for the highest against the lowest red meat intake, roughly 1.5 for seafood, and roughly 1.5 to 2.5 per 12 oz daily serving of beer†. Beer is the strongest dietary association, because it contains both alcohol and purines (guanosine). Spirits carry roughly 1.15 per drink a day, and wine shows no significant association in most cohorts. Sugar-sweetened beverages and fructose carry

roughly 1.4 to 2.0 for the highest intake, and fructose raises urate directly through ATP depletion in hepatocytes.

Protective associations are dairy (roughly 0.5 to 0.6 for high intake), coffee (roughly 0.4 to 0.6 for four or more cups a day), vitamin C, and cherries (roughly 0.65 for attack risk in a case-crossover study)†. Vegetables and legumes show no association with gout despite high purine content, an important and counterintuitive finding. A genome-wide and dietary analysis in large cohorts found that diet explained under 1 per cent of urate variance while genetic variants explained roughly 24 per cent†. That contradicts the common framing of gout as a dietary disease, and matters for how the condition is explained to patients and how blame is assigned.

Drugs that raise urate are thiazide and loop diuretics, the commonest iatrogenic cause, low-dose aspirin, ciclosporin, tacrolimus, pyrazinamide, ethambutol, levodopa, nicotinic acid and testosterone. Drugs that lower urate incidentally are losartan, calcium channel blockers, fenofibrate and SGLT2 inhibitors. SGLT2 inhibitors reduce gout flares in cohort studies, which matters because so many gout patients have diabetes or kidney disease. Other causes of hyperuricaemia are chronic kidney disease, lead exposure (saturnine gout), psoriasis and other high-turnover states, tumour lysis, dehydration, fasting and ketosis, obesity, insulin resistance and hypothyroidism.

Individual attacks are triggered by trauma, surgery, acute illness, dehydration, starting or stopping urate-lowering therapy, alcohol binge, a purine-rich meal and diuretic initiation. Rapid change in urate in either direction precipitates attacks, which is why urate-lowering therapy starts with flare prophylaxis.

*Not known*: why most people with hyperuricaemia never get gout. Whether asymptomatic hyperuricaemia should be treated. Whether urate is causally related to hypertension, chronic kidney disease and cardiovascular disease, or merely associated. Mendelian randomisation studies have mostly been negative for a causal effect on these outcomes, while observational associations are strong, and the randomised trials of allopurinol for kidney and cardiovascular endpoints (CKD-FIX and PERL) were negative.

**Cure status.** The disease, under continuing urate-lowering therapy: CONTROLLABLE. The individual acute flare: SELF-LIMITING. Asymptomatic hyperuricaemia is a laboratory finding and not a disease, and carries no label.

Sustained urate-lowering dissolves the crystal deposits and flares cease entirely, but treatment must usually be lifelong because urate rises again if it stops. A treatment that must be continued for life does not cure.

Sustained urate below roughly 0.36 mmol/L (6 mg/dL), and below 0.30 mmol/L (5 mg/dL) where tophi are present, dissolves tophi progressively over months to years and arrests erosive joint damage. Flares rise at first during crystal mobilisation and then fall to near zero. In long-term cohorts of treat-to-target urate-lowering therapy the great majority of patients become and remain flare-free.

The acute attack resolves over 7 to 14 days without treatment†. Treatment shortens and relieves it and does not change the course of the disease. Disease activity can be abolished by a tablet costing a few dollars to tens of dollars a year, and most patients worldwide never get it. Allopurinol is off-patent and on the WHO Essential Medicines List.

Pegloticase, a pegylated recombinant uricase, dissolves tophi rapidly in refractory tophaceous gout, a complete response occurring in roughly 42 per cent with methotrexate co-administration in the MIRROR randomised trial against roughly 24 to 42 per cent in earlier monotherapy trials†. A course costs hundreds of thousands of dollars. It is for the small group who have already failed everything cheap. Disease activity under it is still CONTROLLABLE.

**Prevention.** Preventing flares in established gout by treat-to-target urate-lowering therapy. The target is below 0.36 mmol/L (6 mg/dL), or below 0.30 mmol/L (5 mg/dL) with tophi. Sustained achievement essentially abolishes flares. STRONG.

Flare prophylaxis when starting urate-lowering therapy, with low-dose colchicine (0.5 mg once or twice a day) or an NSAID for 3 to 6 months, reduces the paradoxical early flare rate by roughly 50 to 85 per cent in randomised trials†. STRONG. Omitting it is the commonest reason patients stop allopurinol in the first months.

Reviewing diuretics. Thiazides and loop diuretics are the commonest iatrogenic cause, and substituting losartan or a calcium channel blocker where an antihypertensive is needed lowers urate. MODERATE.

Weight loss. High body mass index accounts for 34.3 per cent of gout YLDs in the GBD 2021 analysis. Observational and trial data show urate falling roughly 0.03 to 0.06 mmol/L (0.5 to 1.0 mg/dL) per 10 kg lost, and bariatric surgery lowers urate and reduces gout incidence substantially. MODERATE.

Dietary measures are real and modest. Dietary change typically lowers serum urate by roughly 0.01 to 0.06 mmol/L (0.2 to 1.0 mg/dL)†. That is rarely enough to reach target in someone with established gout, and diet explains under 1 per cent of urate variance against roughly 24 per cent for genetics. MODERATE for urate lowering, WEAK as monotherapy for gout. Beer and spirits are the strongest single dietary lever (beer relative risk 1.5 to 2.5 per daily serving), and sugar-sweetened beverages and fructose follow (1.4 to 2.0 for high intake). Dairy, coffee, cherries and vitamin C are associated with lower urate and lower flare risk. Vegetables and legumes need not be restricted, since plant purines show no association with gout.

Treating asymptomatic hyperuricaemia is CONTESTED, and the trials are negative. CKD-FIX, allopurinol in chronic kidney disease, and PERL, allopurinol in type 1 diabetic kidney disease, both found no slowing of kidney function decline. ALL-HEART, allopurinol in ischaemic heart disease, found no cardiovascular benefit. Mendelian randomisation studies have mostly been negative for causal effects of urate on blood pressure, kidney function and cardiovascular disease. The American College of Rheumatology 2020 guideline conditionally recommends against urate-lowering therapy for asymptomatic hyperuricaemia.

Febuxostat cardiovascular safety is CONTESTED. The CARES trial found higher cardiovascular mortality with febuxostat than allopurinol, hazard ratio 1.34 for cardiovascular death, and produced a boxed warning†. The later FAST trial found no excess and was non-inferior. The sources disagree, and allopurinol remains first-line.

*HLA-B*58:01* screening before allopurinol in Han Chinese, Thai, Korean and other Southeast Asian populations. The odds ratio for allopurinol-induced Stevens-Johnson syndrome and toxic epidermal necrolysis is roughly 80 to 100†. Screening is cost-effective in those populations and is recommended. STRONG in high-prevalence populations.

**Treatment.** The acute attack has four routes, all effective, and the choice is driven by comorbidity.

NSAIDs, naproxen, indomethacin or etoricoxib, cost a few dollars an attack. Colchicine in the low-dose regimen, 1.2 mg then 0.6 mg or 1 mg then 0.5 mg, is as effective as the old high-dose regimen with far less diarrhoea in the AGREE trial. It costs a few dollars to tens of dollars an attack at generic international prices. In the United States colchicine was granted market exclusivity in 2009 under the Unapproved Drugs Initiative, and its price rose from cents to a few dollars a tablet. Generics have since returned and prices have fallen, and it remains an instance of an off-patent drug made expensive by regulatory exclusivity. Oral prednisolone, 30 to 35 mg for 5 days, equals naproxen in randomised trials, and intra-articular injection for a single joint is the best option in kidney disease and heart failure. It costs a few dollars an attack. The listing status of ibuprofen, naproxen, colchicine and prednisolone on the WHO Essential Medicines List 24th List needs checking†.

IL-1 inhibitors, canakinumab and anakinra, are for patients in whom all of the above are contraindicated. Canakinumab costs tens of thousands of dollars a dose and anakinra tens of thousands a patient-year, so they are reserved by cost. Rest, elevation and ice help the joint.

Urate-lowering therapy is the treatment that controls the disease. Allopurinol, a xanthine oxidase inhibitor, is first-line. It starts low, 100 mg a day or 50 mg in chronic kidney disease, and is titrated upward to target urate, up to 800 to 900 mg a day if needed†. Under-dosing is the commonest reason for failure, since most patients are left on 300 mg whether or not target is reached. Allopurinol is on the WHO Essential Medicines List 24th List, section 29.1, for gout, as 100 mg oral solid, and also under supportive medicines for tumour lysis syndrome. It is off-patent and costs a few dollars to tens of dollars a patient-year, one of the cheapest chronic treatments of any disease. Allopurinol hypersensitivity syndrome occurs in roughly 0.1 to 0.4 per cent, with mortality up to 20 to 25 per cent when severe†. Risk

is concentrated in *HLA-B*58:01* carriers, in chronic kidney disease, and with high starting doses, hence start low and screen in high-risk populations.

Febuxostat, second-line, lowers urate more potently. It is generic at tens to hundreds of dollars a patient-year, with a cardiovascular boxed warning in the United States after CARES, not replicated in FAST. Uricosurics are used as add-ons. Probenecid costs tens to hundreds of dollars a patient-year. Benzbromarone is more potent, is used in Europe and Asia, and was withdrawn in some markets over hepatotoxicity. Their listing status needs checking against the 24th List†.

Pegloticase, for refractory tophaceous gout, costs hundreds of thousands of dollars a course. Co-administration with methotrexate reduces immunogenicity and raises response rates: in the MIRROR trial roughly 71 per cent against 39 per cent had a sustained urate response at 52 weeks†. This is a different endpoint from the complete-response figure given under cure status, and the two are not the same measure. Low-dose colchicine or an NSAID for the first 3 to 6 months of urate-lowering therapy costs cents to a few dollars and determines whether the patient persists.

Adjuncts and substitutions are losartan in place of another antihypertensive, at tens of dollars a patient-year; fenofibrate; SGLT2 inhibitors in those with diabetes or kidney disease; and stopping or substituting the diuretic. Losartan's listing status needs checking against the 24th List†. Surgery is for tophus debulking, ulceration, infection or nerve compression, and is rarely needed if urate is controlled.

Nurse-led treat-to-target care is the most effective single intervention in the entry. A randomised trial (Doherty et al., *Lancet*, 2018) tested nurse-led gout care with education and treat-to-target urate lowering. Urate was below 6 mg/dL in 95 per cent of patients at 2 years against 30 per cent with usual general practice care, with fewer flares and resolved tophi. It is a service-design intervention using the same cheap drug.

**Simple means.** Allopurinol is oral, off-patent, on the Essential Medicines List, costs a few dollars to tens of dollars a patient-year, and abolishes disease activity when titrated to a urate target. The barrier is not cost or supply. It is dose titration and adherence.

A serum urate measurement costs a few dollars and is the entire basis of treat-to-target care. Without it, allopurinol is prescribed at a fixed dose and the target is not reached. The Doherty trial showed 95 per cent against 30 per cent target achievement when someone measures and titrates.

Low-dose colchicine for the first few months of allopurinol costs cents to a few dollars and prevents the early flares that make patients abandon treatment. Rest, elevation and ice to the joint help, and ice reduced pain in a small randomised trial.

Stopping beer and spirits, where that is the pattern, since beer carries the strongest dietary relative risk and wine shows no significant association. Reducing sugar-sweetened drinks and fructose. Coffee, low-fat dairy, cherries and vitamin C are all ordinary food and are associated with lower urate or lower flare risk. Vegetables, legumes, pulses, mushrooms and whole grains need not be restricted. Plant purines show no association with gout, and the traditional purine-restricted diet needlessly removes cheap, nutritious food. Adequate water matters, because dehydration precipitates attacks.

Weight loss lowers urate by roughly 0.03 to 0.06 mmol/L per 10 kg lost, and high body mass index accounts for 34.3 per cent of gout YLDs. Asking what diuretic the person is on and switching a thiazide to losartan or a calcium channel blocker, where an antihypertensive is needed, lowers urate at no extra cost.

Telling the patient that gout is a disease of urate handling, mostly genetic, and controllable with a cheap daily tablet. The GBD data and the genetic findings, diet under 1 per cent of urate variance against roughly 24 per cent for genetics, contradict the widespread framing of gout as self-inflicted. That framing is a documented barrier to patients accepting treatment.

**Gaps.** The GBD 2021 analysis states that many low- and middle-income countries rely on modelled and not primary data, and that severity and disability data are often missing. The 55.8 million figure carries a 95 per cent uncertainty interval of 44.4 to 69.8 million, and the regional detail is weakest where the Indigenous-population prevalences are highest.

Why most people with hyperuricaemia never develop gout is unknown, and no marker predicts it. For treating asymptomatic hyperuricaemia, CKD-FIX, PERL and ALL-HEART are all negative, and Mendelian randomisation is mostly negative for causality, while observational associations with hypertension, kidney and cardiovascular disease are strong. The associations are probably confounded, and this is not settled. Febuxostat cardiovascular safety stands as CARES positive for harm and FAST negative. The sources disagree, and the boxed warning stands.

Roughly one-third to one-half of gout patients ever receive urate-lowering therapy and one-year adherence is 20 to 40 per cent, for a disease controlled by a drug costing a few dollars to tens of dollars a year. The reason is implementation. The Doherty trial shows it is fixable with nursing time, and almost no health system has done so. Allopurinol is routinely under-dosed, and fixed-dose prescribing without urate measurement is the norm.

The contribution of diet is far smaller than the cultural framing implies, and dietary advice remains the dominant message given to patients in many settings. Pegloticase at hundreds of thousands of dollars a course stands against allopurinol at a few dollars to tens of dollars a patient-year, for the small group in whom cheap treatment has genuinely failed. Much of that is failure of titration and not true refractoriness. Colchicine's United States price history shows that regulatory exclusivity can make an ancient drug expensive, and no systematic data exist on how often this occurs.

The projected rise to 95.8 million by 2050 assumes current prevalence rates persist. Rising obesity could make it higher and better treatment could make it lower, and neither is modelled. Gout in women, and in chronic kidney disease, is under-studied relative to its burden.

---

## Dyslipidaemia

**What it is.** Too much of the wrong kind of cholesterol in the blood, most importantly low-density lipoprotein (LDL). It causes no symptoms. Over decades it builds plaque in artery walls, and the plaque causes heart attacks and strokes.

**Measured.** The World Health Organization reports raised total cholesterol, 5.0 mmol/L or above, in roughly 39 per cent of adults worldwide, 37 per cent of men and 40 per cent of women†. Prevalence is highest in high-income countries, roughly 54 per cent in Europe and 48 per cent in the Americas, against roughly 23 to 30 per cent in Africa and South-East Asia†. The Global Burden of Disease attributes roughly 3.8 to 4.5 million deaths a year and roughly 98 million DALYs to high LDL cholesterol, one of the largest single attributable risk factors for death globally. Almost all of it runs through ischaemic heart disease and ischaemic stroke.

Mean total cholesterol has been falling in high-income Western countries and rising in East and South-East Asia. The NCD Risk Factor Collaboration (*Nature*, 2020) found non-HDL cholesterol fell substantially in north-western Europe, North America and Australasia between 1980 and 2018, and rose in China, Indonesia, Malaysia, Japan and other Asian countries. The highest non-HDL cholesterol levels are now in East and South-East Asia and not the West, a complete reversal of the 1980 pattern.

Familial hypercholesterolaemia (FH), the monogenic form, is the most consequential underdiagnosis in the entry. Heterozygous FH occurs in roughly 1 in 250 to 1 in 311 in general populations, in a meta-analysis of over 11 million people, roughly 30 to 35 million people worldwide and far commoner than the previously assumed 1 in 500†. Homozygous FH occurs in roughly 1 in 300,000 to 1 in 400,000. Founder populations are higher: Afrikaners roughly 1 in 70 to 100, French Canadians roughly 1 in 270, Christian Lebanese roughly 1 in 85 and Ashkenazi Jews roughly 1 in 67, with Finns and South African Indians also affected†.

Fewer than 10 per cent of people with FH are diagnosed worldwide, and under 1 per cent in most low- and middle-income countries. In the best-performing country, the Netherlands, roughly 70 per cent are identified†. Untreated heterozygous FH leads to a coronary event in roughly 50 per cent of men by age 50 and roughly 30 per cent of women by age 60. Untreated homozygous FH causes coronary disease in childhood and death typically before age 20 to 30†. Statin treatment reduces coronary mortality in FH by roughly 75 to 80 per cent in cohort studies, and life expectancy approaches normal if treatment starts in childhood or early adulthood.

Treatment and control gaps are large. In the EUROASPIRE and similar surveys roughly 70 to 80 per cent of patients with established coronary disease do not reach an LDL target below 1.8 mmol/L, and roughly half of high-risk patients in primary care are not on a statin. Statin discontinuation within one year is roughly 25 to 50 per cent†.

**Where it starts.** The mechanism is established beyond reasonable dispute. LDL and other apolipoprotein-B-containing lipoproteins enter the arterial intima, are retained and modified, and provoke a chronic inflammatory response that produces plaque. The evidence for causality is unusually complete and comes from four independent directions. Observational epidemiology gives a log-linear relationship between LDL and coronary risk. Mendelian randomisation shows that variants in *HMGCR*, *PCSK9*, *NPC1L1*, *LDLR*, *APOB* and others each lower LDL and lower coronary risk by the amount predicted per unit of LDL, regardless of mechanism. Randomised trials supply the Cholesterol Treatment Trialists' meta-analyses. The monogenic extremes complete it: FH raises LDL and causes premature coronary disease, and loss-of-function *PCSK9* lowers LDL lifelong and confers protection. This convergence is why LDL is treated as causal and not merely associated.

The Cholesterol Treatment Trialists' Collaboration meta-analyses of statin trials found a roughly 21 to 22 per cent proportional reduction in major vascular events per 1 mmol/L (about 39 mg/dL) reduction in LDL cholesterol, and roughly a 10 per cent reduction in all-cause mortality per 1 mmol/L†. The effect was consistent across people with and without diabetes, with and without prior vascular disease, across age and sex, and at all baseline LDL levels studied. The benefit accumulates with duration, smaller in year one and larger thereafter.

In monogenic FH, *LDLR* accounts for roughly 85 to 90 per cent of identified mutations, *APOB* roughly 5 to 10 per cent, gain-of-function *PCSK9* roughly 1 to 3 per cent, and recessive *LDLRAP1* the rest†. Over 2,000 *LDLR* variants are described. Roughly 20 to 40 per cent of people with an FH phenotype have no single-gene mutation but a high LDL polygenic score, the commonest cause of severe hypercholesterolaemia.

Lipoprotein(a), Lp(a), is roughly 70 to 90 per cent genetically determined by the *LPA* gene. It varies more than 1,000-fold between individuals, is not meaningfully altered by diet, exercise or statins, and is causally associated with coronary disease and aortic stenosis by Mendelian randomisation. Roughly 20 per cent of the world's population has Lp(a) above 50 mg/dL, the commonly used risk threshold, with the highest prevalence in people of African and South Asian ancestry. It is the commonest genetic cardiovascular risk factor, and until recently there was nothing to do about it.

Familial combined hyperlipidaemia occurs in roughly 1 in 50 to 100, polygenic, with mixed cholesterol and triglyceride elevation and insulin resistance. Severe hypertriglyceridaemia arises from *LPL*, *APOC2*, *APOA5*, *GPIHBP1* and *LMF1* variants, causing familial chylomicronaemia syndrome, roughly 1 in 1,000,000, and recurrent pancreatitis. Heritability is roughly 0.4 to 0.6 for LDL, 0.5 to 0.6 for HDL and 0.7 to 0.9 for Lp(a)†.

Diet effects are smaller for cholesterol than popularly assumed and larger for clinical events when the whole pattern changes. Metabolic ward studies and meta-regressions measured a roughly 0.03 to 0.05 mmol/L fall in LDL per 1 per cent of energy substituted from saturated to polyunsaturated fat, a substantial dietary change yielding roughly 0.2 to 0.5 mmol/L†. A Cochrane review of reducing saturated fat found a roughly 17 per cent reduction in cardiovascular events, relative risk 0.83, with no clear effect on mortality†. The benefit depended on the replacement: polyunsaturated fat and whole grains yes, refined carbohydrate no. Dietary cholesterol has a small effect on serum LDL in most people, far smaller than saturated and trans fat, which is why dietary cholesterol limits were dropped from several guidelines.

Industrial trans fat raises LDL and lowers HDL and has the largest adverse effect per gram of any dietary fat. The WHO REPLACE programme has driven elimination: by 2023 roughly 53 countries covering roughly 3.7 billion people had best-practice trans fat policies. Denmark's 2003 ban was followed by a measurable fall in cardiovascular mortality†. Soluble fibre, plant sterols and stanols, soy protein and nuts each lowered LDL by roughly 3 to 10 per cent in trials, and combined portfolio dietary patterns by roughly 10 to 30 per cent†. Trans fat elimination, salt reduction and saturated fat replacement are the three population dietary measures with the strongest evidence.

Other determinants are physical inactivity, obesity and insulin resistance (raising triglycerides and lowering HDL), smoking (lowers HDL, oxidises LDL), alcohol (raises triglycerides and HDL), hypothyroidism (raises LDL, and must be excluded before treating), nephrotic syndrome, cholestasis, and drugs: thiazides, beta-blockers, corticosteroids, antiretrovirals, antipsychotics, isotretinoin and ciclosporin.

*Not known*: whether raising HDL has any benefit. Multiple randomised trials of HDL-raising drugs, niacin in AIM-HIGH and HPS2-THRIVE and the CETP inhibitors torcetrapib, dalcetrapib and evacetrapib, were negative or harmful, while HDL remains strongly inversely associated with risk. Mendelian randomisation is negative for HDL causality. It is one of the clearest cases in medicine of a strong biomarker association that is not causal. Also not known: the optimal LDL target, since trials show benefit down to roughly 0.5 mmol/L with no observed lower threshold and no safety signal†. And whether treating Lp(a) lowers events, since the outcome trials are running now.

**Cure status.** CONTROLLABLE. No treatment cures the underlying lipoprotein metabolism, and the risk reduction depends on continued treatment.

Statins reduce major vascular events by roughly 21 to 22 per cent per 1 mmol/L of LDL reduction, and the effect accumulates with duration. Stopping returns LDL to baseline within weeks. The lifetime framing is measured: Mendelian randomisation shows that lifelong genetically lower LDL confers roughly three times the risk reduction per 1 mmol/L compared with a statin started in middle age, because the exposure is cumulative. Treatment started late therefore recovers only part of the available benefit. That is the strongest argument for early identification of FH.

Homozygous FH is CONTROLLABLE. Statins work poorly because there is little or no LDL receptor function. Treatment is lipoprotein apheresis every 1 to 2 weeks, lowering LDL by roughly 50 to 70 per cent acutely, lomitapide, evinacumab, and in some cases liver transplantation, which supplies functioning LDL receptors and is rarely appropriate. Transplantation carries lifelong immunosuppression, which keeps it within the rule that a treatment continued for life does not cure.

Gene editing is in early trials. Base editing of *PCSK9* (VERVE-101 and 102) produced durable LDL reductions of roughly 50 to 55 per cent in the highest dose cohorts of its phase 1b study from a single infusion†. It is a potential one-time treatment, with tens of patients so far. In familial chylomicronaemia syndrome, olezarsen and plozasiran, which target APOC3, reduce triglycerides by roughly 70 to 80 per cent and markedly reduce pancreatitis episodes in phase 3 trials†. Volanesorsen was approved in Europe, with thrombocytopenia limiting use. That is control, not cure.

**Prevention.** Statins for primary prevention in people at raised risk. The Cholesterol Treatment Trialists' meta-analyses show the same proportional benefit, roughly 21 to 22 per cent per 1 mmol/L, in people without prior vascular disease, so absolute benefit tracks baseline risk. STRONG.

Industrial trans fat elimination. Denmark banned industrial trans fat in 2003 and a later analysis found a measurable decline in cardiovascular mortality beyond the secular trend. New York City's restaurant ban was followed by reduced trans fat intake and reduced myocardial infarction and stroke in the restricted counties. By 2023 roughly 53 countries covering 3.7 billion people had best-practice policies†. STRONG.

Replacing saturated with polyunsaturated fat gave a roughly 17 per cent reduction in cardiovascular events in the Cochrane review. MODERATE.

Finland's North Karelia project, the longest-running population cardiovascular prevention programme, combined dietary change, smoking reduction and blood pressure treatment. Coronary heart disease mortality in working-age men in North Karelia fell by roughly 80 to 85 per cent between 1972 and 2014, with roughly two-thirds to four-fifths of the decline attributable to the measured changes in cholesterol, blood pressure and smoking. It is the single most important population prevention dataset in cardiovascular disease. STRONG.

Salt reduction, sugar-sweetened beverage taxes, front-of-pack labelling and marketing restrictions have demonstrated effects on intake and on blood pressure, and smaller effects on lipids specifically. MODERATE overall.

Cascade screening for FH. Testing first-degree relatives of an index case identifies affected individuals with roughly 50 per cent yield per relative, and the Dutch national programme raised FH detection to roughly 70 per cent†. Universal lipid screening in childhood, practised in Slovenia and recommended in some United States guidelines at ages 9 to 11 and 17 to 21, with reverse cascade screening from affected children to parents, identifies families earlier. STRONG for detection. MODERATE for outcomes, since the outcome evidence is cohort-based.

Not smoking: STRONG. Physical activity and weight change have modest lipid effects and substantial cardiovascular effects in trials: MODERATE. Excluding and treating secondary causes, hypothyroidism especially, before attributing hypercholesterolaemia to a primary disorder: STRONG.

Polypill strategies. The TIPS-3, PolyIran and SECURE trials showed that a fixed-dose combination of a statin, antihypertensives and in some cases aspirin reduced cardiovascular events substantially. PolyIran, a cluster-randomised village-based trial, found a roughly 34 per cent reduction in major cardiovascular events, and SECURE a roughly 24 per cent reduction after myocardial infarction†. The polypill is made of generics. STRONG, and it is the most directly relevant finding for low-resource settings.

**Treatment.** Statins are first-line, and their evidence base is the largest in cardiovascular medicine: atorvastatin, simvastatin, rosuvastatin and pravastatin. All are off-patent. They cost a few dollars to tens of dollars a patient-year at generic international prices, and in many low-income country tenders a few dollars. Their listing on the WHO Essential Medicines List 24th List needs checking, including which statin is the listed medicine and which are alternatives.

The effect is a roughly 21 to 22 per cent reduction in major vascular events and a roughly 10 per cent reduction in all-cause mortality per 1 mmol/L LDL reduction†. High-intensity statins lower LDL by roughly 50 per cent and moderate-intensity by roughly 30 to 40 per cent. Muscle symptoms are the dominant reason for discontinuation, and the randomised evidence is that most statin-attributed muscle symptoms are not caused by the statin. SAMSON, an n-of-1 randomised crossover with placebo and no-tablet periods, found that roughly 90 per cent of the symptom burden occurred equally on placebo, and StatinWISE found no difference in muscle symptoms between statin and placebo periods. Objectively confirmed rhabdomyolysis is roughly 1 to 3 per 100,000 patient-years†. This matters because discontinuation runs at 25 to 50 per cent.

Ezetimibe, a cholesterol absorption inhibitor, lowers LDL by a further roughly 15 to 25 per cent on a statin. IMPROVE-IT found a further 6.4 per cent relative reduction in cardiovascular events on top of simvastatin, consistent with the LDL reduction achieved. It is off-patent and costs tens to hundreds of dollars a patient-year. Its listing status needs checking against the 24th List†.

PCSK9 inhibitors, evolocumab and alirocumab, are monoclonal antibodies given subcutaneously every 2 to 4 weeks. They lower LDL by roughly 50 to 60 per cent on top of a statin. FOURIER (evolocumab) found a 15 per cent reduction in the primary composite endpoint, and ODYSSEY OUTCOMES (alirocumab) a 15 per cent reduction, with a mortality signal in the higher-risk subgroup. They are patented, with biosimilars in development. The United States list price has fallen by more than half since launch in 2015, to thousands of dollars a patient-year, and European prices are of the same order. That is two to three orders of magnitude above a generic statin for an incremental benefit. Their listing status needs checking against the 24th List†.

Inclisiran, a small interfering RNA against PCSK9, is given twice yearly after loading and lowers LDL by roughly 50 per cent. Its cardiovascular outcome trials, ORION-4 and VICTORION-2P, are still running, so its event reduction is inferred from LDL and not demonstrated. It costs thousands of dollars a patient-year. The twice-yearly dosing is its main advantage, and the NHS England population-health agreement for it is a notable procurement model. Bempedoic acid, an oral ACL inhibitor, gave a 13 per cent reduction in major cardiovascular events in statin-intolerant patients in the CLEAR Outcomes trial. It is patented at thousands of dollars a patient-year.

For homozygous FH and refractory cases, lipoprotein apheresis costs tens of thousands to over a hundred thousand dollars a patient-year in high-income settings, lomitapide hundreds

of thousands, and evinacumab, an anti-ANGPTL3 antibody lowering LDL by roughly 47 per cent in homozygous FH, hundreds of thousands†.

For hypertriglyceridaemia, fibrates (fenofibrate and gemfibrozil) are off-patent and cost tens of dollars a patient-year, and their listing status needs checking against the 24th List†. The PROMINENT trial of pemafibrate was negative for cardiovascular events despite lowering triglycerides, an important negative for the triglyceride hypothesis. Icosapent ethyl gave a 25 per cent event reduction in REDUCE-IT, though the mineral oil comparator is contested, and STRENGTH with a different omega-3 formulation was negative†. Omega-3 fatty acids in general were negative in most outcome trials (VITAL, ASCEND, OMEMI). Olezarsen and plozasiran are for familial chylomicronaemia.

For Lp(a), nothing currently licensed lowers it meaningfully. Niacin and PCSK9 inhibitors lower it modestly. Pelacarsen (antisense, Lp(a)HORIZON outcome trial), olpasiran, lepodisiran and the oral muvalaplin lower Lp(a) by roughly 80 to 95 per cent, and the first cardiovascular outcome results are expected from 2026†. Until then Lp(a) is a measurable, common, causal risk factor with no treatment, and care intensifies LDL lowering instead.

The polypill, a fixed-dose combination of a statin with antihypertensives, has all components off-patent and costs tens of dollars a patient-year. With the PolyIran and SECURE event reductions of roughly 34 and 24 per cent, it is the highest-value cardiovascular intervention available in resource-limited settings. Secondary causes are treated first: levothyroxine for hypothyroidism, which is on the 24th List.

**Simple means.** A generic statin costs a few dollars to tens of dollars a patient-year, is off-patent, and reduced major vascular events by roughly 21 to 22 per cent and all-cause mortality by roughly 10 per cent per 1 mmol/L of LDL lowered in the trial meta-analyses. Set against the 3.8 to 4.5 million annual deaths attributed to high LDL, it is among the highest-value medicines in existence.

The polypill uses generic components at tens of dollars a patient-year. In randomised trials it gave 34 per cent (PolyIran) and 24 per cent (SECURE) event reductions, in village and post-infarction settings. It needs no laboratory and no titration.

Finland's North Karelia project replaced animal and hydrogenated fats with vegetable oils at population scale, alongside smoking reduction and blood pressure treatment. Coronary mortality in working-age men fell roughly 80 to 85 per cent over four decades, with most of the fall attributable to the measured risk factor changes. The mechanism was dietary substitution and not a product.

Eliminating industrial trans fat is a regulatory act costing the public purse almost nothing. It now covers roughly 3.7 billion people, with measured mortality effects in Denmark and New York. It is the cheapest cardiovascular intervention ever implemented. Soluble fibre, legumes, oats, barley, nuts and plant sterols each lowered LDL by roughly 3 to 10 per cent, and combined dietary patterns by roughly 10 to 30 per cent in trials. Not smoking is independently the largest modifiable cardiovascular risk factor. Physical activity has a modest lipid effect and a substantial event effect.

A total cholesterol measurement, or even a family history, finds FH. It affects roughly 1 in 250 to 311 people, fewer than 10 per cent are diagnosed, and untreated it causes coronary events in half of men by 50. Asking whether a parent or sibling had a heart attack before age 55 to 60, and looking for tendon xanthomata and corneal arcus, costs nothing and is the entry point. Cascade testing yields roughly 50 per cent per first-degree relative.

In trials the attribution of muscle aches to statins did not hold. SAMSON and StatinWISE showed that roughly 90 per cent of statin-attributed symptom burden occurs equally on placebo. A structured re-challenge is free and recovers a large benefit.

**Gaps.** The highest non-HDL cholesterol levels are now in East and South-East Asia and not the West (NCD-RisC, 2020), a complete reversal since 1980. The reasons, dietary transition, measurement, or both, are not fully disentangled.

Fewer than 10 per cent of people with FH are diagnosed worldwide, and under 1 per cent in most low- and middle-income countries, for a condition affecting roughly 1 in 250 to 311 people and treatable with a generic costing a few dollars a year. Roughly 70 to 80 per cent of patients with established coronary disease do not reach LDL targets, and statin discontinuation is 25 to 50 per cent, despite the drugs being among the cheapest in medicine.

HDL-raising has failed in every outcome trial, niacin in AIM-HIGH and HPS2-THRIVE and the CETP inhibitors, while the inverse association remains strong. The biomarker is not a target, and establishing that took two decades and several large trials. Triglyceride lowering has mostly failed too: PROMINENT negative, omega-3 trials largely negative, REDUCE-IT positive with a contested mineral oil comparator, and STRENGTH negative. The sources disagree.

Inclisiran's cardiovascular outcome trials have not reported, so its benefit is inferred from LDL reduction, and it is already in large-scale use under population procurement agreements. Lp(a) is a common, highly heritable, causal risk factor with no licensed treatment, above the risk threshold in roughly 20 per cent of the population, and the outcome trials report from 2026. The optimal LDL target is unknown. Benefit extends to roughly 0.5 mmol/L with no observed threshold and no safety signal, so guidelines set targets by consensus and not by data.

PCSK9 inhibitors cost two to three orders of magnitude more than a generic statin for an incremental 15 per cent event reduction on top of statins. Cost-effectiveness thresholds vary by country and there is no consensus. Statin-associated muscle symptoms are commonly reported by patients and clinicians, the randomised n-of-1 evidence says most are not drug-attributable, and sources disagree sharply in tone. It is a communication failure with large measured consequences.

GBD attributable-death figures for high LDL depend on counterfactual assumptions and differ between GBD cycles. Almost no trial data exist on statin primary prevention in sub-Saharan Africa or South Asia, where lipid distributions and competing risks differ.

---

## Metabolic syndrome

**What it is.** A cluster of findings that tend to occur together: central obesity, raised blood pressure, raised fasting glucose, raised triglycerides and low HDL cholesterol. It is not a disease in itself. It is a label for a pattern that predicts diabetes and cardiovascular disease.

**Measured.** About 25 per cent of adults in the United States have metabolic syndrome, rising with age and higher among racial and ethnic minority populations. On one analysis roughly 32 per cent of United States adults met the criteria in 2000, and more recent estimates are about 34 per cent†. Globally the figure is about 20 to 25 per cent of the world's adults†. The spread between 25, 32 and 34 per cent reflects the criteria applied and the survey years, and no prevalence figure is interpretable without both.

Five competing definitions are the central measurement problem.

- NCEP ATP III (2001, widely used in the United States): at least 3 of 5 components. These are waist 102 cm or more in men or 88 cm or more in women; triglycerides 150 mg/dL or more; HDL below 40 mg/dL in men or 50 in women; blood pressure 130/85 mmHg or more, or treated hypertension; fasting glucose 110 mg/dL or more.
- IDF (2005, harmonised 2009): waist circumference by population-specific cut points plus any 2 of the other four, with fasting glucose 100 mg/dL or more. The 2009 harmonised statement treats it as 3 or more of the 5 components without requiring central obesity.
- WHO (1999): diabetes, impaired glucose tolerance, impaired fasting glucose or insulin resistance, plus 2 of blood pressure 140/90 mmHg or more, dyslipidaemia, central obesity by waist-hip ratio or body mass index, and microalbuminuria.
- EGIR (1999): insulin resistance, the top 25 per cent of fasting insulin among non-diabetics, plus 2 or more of the other criteria.

The IDF waist cut-points differ by ancestry: 90 cm for men and 80 cm for women of South Asian, Chinese, and South and Central American ancestry, against 94 and 80 cm for Europeans and 102 and 88 cm in the United States criteria. The same person can have the syndrome under one definition and not another.

Prevalence rises steeply with age, roughly 10 per cent in United States adults aged 20 to 29 and roughly 45 to 50 per cent over 60†. Sex differences depend on the criteria, because the waist and HDL thresholds differ by sex.

Predictive value is what the label is for. Metabolic syndrome is associated with roughly a 5-fold increased risk of incident type 2 diabetes in meta-analyses†. For cardiovascular disease it is associated with roughly a 2-fold increase in events and roughly a 1.5-fold increase in all-cause mortality. A meta-analysis of prospective cohorts (Mottillo et al., *Journal of the American College of Cardiology*, 2010) gave relative risks of 2.35 for cardiovascular disease, 2.40 for cardiovascular mortality, 1.58 for all-cause mortality, 1.99 for myocardial infarction and 2.27 for stroke.

The components predict as well or better individually. The source consulted notes that researchers debate whether the syndrome adds risk beyond the sum of its individual components. Multiple analyses have found that established risk scores (Framingham, SCORE2, QRISK) using the continuous values of the same variables outperform the dichotomous label. This is the central criticism, and it is empirical and not semantic.

Associated conditions are metabolic dysfunction-associated steatotic liver disease, present in roughly 60 to 80 per cent of people with the syndrome†, obstructive sleep apnoea, polycystic ovary syndrome, hyperuricaemia and gout, chronic kidney disease and several cancers.

**Where it starts.** Insulin resistance and visceral adiposity are the common thread, and the pathway is established even though the construct is disputed. Energy storage exceeds the capacity of subcutaneous adipose tissue, so lipid accumulates in visceral depots, liver, muscle and pancreas (ectopic fat). Visceral adipose tissue is lipolytically active and drains into the portal vein, delivering free fatty acids to the liver. That drives hepatic insulin resistance, gluconeogenesis and overproduction of VLDL, producing raised triglycerides, small dense LDL and low HDL, the atherogenic dyslipidaemia triad.

Insulin resistance with hyperinsulinaemia raises renal sodium reabsorption and sympathetic tone, contributing to hypertension. Adipose tissue inflammation, with macrophage infiltration, TNF-alpha, IL-6 and reduced adiponectin, links the components. The twin cycle described under type 2 diabetes is the same physiology viewed from the diabetes end.

Adiposity is the dominant driver, and visceral and ectopic fat predict the syndrome better than body mass index. Waist circumference and waist-to-height ratio outperform body mass index for this purpose, and the waist-to-height ratio is robust across ancestries.

At any given body mass index or waist circumference, South Asian, East Asian, Hispanic and Middle Eastern populations have more visceral and hepatic fat and more insulin resistance, the thin-fat phenotype. This is why the IDF uses population-specific cut-points, and the biological explanation is unknown.

Physical inactivity contributes independently of adiposity. High intake of sugar-sweetened beverages, refined carbohydrate and ultra-processed food associates with the syndrome. A metabolic-ward crossover trial (Hall) measured higher energy intake on an ultra-processed diet than on an unprocessed one. Fructose specifically raises hepatic de novo lipogenesis and liver fat in controlled feeding studies. Short sleep, sleep fragmentation and obstructive sleep apnoea each associate independently. Low birthweight followed by rapid catch-up growth, and maternal obesity and gestational diabetes, are developmental contributors.

Drugs matter. Metabolic syndrome develops in roughly 30 to 50 per cent of patients on olanzapine and clozapine†. Corticosteroids, antiretrovirals (especially older protease inhibitors, causing lipodystrophy), and the combination of beta-blockers and thiazides also contribute. Smoking raises insulin resistance and central fat distribution despite lowering body weight.

Lipodystrophy syndromes are the extreme natural experiment. Congenital generalised lipodystrophy (*AGPAT2*, *BSCL2*) and familial partial lipodystrophy (*LMNA*, *PPARG*) produce severe insulin resistance, hypertriglyceridaemia, fatty liver and diabetes with little or no subcutaneous fat. They show that the problem is where fat is stored and not simply how much there is, and they are treatable with metreleptin.

Heritability of the individual components is roughly 0.3 to 0.6, and of the syndrome as a construct roughly 0.1 to 0.3 beyond its components†. Over 1,000 loci across the component traits are known and there is no metabolic syndrome gene.

*Not known*: whether metabolic syndrome is a meaningful entity. The source consulted states the debate plainly, whether it adds risk beyond the sum of its components. The empirical answer from prediction studies is largely no, since continuous risk scores outperform the label, and the construct's defenders argue it has clinical and communicative value in iden-

tifying clustered risk. Also unknown: why the same degree of adiposity produces the syndrome in some people and not others. Roughly 10 to 30 per cent of people with obesity are metabolically healthy by these criteria and roughly 5 to 20 per cent of lean people have the syndrome†. Longitudinal data suggest most people with metabolically healthy obesity convert over a decade.

**Cure status.** CONTROLLABLE. The components can resolve under weight loss and the syndrome as defined then disappears, but they return when the weight does, so the state is held and not removed.

In the Diabetes Prevention Program, among participants with metabolic syndrome at baseline, intensive lifestyle intervention reduced the prevalence of metabolic syndrome by roughly 41 per cent and metformin by roughly 17 per cent over roughly 3 years†. The diagnosis was removed in a large fraction of people. Look AHEAD found that intensive lifestyle intervention reduced metabolic syndrome prevalence substantially, alongside roughly 8.6 per cent weight loss at year 1†.

DiRECT and DIADEM-I achieved diabetes remission in 46 and 36 per cent at 12 and 24 months and 61 per cent at 12 months respectively, with diet-based weight loss, which by definition resolves the glucose component. Bariatric surgery resolves metabolic syndrome in roughly 60 to 80 per cent of patients at 1 to 2 years†. In SELECT, semaglutide 2.4 mg reduced major adverse cardiovascular events by 20 per cent in people with overweight or obesity and cardiovascular disease without diabetes, and the component measures all improved.

Weight regain restores the syndrome. As in obesity, the physiology is defended and the condition recurs.

Because the syndrome is a set of threshold crossings, resolving it can mean moving someone from 3 abnormal components to 2 without changing underlying risk much. What matters is whether hard outcomes change. For that the evidence is the diabetes prevention trials, with a 58 per cent risk reduction in the Diabetes Prevention Program, the statin trials at roughly 21 to 22 per cent per 1 mmol/L†, the blood pressure trials, and SELECT. All of them act on components and not on the syndrome.

Severe lipodystrophy: CONTROLLABLE. Metreleptin produces large improvements in triglycerides, glucose and liver fat, a mechanism-matched treatment for the extreme form.

**Prevention.** Prevention of metabolic syndrome is prevention of its components, and the trial evidence is set out under type 2 diabetes, obesity and dyslipidaemia. The measures with demonstrated effects follow.

Intensive lifestyle intervention in people at risk. The Diabetes Prevention Program randomised 3,234 participants to placebo, metformin or intensive lifestyle change, with average follow-up of 2.8 years. Cumulative incidence of diabetes at 3 years was 28.9 per cent on placebo, 21.7 per cent on metformin and 14.4 per cent on lifestyle intervention. The relative reductions were 58 per cent (95% confidence interval 48 to 66) for lifestyle and 31 per cent (17 to 43) for metformin. The numbers needed to treat for 3 years to prevent one case were 6.9 (5.4 to 9.5) for lifestyle and 13.9 (8.7 to 33.9) for metformin. Both reproduce exactly from the cumulative incidences: 1 / 0.145 is 6.9 and 1 / 0.072 is 13.9. The Finnish Diabetes Prevention Study found a 58 per cent reduction†. The Da Qing study found reduced cardiovascular events, microvascular complications and all-cause mortality, and roughly 1.44 years greater life expectancy at 30 years†. STRONG.

Metformin gave a 31 per cent reduction in incident diabetes in the Diabetes Prevention Program and a roughly 17 per cent reduction in metabolic syndrome prevalence†. It is off-patent and costs a few dollars a patient-year. STRONG. In that program each kilogram lost was associated with roughly 16 per cent lower diabetes risk†. STRONG, for weight loss by any means. Physical activity is effective independently of weight change for insulin sensitivity and blood pressure. STRONG for the components.

Population dietary and fiscal measures. Sugar-sweetened beverage taxes reduced purchases by roughly 10 to 20 per cent in Mexico, Chile, the United Kingdom and United States cities. The United Kingdom Soft Drinks Industry Levy was followed by a roughly 30 per cent reduction in soft drink sugar content through reformulation. Chile’s labelling law reduced purchases of high-in sugary drinks by roughly 24 to 27 per cent†. Industrial trans fat elimi-

nation now covers roughly 53 countries and 3.7 billion people†. MODERATE for intake and reformulation. WEAK for demonstrated effect on metabolic syndrome prevalence.

Sleep adequacy and treating obstructive sleep apnoea. CPAP improves blood pressure modestly and insulin sensitivity inconsistently, and the SAVE trial found no reduction in cardiovascular events. CONTESTED for cardiovascular outcomes. STRONG for symptoms. Not smoking: STRONG.

Choosing weight-neutral alternatives to obesogenic drugs where clinically possible, particularly antipsychotics, where metabolic syndrome develops in roughly 30 to 50 per cent on olanzapine and clozapine and metformin co-prescription attenuates weight gain in randomised trials. MODERATE. Treating the components to target and not the label, with statins, antihypertensives, and metformin or GLP-1 agonists for glucose. STRONG for each component.

**Treatment.** No treatment exists for metabolic syndrome as such. Treatment is of the components, and the drugs and prices are set out under type 2 diabetes, obesity and dyslipidaemia.

Structured lifestyle intervention is the foundation and the comparator in every trial. Its resource requirement is personnel time and not product. Metformin is on the WHO Essential Medicines List 24th List for type 2 diabetes, as 500 mg oral solid for adolescents and adults, first added in 1997. It is off-patent and costs a few dollars a patient-year. A generic statin costs a few dollars to tens of dollars a patient-year and gave a 21 to 22 per cent reduction in major vascular events per 1 mmol/L LDL reduction†. The listing status of statins on the 24th List needs checking†.

Antihypertensives are thiazide-like diuretics, ACE inhibitors, ARBs and calcium channel blockers, all off-patent, at a few dollars to tens of dollars a patient-year. Their listing status needs checking against the 24th List†. ACE inhibitors and ARBs are often preferred in insulin-resistant patients because thiazides and beta-blockers worsen glucose and lipids, though the outcome differences are small. The polypill, with generic components at tens of dollars a patient-year, gave PolyIran and SECURE event reductions of 34 and 24 per cent†. For a clustered-risk population it is the most directly applicable intervention and needs no laboratory.

GLP-1 receptor agonists and tirzepatide are patented, and their effect sizes are given under type 2 diabetes and obesity. United States list prices run to many thousands of dollars a patient-year, direct cash channels lower, and European prices lower again. A published minimum production cost estimate for semaglutide is roughly US$11 to US$57 a patient-year (Barber, Hill et al., 2024). Their listing status on the 24th List needs checking†. SGLT2 inhibitors have originator prices in the thousands of dollars a patient-year in the United States and Indian generics in the tens to low hundreds, with cardiovascular, renal and heart failure benefits. Their listing status needs checking against the 24th List†.

Bariatric and metabolic surgery resolves the syndrome in roughly 60 to 80 per cent, and the Swedish Obese Subjects study measured a mortality reduction of roughly 24 to 30 per cent†. Associated conditions are treated separately. Resmetirom (United States approval 2024) is the first licensed drug for metabolic dysfunction-associated steatohepatitis with fibrosis and costs tens of thousands of dollars a patient-year. CPAP treats sleep apnoea, allopurinol gout, which is on the 24th List, and metformin and combined oral contraceptives polycystic ovary syndrome. Metreleptin for generalised lipodystrophy is mechanism-matched and priced in the hundreds of thousands a patient-year.

**Simple means.** This section reports what trials measured. It sets out no protocol.

A tape measure. Waist circumference, or waist-to-height ratio, costs cents and adds information that body mass index does not. It is robust across ancestries in a way body mass index is not, and the IDF criteria are built on it. It is the cheapest and most useful measurement in the entry. A blood pressure cuff and a finger-prick glucose detect two of the five components between them.

Diet-based weight loss delivered in primary care. DiRECT and DIADEM-I achieved diabetes remission in 46 and 36 per cent, and 61 per cent, using a formula diet followed by structured food reintroduction, with nurses and dietitians in ordinary practice, and with no drug, device or surgery. In the Diabetes Prevention Program each kilogram lost was associated with roughly 16 per cent lower diabetes risk, and lifestyle intervention reduced metabolic syndrome prevalence by roughly 41 per cent†.

Walking and other physical activity. In Da Qing the exercise arm alone was effective, and at 30 years the intervention groups had fewer cardiovascular events, fewer microvascular complications, lower all-cause mortality and roughly 1.44 years greater life expectancy†.

Metformin costs a few dollars a patient-year, is off-patent, gave a 31 per cent reduction in incident diabetes and a roughly 17 per cent reduction in metabolic syndrome prevalence†. A generic statin gave 21 to 22 per cent fewer major vascular events per 1 mmol/L of LDL lowered. The polypill, generics in one tablet, gave 24 to 34 per cent event reductions in randomised trials†.

Sugar-sweetened beverages. Each daily serving was associated with 13 to 26 per cent higher diabetes risk, taxes reduced purchases by 10 to 20 per cent, and the United Kingdom levy cut soft drink sugar content by roughly 30 per cent through reformulation†. In the Hall crossover trial, an unprocessed diet eaten without restriction produced lower energy intake and some weight loss over two weeks compared with an ultra-processed diet. Sleep, and snoring as a question, matter for sleep apnoea. Not smoking matters. Reviewing obesogenic drugs matters, particularly antipsychotics, where metformin co-prescription attenuates weight gain in randomised trials.

**Gaps.** Five competing definitions, WHO 1999, EGIR 1999, NCEP ATP III 2001, IDF 2005 and the harmonised 2009 statement, classify different people. No prevalence figure is interpretable without the criteria and the survey year. The figures quoted here, 25, 32 and 34 per cent for the United States and 20 to 25 per cent globally, come from different criteria and periods.

Whether the syndrome adds predictive value beyond its components is disputed. The empirical evidence from prediction studies largely says it does not, since continuous risk scores outperform the dichotomous label. The source consulted gives no numeric relative risks for cardiovascular disease or type 2 diabetes. The figures here, roughly 2-fold for cardiovascular disease and roughly 5-fold for diabetes, come from the wider meta-analytic literature.

Dichotomising five continuous variables discards information, and a person can leave the syndrome by crossing one threshold without materially changing risk. Waist cut-points are population-specific and empirically derived. The biological reason South Asian and East Asian populations have more visceral fat at a given anthropometry is unknown. Metabolically healthy obesity, roughly 10 to 30 per cent of people with obesity, may not be a stable state, and the proportion and determinants are unresolved.

No treatment trial has used metabolic syndrome as an inclusion criterion with hard outcomes as the endpoint. Every effect size in this entry is borrowed from trials of diabetes prevention, lipid lowering, blood pressure lowering or weight loss. CPAP did not reduce cardiovascular events in SAVE despite obstructive sleep apnoea being strongly associated with the syndrome.

Almost all prevalence data come from the United States, Europe and East Asia. African and Latin American data are thinner, and the criteria used there are often the European or United States ones and not the population-specific ones. Whether the label helps or harms patients, by prompting action or by medicalising risk, has not been tested.

---

## Phenylketonuria

**What it is.** An inherited inability to break down phenylalanine, an amino acid present in all protein. It builds up and poisons the developing brain. Detected at birth and treated by diet, the child develops normally. Undetected, it causes severe permanent intellectual disability.

**Measured.** Incidence is about 1 in 12,000 newborns overall, with males and females affected equally†. National figures vary enormously. Turkey has 1 in 2,600, the highest documented rate, and Ireland 1 in 4,500†. Finland has 1 in 200,000 and Japan 1 in 125,000, and the source consulted states that Finland and Japan have extremely low rates, fewer than one case in 100,000 births†. Italy, Scotland, the Czech Republic and parts of China, roughly 1 in 11,000 to 17,000, are also high.

For the United States the source consulted gives two figures that conflict: 1 in 10,000 for Caucasians in the text and 1 in 25,000 in its country table. Both stand, and the disagreement is not reconciled.

PKU was the first disorder routinely diagnosed through widespread newborn screening. Robert Guthrie introduced the test in the early 1960s. Ireland started the first national programme in February 1966, followed by Austria in 1966 and England in 1968†. Screening uses a heel-prick blood sample, usually taken 2 to 7 days after birth, and a repeat test around two weeks of age catches missed cases. Methods include the Guthrie bacterial inhibition assay, immunoassays and tandem mass spectrometry. Coverage is near-universal in high-income countries and in much of Latin America, the Middle East and East Asia. It remains absent or very limited across most of sub-Saharan Africa and parts of South and Central Asia, where affected children still present with established intellectual disability.

The outcome contrast is large. Untreated, there is progressive intellectual disability with IQ typically below 50 and often below 30, microcephaly, seizures in roughly 25 per cent, eczema, a musty body odour, hypopigmentation, autistic features and self-injurious behaviour. Institutional care was the historical norm. Treated from the first weeks of life, according to the source consulted, early diagnosis and a strict low-phenylalanine diet can allow normal health and a normal lifespan, and treated people may have no detectable physical, neurological or developmental problems. The window is narrow. The diet must begin within about two weeks of birth, and otherwise permanent intellectual disability is likely even if treatment starts later.

Residual morbidity in treated patients is measured. Even with good control, mood disorders occur at roughly 230 per cent of control rates and dizziness at roughly 180 per cent†. Treated adults have higher rates of anxiety, depression, attention deficit, executive dysfunction and reduced processing speed than the general population, correlating with lifetime phenylalanine exposure. Patients whose diets lack added amino acids may have slightly suboptimal neurocognitive and growth outcomes.

Maternal PKU syndrome arises when maternal phenylalanine is high in an untreated or poorly controlled pregnancy. It is teratogenic, causing microcephaly, congenital heart disease, intrauterine growth restriction and intellectual disability in the infant, with risk rising steeply above maternal phenylalanine of roughly 360 µmol/L†. The infant does not have PKU, and the damage is from maternal exposure. Congenital heart disease exceeds 10 per cent where maternal phenylalanine is above 900 µmol/L in the first trimester†. It is entirely preventable by strict control from before conception.

Dietary adherence falls sharply in adolescence and adulthood, with roughly 50 to 80 per cent of adults in several national cohorts having phenylalanine above target. Many adults were historically told they could stop the diet, and that advice was later reversed.

**Where it starts.** The cause is biallelic loss-of-function variants in *PAH*, encoding phenylalanine hydroxylase, which converts phenylalanine to tyrosine using the cofactor tetrahydrobiopterin (BH4). Inheritance is autosomal recessive. Over 1,000 *PAH* variants are described, and genotype predicts phenotype reasonably well: residual enzyme activity determines whether the picture is classical PKU, mild PKU or mild hyperphenylalaninaemia not requiring treatment.

High phenylalanine competes with other large neutral amino acids for the LAT1 transporter at the blood-brain barrier, so tyrosine and tryptophan transport into the brain falls, reducing dopamine and serotonin synthesis. Phenylalanine also directly impairs myelination and protein synthesis. The mechanism explains why large neutral amino acid supplementation works as a treatment and why the damage is developmental.

BH4-responsive PKU is a subset, generally with residual enzyme activity, that responds to pharmacological doses of BH4 (sapropterin) with a fall in blood phenylalanine. The response is genotype-linked. BH4 deficiency disorders, roughly 1 to 2 per cent of hyperphenylalaninaemia, arise from *PTS*, *QDPR*, *PCBD1*, *GCH1* and *DNAJC12*†. They cause raised phenylalanine plus deficient dopamine and serotonin synthesis, and diet alone does not treat them. They need BH4 plus neurotransmitter precursors (L-dopa, carbidopa, 5-hydroxytryptophan). Missing the diagnosis means treating the wrong disease, which is why every positive newborn screen requires PKU to be told from BH4 defects.

Carrier frequency is roughly 1 in 50 to 1 in 60 in European populations, consistent with birth incidence†. Carriers are healthy. Incidence varies so much between populations through founder effects and historical population structure. The high Turkish and Irish rates and the

very low Finnish and Japanese rates reflect different *PAH* variant frequencies and not any environmental factor.

*Not known*: why residual neurocognitive and psychiatric morbidity persists in well-treated patients, whether from early exposure before diagnosis, fluctuations across childhood, tyrosine or neurotransmitter precursor deficiency, or the nutritional adequacy of the diet itself. The optimal phenylalanine target across the lifespan, and whether adults need the same control as children. Current consensus says yes, reversing earlier advice, but the evidence is observational. Whether the *PAH* genotype can set individual treatment intensity.

**Cure status.** Diagnosed at birth and treated by lifelong diet: CONTROLLABLE. Diagnosed after irreversible damage is established: RELIEF ONLY.

The label is CONTROLLABLE and not curable because the enzyme defect is not corrected. The diet substitutes for it, the normal phenotype lasts exactly as long as the diet does, and a treatment that must be continued for life does not cure.

A phenylalanine-restricted diet begun within about two weeks of birth and maintained prevents the disease. The target blood phenylalanine is 2 to 6 mg/dL (120 to 360 µmol/L), monitored by regular blood tests†. It is not reversible once damage is done. Starting the diet in an older child with established disability improves behaviour and seizures but does not restore cognition. That distinction is the whole justification for newborn screening.

Sapropterin dihydrochloride, synthetic BH4, may be useful in some patients and can lower blood phenylalanine in some people, according to the source consulted. Response rates in trials are roughly 20 to 50 per cent of unselected classical and mild PKU patients, concentrated in those with residual enzyme activity. Responders can liberalise protein intake substantially and some achieve control without a restricted diet.

Pegvaliase, a pegylated phenylalanine ammonia lyase, is an enzyme substitute approved in the United States in 2018 for adults poorly managed on other treatments. It degrades phenylalanine independently of PAH. In phase 3 (PRISM-2), roughly 60 to 70 per cent of patients achieved blood phenylalanine below 600 µmol/L and a substantial proportion reached normal levels on an unrestricted diet. For responders it functionally removes the dietary requirement. Anaphylaxis occurs in roughly 5 to 9 per cent, requiring adrenaline availability and a long induction titration. Gene therapy and mRNA therapy, liver-directed AAV and lentiviral *PAH* gene transfer and *PAH* mRNA, are in early clinical trials, and nothing is approved. Genome editing of *PAH* is preclinical.

**Prevention.** Newborn screening is the measure and the model for all newborn screening. The test is a heel-prick dried blood spot at 2 to 7 days, with a repeat around two weeks. It converts a disease causing lifelong severe intellectual disability into one with a normal outcome. No randomised trial exists and none was needed, since the before-and-after is unambiguous. The PKU assay costs a few dollars per newborn as part of a multiplex panel, and the full multi-disorder tandem mass spectrometry panel tens of dollars per newborn, depending on the programme. Cost-effectiveness analyses consistently find PKU screening cost-saving, because the lifetime cost of institutional care for one untreated case far exceeds the cost of screening a whole birth cohort. STRONG.

Prevention of maternal PKU syndrome by strict phenylalanine control from before conception through pregnancy. The Maternal PKU Collaborative Study showed that phenylalanine below roughly 360 µmol/L before conception essentially eliminates the excess congenital heart disease and microcephaly. Poor control above 900 µmol/L in the first trimester is associated with congenital heart disease in over 10 per cent of pregnancies†. STRONG. This is the strongest argument for keeping women with PKU in lifelong follow-up and not discharging them in adolescence.

Lifelong dietary control and not stopping in adolescence. Earlier practice allowed relaxation after childhood, and that advice was reversed on observational evidence of neurocognitive and psychiatric morbidity in untreated adults. MODERATE: the evidence is observational, and the reversal of advice is itself evidence of earlier error.

Carrier screening and genetic counselling in high-incidence populations and affected families, with prenatal and preimplantation diagnosis where available and acceptable. STRONG for birth prevalence in known families. Separating BH4 deficiency from PKU on every positive

screen, because diet alone does not treat BH4 deficiency and the neurotransmitter deficits progress untreated. STRONG.

Extending newborn screening to countries without it is the largest remaining preventable burden. In populations without screening, PKU still causes the disability it caused everywhere before 1966, and the test costs a few dollars. STRONG.

**Treatment.** A phenylalanine-restricted diet with a phenylalanine-free amino acid substitute. Natural protein is restricted and the remaining protein requirement is supplied as a phenylalanine-free, tyrosine-enriched amino acid mixture with added vitamins and minerals. Low-protein manufactured foods, bread, pasta and flour substitutes, make the diet practicable. These are medical foods and not listed medicines, and whether any is on the WHO Essential Medicines List 24th List needs checking†. Patent status does not apply, since they are formulated products from a small number of manufacturers.

The amino acid substitute plus prescribed low-protein foods cost thousands to tens of thousands of dollars a patient-year in high-income countries. The dietary treatment is cheap in principle and expensive in practice, because the substitute products are manufactured medical foods with few suppliers. Where they are not reimbursed, families pay, and adherence collapses. Monitoring is by dried blood spot phenylalanine, roughly weekly in infancy and monthly to quarterly later, with a target of 120 to 360 µmol/L. Tyrosine is supplemented where levels are low.

Sapropterin dihydrochloride is for responders, identified by a loading test, and allows substantial liberalisation of protein intake. Generics have entered since the United States and European patents expired around 2020 to 2021†. The originator costs tens to hundreds of thousands of dollars a patient-year, with dose weight-based so that adult costs are at the top of the range, and generic sapropterin tens of thousands. Its listing status needs checking against the 24th List†.

Pegvaliase is a daily subcutaneous injection for adults with inadequate control and allows an unrestricted diet in responders. It is patented and costs hundreds of thousands of dollars a patient-year, among the most expensive long-term treatments in the chapter. Anaphylaxis occurs in roughly 5 to 9 per cent, an adrenaline autoinjector is required, and induction is long. Its listing status needs checking against the 24th List†.

Large neutral amino acid supplementation competes with phenylalanine at the LAT1 transporter and reduces brain phenylalanine without lowering blood levels much. It is used as an adjunct in adults with poor dietary adherence, at thousands of dollars a patient-year. Evidence is limited and it does not replace dietary control in children or in pregnancy. Glycomacropeptide-based medical foods, whey-derived protein naturally very low in phenylalanine and more palatable than amino acid mixtures, improve adherence in trials.

BH4 deficiency disorders are treated with sapropterin plus L-dopa and carbidopa plus 5-hydroxytryptophan, and folinic acid in *QDPR* deficiency. The precursors are off-patent and relatively cheap. Maternal PKU is managed by strict control from before conception, with intensive dietary support and frequent monitoring throughout pregnancy. Follow-up is multidisciplinary for life, with metabolic dietitian, metabolic physician and psychologist, and the service and not the drug determines outcome.

**Simple means.** The heel-prick test is a few drops of blood on filter paper at 2 to 7 days, costing a few dollars for the PKU assay within a panel. It is the whole difference between a normal life and permanent severe intellectual disability. It was the first newborn screening test ever introduced, and it remains unavailable to a large share of the world’s newborns. No intervention in this chapter has a larger ratio of benefit to cost.

The word simple needs qualifying for the treatment that follows. The diet is food, and the amino acid substitute is a manufactured medical food costing thousands of dollars a patient-year in high-income countries. Breastfeeding is compatible with PKU management and is used together with the substitute under monitoring, since breast milk is relatively low in phenylalanine compared with standard formula. Where manufactured low-protein foods are unaffordable, a low-protein diet can be built from ordinary food, fruit, most vegetables, measured starches, fats and sugars, with careful counting, and this is done. What cannot be improvised is the amino acid substitute. It supplies the protein, vitamins and minerals that the restricted diet cannot, and without it the child becomes malnourished. That is the honest limit of the simple means here.

Dried blood spot monitoring can be taken at home, posted and processed centrally, at a few dollars a test, and it is what makes the diet work. Aspartame is a phenylalanine-containing dipeptide, and avoiding it costs nothing. Telling women with PKU about pregnancy early and repeatedly is free, and phenylalanine below roughly 360 µmol/L before conception essentially eliminates maternal PKU syndrome. Testing siblings and informing the family is simple: inheritance is autosomal recessive, carrier frequency is roughly 1 in 50 to 60 in European populations, and the risk is 1 in 4 per subsequent pregnancy. The diet is not stopped in adolescence, as once advised. A urine pterin profile and a dihydropteridine reductase assay, both cheap, check for BH4 deficiency on every positive newborn screen.

**Gaps.** The source consulted gives two conflicting United States incidence figures, 1 in 10,000 for Caucasians in the text and 1 in 25,000 in the country table. The global figure of about 1 in 12,000 and the national figures rest on that source. It gives no response rate for sapropterin, stating only that it may be useful in some patients, so the 20 to 50 per cent figure comes from the wider trial literature. The pegvaliase trial figures, PRISM-2, are also from the wider literature. The source describes PEG-PAL as a separate investigational agent placed on clinical hold in September 2021, with an FDA request for oncogenic risk data in February 2022. Pegvaliase is itself a PEGylated phenylalanine ammonia lyase, and whether the two names refer to one molecular class or to different products is unresolved.

No global estimate exists of how many children are born with undetected PKU in countries without newborn screening. At an incidence of roughly 1 in 12,000 and roughly 130 million annual births, the theoretical global birth burden is roughly 10,000 to 11,000 a year, and the proportion reached by screening is not systematically reported.

Why residual neurocognitive and psychiatric morbidity persists in well-treated patients is unknown, and mood disorders at roughly 230 per cent of control rates are a substantial and unexplained residual. The optimal lifelong phenylalanine target is not established by trial, and the reversal of the earlier advice that diet for life is unnecessary was made on observational grounds. Adult adherence is poor, roughly 50 to 80 per cent above target in several cohorts, for reasons of palatability, cost and loss of paediatric support structures.

The dietary treatment costs thousands to tens of thousands of dollars a patient-year because the amino acid substitutes are manufactured medical foods with few suppliers. There is no generic pathway for medical foods, and reimbursement varies even within high-income countries. It is a structural affordability problem that patent expiry does not solve. Pegvaliase at hundreds of thousands of dollars a patient-year and sapropterin at tens to hundreds of thousands stand against a diet that in principle requires only food plus a nutrient mixture. Long-term outcome data for pegvaliase and for generic sapropterin are limited.

---

## Cystic fibrosis

**What it is.** An inherited fault in a chloride channel makes mucus thick and sticky. The lungs become chronically infected and scarred, the pancreas stops delivering digestive enzymes, and most men are infertile. It used to kill in childhood. It now kills in middle age, and new drugs have changed it again.

**Measured.** Incidence in northern European ancestry is about 1 in 3,000 newborns, and the disease is least common in Africa and Asia†. Other commonly cited figures are roughly 1 in 2,500 to 3,500 in white European populations, 1 in 4,000 to 10,000 in Hispanic populations, 1 in 15,000 to 20,000 in African-ancestry populations and 1 in 30,000 to 100,000 in East Asian populations†. Ashkenazi Jewish populations are roughly 1 in 2,300 to 3,000, and Amish and Hutterite communities are higher.

Carrier frequency in northern European ancestry is up to about 1 in 25. In the United States it is about 1 in 25 white Americans, 1 in 46 Hispanic Americans, 1 in 65 African Americans and 1 in 90 Asian Americans, and over 10 million Americans carry one mutant allele†.

No authoritative global count of people with CF exists. Registry counts are roughly 40,000 in the United States and roughly 55,000 across the European CF Society Patient Registry countries†. The source consulted gives about 50,000 individuals followed in the United States registry since its inception in 1986, a cumulative figure and not a current population. Modelled worldwide estimates run from roughly 105,000 to 162,000, a range reflecting how little

is known about CF in Africa, South Asia and Latin America, where it is under-diagnosed and not absent.

Survival is the central measured fact. Average life expectancy is about 42 to 50 years in the developed world, with a cited median of 40.7 years, and newer treatments have raised estimated median survival to about 65 years in Canada, the United States and the United Kingdom†. These are different quantities that are routinely quoted interchangeably: current median age at death, median survival of a historical cohort, and median predicted survival of a birth cohort. The last is a projection and not an observation.

For context, median survival was under 1 year in the 1930s, roughly 10 years in the 1960s and roughly 30 years by 1990†. Median predicted survival for a child born today in a high-income country with modulator access is in the 60s, a gain of roughly 60 years within a century. Almost all of it came from incremental care, nutrition, airway clearance, antibiotics and centralised specialist care, and from no single breakthrough until the modulators arrived. More adults than children now live with CF in high-income countries, an inversion that occurred around 2014 in the United States and United Kingdom.

Respiratory failure causes roughly 70 to 80 per cent of deaths, and the remainder come from transplant complications, liver disease and CF-related diabetes complications. Pancreatic insufficiency affects roughly 85 per cent†. CF-related diabetes affects roughly 20 per cent of adolescents and 40 to 50 per cent of adults†. CF liver disease with cirrhosis affects roughly 5 to 10 per cent, male infertility roughly 97 to 98 per cent (congenital bilateral absence of the vas deferens), and chronic *Pseudomonas aeruginosa* infection roughly 40 to 50 per cent of adults†. Distal intestinal obstruction syndrome, osteoporosis, sinus disease and nasal polyps are also common.

**Where it starts.** The cause is biallelic variants in *CFTR*, encoding a cAMP-regulated chloride and bicarbonate channel at the apical membrane of epithelial cells. Inheritance is autosomal recessive. Over 2,100 *CFTR* variants are catalogued, of which roughly 400 to 700 are established as disease-causing†. *F508del* is the commonest, on roughly 70 per cent of alleles in northern European populations and present as at least one allele in roughly 85 to 90 per cent of patients†.

Variant classes determine the mechanism and the drug. Class I is no protein (nonsense and frameshift, for example *G542X* and *W1282X*), class II misfolding and failure to traffic (*F508del*), class III a gating defect (*G551D*), class IV a conductance defect, class V reduced quantity and class VI reduced stability. The modulator drugs are class-specific, which is why genotype determines treatment eligibility.

The lungs fail because loss of CFTR-mediated chloride and bicarbonate secretion dehydrates the airway surface liquid and lowers its pH, impairing mucociliary clearance and antimicrobial peptide function. Mucus stasis permits chronic infection with *Staphylococcus aureus*, then *Haemophilus influenzae*, then *Pseudomonas aeruginosa*, and in some patients *Burkholderia cepacia* complex and non-tuberculous mycobacteria. Neutrophilic inflammation, protease release and bronchiectasis follow.

Heterozygote advantage has been proposed for why the allele is common: resistance to typhoid, since CFTR is the receptor for *Salmonella typhi* entry, to cholera and to tuberculosis. None is established, and drift and founder effects may suffice. Lung disease severity varies widely at identical genotype. Modifiers include *SLC26A9*, *SLC9A3*, *EHF*, *MUC4/MUC20*, *AGTR2* and *TGFB1*, and meconium ileus has its own modifier loci. Modifier effects are modest, and a large part of the variance is environmental: socioeconomic status, air pollution, smoke exposure, adherence, centre of care and age at diagnosis all measurably affect outcome.

CFTR-related disorders are milder variant combinations causing isolated chronic pancreatitis, isolated congenital bilateral absence of the vas deferens, or bronchiectasis or sinusitis without full CF. The boundary is a spectrum, which complicates diagnosis and prevalence counts.

*Not known*: why lung disease severity varies so much at identical genotype, since the known modifiers explain only part of it. Whether the modulators, which correct the basic defect biochemically, will translate into the normal lifespan the biomarker changes imply, since the oldest treated cohorts have under a decade of follow-up. Whether CF is genuinely rare in Africa and much of Asia or substantially undiagnosed. Carrier frequencies of 1 in 65 and 1 in

90 suggest the disease exists in those populations at rates well above the near-zero figures sometimes reported, and the likeliest explanation is diagnostic absence and not biological absence.

**Cure status.** CONTROLLABLE. The basic defect can now be corrected pharmacologically in roughly 90 per cent of patients†, without the disease being cured.

CFTR modulators correct the protein defect and change the disease course. Elexacaftor, tezacaftor and ivacaftor (Trikafta, Kaftrio), approved from 2019, are effective in patients with at least one *F508del* allele, roughly 85 to 90 per cent of all patients†. Pulmonary exacerbations decreased by 63 per cent and sweat chloride by 41.8 mmol/L, and the pivotal trials showed an FEV1 improvement of roughly 10 to 14 percentage points against placebo or against tezacaftor and ivacaftor, with weight gain and large improvements in respiratory symptom scores. Ivacaftor alone for gating mutations, roughly 4 to 5 per cent of patients†, for example *G551D*, was the first, approved in 2012. Vanzacaftor, tezacaftor and deutivacaftor (Alyftrek), approved in December 2024, are a once-daily next-generation combination.

Registries show population-level effects since modulator introduction. Lung transplant listings for CF in the United States and several European countries fell by roughly 60 to 80 per cent after 2019 to 2020, the rate of decline in FEV1 across the treated population flattened or reversed, and CF-attributed deaths fell sharply. These are among the clearest population-level drug effects recorded in a genetic disease.

It is not a cure. The modulators must be taken daily for life, and they do not reverse established bronchiectasis or cirrhosis or restore fertility in men. Roughly 10 per cent of patients, those with two class I variants, have no effective modulator at all, and that group is disproportionately of non-European ancestry, which compounds existing inequity. Gene and RNA therapy are the route to a cure, and nothing is approved. Inhaled *CFTR* mRNA, lentiviral and AAV gene transfer, and base and prime editing are in phase 1 to 2. The earlier non-viral trial of the UK Cystic Fibrosis Gene Therapy Consortium showed a small but statistically significant FEV1 benefit, establishing proof of principle without clinical utility.

Median survival after lung transplantation for CF is roughly 8 to 10 years, better than for most other indications, and listings have fallen sharply since modulators. Newborn screening does not cure but changes the trajectory. Screened children have better nutritional status, lung function and survival than those diagnosed clinically, which is why screening is now near-universal in high-income countries.

**Prevention.** Newborn screening by immunoreactive trypsinogen, with *CFTR* genotyping or sweat testing as the second tier, introduced progressively from the 1980s and now near-universal in high-income countries. Measured effects are earlier diagnosis, median weeks and not years, better growth, better lung function, fewer hospitalisations and improved survival compared with clinical diagnosis, in the Wisconsin randomised trial and multiple cohort comparisons. STRONG.

Carrier screening and genetic counselling. Population carrier screening in people of northern European ancestry is offered in the United States, Australia and parts of Europe, with cascade testing in affected families and prenatal and preimplantation genetic diagnosis. STRONG for birth prevalence where it is implemented and acceptable.

Prevention of infection and cross-infection is a major measured success. Cohorting and then full segregation of patients, introduced after *Burkholderia cepacia* epidemics in the 1990s, reduced transmission of *B. cepacia* and epidemic *Pseudomonas* strains markedly. STRONG. Early eradication of first *Pseudomonas aeruginosa* isolation with inhaled tobramycin or colistin achieved eradication in roughly 65 to 90 per cent in the ELITE and EPIC trials and delayed chronic infection†. STRONG. Routine and influenza vaccination, and palivizumab in selected infants: MODERATE. Avoiding smoke exposure: active and passive smoking measurably accelerate lung function decline. STRONG.

Prevention of malnutrition produced most of the twentieth-century survival gain. The shift to high-energy, high-fat diets with adequate pancreatic enzyme replacement, from the 1980s, is credited with much of the survival improvement. The 1980s comparison between Toronto and Boston cohorts, with the same care except that Toronto used a high-fat unrestricted diet and Boston a low-fat diet, showed a median survival difference of roughly 9 years in favour of the high-fat approach†. It is one of the clearest natural experiments in CF care. STRONG.

Annual screening for CF-related diabetes from age 10 by oral glucose tolerance test. Diabetes develops in 40 to 50 per cent of adults and its onset is associated with preceding lung function and weight decline, so detection and insulin treatment improve both. STRONG. Centralised specialist multidisciplinary care, since outcomes correlate strongly with centre volume and multidisciplinary staffing in registry analyses: MODERATE.

Preventing the inequity means ensuring *CFTR* genotype is determined and non-*F508del* variants are reported properly in populations where CF has historically been assumed absent, because roughly 10 per cent of patients have no effective modulator and they are disproportionately of non-European ancestry.

**Treatment.** CFTR modulators are the first-line disease-modifying treatment where genotype permits. Elexacaftor, tezacaftor and ivacaftor reduced exacerbations 63 per cent, sweat chloride 41.8 mmol/L and improved FEV1 roughly 10 to 14 points. They are patented, and their listing status on the WHO Essential Medicines List 24th List needs checking†. CFTR modulators generally carry United States list prices of hundreds of thousands of dollars a year. Negotiated prices in England, Scotland, Ireland, Canada, Australia and New Zealand are confidential and substantially lower.

Access is the dominant issue. Several high-income countries took years to reach agreement, and most middle- and low-income countries have no access at all. A published analysis of generic production cost (Hill and colleagues' group, using the method applied to insulin and semaglutide) estimated that the three-drug combination could be manufactured and sold profitably for a few thousand dollars a patient-year at scale. That is a factor of roughly 50 to 70 below United States list price†. Argentina and Ukraine, among others, have pursued or implemented generic or compulsory-licence routes. The estimate is modelled and contested by the manufacturer, and no audited figure exists.

Airway clearance, by physiotherapy, positive expiratory pressure devices, oscillating devices, autogenic drainage and exercise, needs no product for the manual techniques. It is daily, lifelong and time-consuming, historically roughly 1 to 2 hours a day.

Inhaled mucoactive agents. Dornase alfa, recombinant human DNase, improves FEV1 by roughly 5 to 6 per cent and reduces exacerbations by roughly 30 per cent in the pivotal trial†. It is off-patent in few markets and costs tens of thousands of dollars a patient-year. Hypertonic saline, 7 per cent, improves FEV1 modestly and reduced exacerbations by roughly 56 per cent in the Australian trial†. It costs hundreds of dollars a patient-year, and nebulised 7 per cent saline can in principle be prepared from sterile saline and salt at trivial cost. It is the cheap alternative to dornase alfa, with comparable effect sizes. Mannitol dry powder is an alternative. The listing status of dornase alfa and hypertonic saline needs checking against the 24th List†.

Inhaled antibiotics for chronic *Pseudomonas*: tobramycin in alternate months improves FEV1 and reduces exacerbations and hospitalisation, with colistin, aztreonam and levofloxacin as alternatives. Tobramycin and colistin are off-patent. Branded nebuliser solution costs tens of thousands of dollars a patient-year. Generic tobramycin injection used off-label for nebulisation costs hundreds to a few thousand dollars, and this substitution is widely practised in middle-income countries. The listing status of tobramycin, inhaled and injectable, needs checking against the 24th List†.

Azithromycin, long-term three times a week, reduces exacerbations by roughly 35 to 40 per cent in patients with chronic *Pseudomonas*†. It costs tens to low hundreds of dollars a patient-year and is one of the best value-for-money treatments in CF. Azithromycin is on the 24th List, in the Watch group, and the indications recorded there are cholera, enteric fever, gonorrhoea, chlamydial infection, trachoma and yaws; cystic fibrosis is not among them.

Pancreatic enzyme replacement is essential in the 85 per cent with pancreatic insufficiency, since without it fat malabsorption causes malnutrition and death. Pancreatic enzymes are on the 24th List, in gastrointestinal medicines and in medicines for cystic fibrosis, as modified-release capsules of 10,000 lipase, 8,000 amylase and 600 protease, and 25,000, 18,000 and 1,000. The product is old and the formulations proprietary, and United States supply has been subject to shortages and price rises. It costs thousands to tens of thousands of dollars a patient-year in high-income countries and far less where generic porcine pancreatin is available. Fat-soluble vitamins A, D, E and K are cheap, and their listing status needs checking against the 24th List†.

High-energy nutrition, salt supplementation in hot climates and gastrostomy feeding where growth fails. Exacerbations are treated with intravenous antibiotics, typically two agents against *Pseudomonas* for 14 days, with intensified airway clearance. Most of these antibiotics (ceftazidime, meropenem, tobramycin, colistin, piperacillin-tazobactam) are off-patent. CF-related diabetes is treated with insulin and not oral agents, and human insulin is on the 24th List for diabetes types 1 and 2. CF liver disease is treated with ursodeoxycholic acid, which is contested, management of portal hypertension, and transplantation. End-stage lung disease is treated by lung transplantation.

Men are almost universally infertile but produce sperm, so surgical sperm retrieval with ICSI achieves fatherhood. Women are subfertile but often conceive, and pregnancy outcomes have improved markedly with modulators.

**Simple means.** Airway clearance by breathing technique and percussion. Autogenic drainage, the active cycle of breathing techniques, and manual percussion and postural drainage need no equipment at all and are the foundation of CF care worldwide. Positive expiratory pressure can be generated with a simple device costing a few dollars, or by blowing through a tube into water. Exercise is independently associated with slower lung function decline and better survival in registry analyses, and is also an airway clearance technique.

Nebulised hypertonic saline reduced exacerbations by roughly 56 per cent in a randomised trial and improves FEV1, and the active ingredient is salt. Against dornase alfa at tens of thousands of dollars a patient-year, it is the most consequential cheap substitution in CF care. Azithromycin three times a week costs tens to low hundreds of dollars a patient-year, with roughly 35 to 40 per cent fewer exacerbations. Generic tobramycin injection solution used for nebulisation costs hundreds to a few thousand dollars a patient-year against tens of thousands for the branded inhalation solution, and is standard practice in much of the world.

High-fat, high-energy food. The Toronto-versus-Boston comparison suggests a median survival difference of roughly 9 years attributable largely to the unrestricted high-fat diet with adequate enzyme replacement. The intervention is ordinary food in larger amounts, and the removal of a harmful restriction. Extra salt in hot weather costs nothing: CF causes excessive salt loss in sweat, and supplementation prevents hyponatraemic dehydration. Pancreatic enzymes and fat-soluble vitamins are not free, but generic porcine pancreatin is cheap where available, and without enzyme replacement the high-fat diet does not work.

The sweat test, pilocarpine iontophoresis with chloride measurement, has been the diagnostic test since 1959, costs tens to low hundreds of dollars and needs no genetic analysis. Where newborn screening or genotyping is absent, a sweat test in a child with failure to thrive, chronic cough or recurrent pneumonia is the whole diagnostic pathway. Infection segregation, keeping patients apart at clinic and avoiding social contact between patients, is a free organisational measure that stopped the *Burkholderia cepacia* epidemics. No household smoke, handwashing and nebuliser hygiene complete the list.

**Gaps.** No authoritative global count of people with CF exists. The source consulted gives no worldwide number, and the registry figure it gives, roughly 50,000 followed since 1986, is cumulative and not current. Modelled global estimates range from roughly 105,000 to 162,000. CF is probably substantially under-diagnosed in Africa, South Asia, the Middle East and Latin America. Carrier frequencies of 1 in 65 and 1 in 90 are inconsistent with the near-zero incidence sometimes reported.

Survival figures conflict within the same source: about 42 to 50 years, a cited median of 40.7 years, and about 65 years with newer treatments. They are different quantities, and the last is a projection. The source gives no specific FEV1 figure for elexacaftor, tezacaftor and ivacaftor, reporting only substantial improvements, so the 10 to 14 percentage point figure comes from the pivotal trials. It gives no price for the triple combination, only a general range for modulators of hundreds of thousands of dollars a year. Negotiated prices elsewhere are confidential.

Roughly 10 per cent of patients have no effective modulator and are disproportionately of non-European ancestry. The disparity is structural and widening as the rest of the population improves. Modulator long-term outcomes are unknown, since the oldest treated cohorts have under a decade of follow-up, so whether corrected sweat chloride translates into normal lifespan is a projection. Generic production-cost estimates for modulators are modelled and contested by the manufacturer.

Pancreatic enzyme replacement is subject to supply shortages and price rises despite being an old product. Ursodeoxycholic acid for CF liver disease is contested, and Cochrane found insufficient evidence. Whether heterozygote advantage explains the allele frequency is unresolved, and so is why lung disease severity varies so widely at identical genotype.

---

## Lysosomal storage diseases (Gaucher, Fabry, Pompe)

**What it is.** Lysosomes are the cell's recycling compartments. In these inherited diseases one of their enzymes is missing, so the material it should break down accumulates and progressively damages organs. There are about seventy such diseases. Three are treatable with replacement enzymes and are the examples here.

**Measured.** The class has roughly 70 distinct diseases, with a combined birth incidence of roughly 1 in 5,000 to 1 in 8,000 live births and as high as 1 in 4,000 in some studies†. Dutch and Australian population-based studies give roughly 1 in 7,700 and 1 in 7,000 respectively†. They are individually rare and collectively not rare.

Gaucher disease is glucocerebrosidase deficiency. Type 1, non-neuronopathic, occurs in roughly 1 in 40,000 to 1 in 60,000 in general populations and roughly 1 in 450 to 900 in Ashkenazi Jewish populations, with a carrier frequency of roughly 1 in 15 to 18, one of the strongest founder effects in medicine†. Type 2, acute neuronopathic and infantile, occurs in roughly 1 in 150,000 and is fatal by age 2 to 4. Type 3, chronic neuronopathic, occurs in roughly 1 in 100,000 and is higher in the Norrbottnian population of northern Sweden. Type 1 is roughly 90 to 95 per cent of cases in Western countries.

Fabry disease is alpha-galactosidase A deficiency, X-linked. Classical incidence is roughly 1 in 40,000 to 1 in 117,000 males on clinical ascertainment, but newborn screening finds roughly 1 in 1,250 to 1 in 7,000, a 10-to-50-fold discrepancy†. Screening detects later-onset and variant forms, including the *IVS4+919G>A* variant, which reaches roughly 1 in 1,250 to 1,600 males in Taiwan. Females are affected, often substantially, through X-inactivation mosaicism, and the old description of female carriers is wrong. Fabry disease accounts for roughly 0.2 to 1 per cent of patients on dialysis and a similar share of young stroke patients in screening studies.

Pompe disease is acid alpha-glucosidase deficiency. Combined incidence is roughly 1 in 40,000, with infantile-onset roughly 1 in 138,000 and late-onset roughly 1 in 57,000 in Dutch data†. Newborn screening in Taiwan, Japan and United States states finds roughly 1 in 15,000 to 30,000, higher than clinical ascertainment because of late-onset and pseudodeficiency variants. Untreated infantile-onset Pompe disease has a median survival of roughly 6 to 8.7 months, with death from cardiorespiratory failure, and virtually none survived beyond 2 years†.

Diagnostic delay has a median of roughly 4 to 7 years for Gaucher, roughly 13 to 16 years for Fabry, one of the longest in medicine and longer in women, and roughly 7 to 12 years for late-onset Pompe†. Patients are typically misdiagnosed with rheumatological, haematological, muscular or psychiatric conditions first.

Cost is the defining economic feature of the class. Enzyme replacement therapy costs hundreds of thousands of dollars a patient-year depending on drug, dose and body weight. These are among the most expensive medicines in continuous long-term use anywhere, and the orphan-drug framework that produced them is the reason they exist and the reason they cost what they do.

**Where it starts.** Deficiency of a single lysosomal hydrolase, or of a transporter, activator or trafficking protein, causes its substrate to accumulate in lysosomes, with secondary effects on autophagy, inflammation, mitochondrial function and cell signalling. The stored substrate is not merely inert. Much of the pathology comes from the secondary cascade, which is why enzyme replacement reverses some manifestations and not others. All the genotypes are Mendelian.

Gaucher disease arises from *GBA1* variants, autosomal recessive. Glucosylceramide accumulates in macrophages, producing Gaucher cells that infiltrate bone marrow, spleen and liver, with splenomegaly, hepatomegaly, anaemia, thrombocytopenia, bone pain, avascular necrosis and fractures. *N370S* (N409S) is associated with non-neuronopathic type 1 and

is the predominant Ashkenazi allele, and *L444P* (L483P) with neuronopathic disease. *GBA1* heterozygosity is the single largest genetic risk factor for Parkinson disease, with odds ratios of roughly 5 to 7, higher for severe variants, and roughly 5 to 10 per cent of Parkinson patients carry a *GBA1* variant†. Patients with Gaucher disease have a markedly raised Parkinson risk, roughly 20 to 30-fold†. This links a rare storage disease to a common neurodegenerative one and has made *GBA1* a major Parkinson drug target.

Fabry disease arises from *GLA* variants, X-linked. Globotriaosylceramide (Gb3) and lyso-Gb3 accumulate in vascular endothelium, podocytes, cardiomyocytes, dorsal root ganglia and autonomic neurons. The result is acroparaesthesia and neuropathic pain, hypohidrosis, angiokeratomas, corneal verticillata, proteinuria progressing to renal failure, left ventricular hypertrophy and arrhythmia, and early stroke. Over 1,000 *GLA* variants exist. Classical disease, with absent enzyme, and later-onset disease, with residual enzyme, for example *N215S* and *IVS4+919G>A*, differ substantially. Females are affected over a wide severity range determined by X-inactivation patterns.

Pompe disease arises from *GAA* variants, autosomal recessive. Glycogen accumulates in lysosomes of cardiac, skeletal and smooth muscle, with secondary autophagic build-up. Infantile-onset disease, with essentially no enzyme activity, brings hypertrophic cardiomyopathy, profound hypotonia, feeding difficulty and respiratory failure, and death in infancy untreated. Late-onset disease, with residual activity, brings progressive proximal and axial myopathy and diaphragmatic weakness, with respiratory failure often preceding loss of ambulation. CRIM status (cross-reactive immunologic material) determines whether the infant makes any endogenous protein, and CRIM-negative infants develop high-titre antibodies to replacement enzyme and do badly without immune tolerance induction.

Why severity varies at identical genotype is not well explained. Modifier genes, X-inactivation in Fabry disease and immune response to therapy in Pompe disease each contribute.

*Not known*: why newborn screening finds 10 to 50 times more Fabry disease and several times more Pompe disease than clinical ascertainment. Specifically, how many of the screen-detected later-onset genotypes will ever develop clinical disease, and therefore whether screening identifies patients or healthy variant carriers. This is the central unresolved question in the class and it determines whether screening is beneficial. Also not known: why enzyme replacement fails to reach the brain and bone adequately, and why anti-drug antibodies develop in some patients and not others.

**Cure status.** Gaucher type 1: CONTROLLABLE. Gaucher type 1 after allogeneic haematopoietic stem cell transplant: CURABLE, for the visceral and haematological disease. Gaucher type 2: RELIEF ONLY. Gaucher type 3: CONTROLLABLE for the visceral and haematological disease, and RELIEF ONLY for the neurological disease. Fabry disease: CONTROLLABLE. Infantile-onset Pompe disease: CONTROLLABLE. Late-onset Pompe disease: CONTROLLABLE.

Gaucher type 1 treatment is highly effective, arguably the most successful enzyme replacement therapy in medicine. Imiglucerase, velaglucerase and taliglucerase are given intravenously every 2 weeks. They regress splenomegaly and hepatomegaly by roughly 30 to 50 per cent within 2 years and normalise haemoglobin and platelet counts in most patients within 1 to 2 years†. They substantially reduce bone pain and crises, with bone density improving over years. Life expectancy in treated type 1 approaches normal. Eliglustat, an oral substrate reduction therapy, is non-inferior to enzyme replacement for maintenance in suitable patients in the ENCORE trial and is first-line oral therapy. Miglustat is less effective and less tolerated. Established avascular necrosis and fibrosis do not reverse, and enzyme replacement does not cross the blood-brain barrier, so neuronopathic disease is not treated by it. Type 2 remains uniformly fatal. Allogeneic transplant cures the visceral and haematological disease, because donor macrophages supply the enzyme, but it carries transplant mortality and is rarely used now that enzyme replacement exists.

Fabry disease is CONTROLLABLE, with the qualification that the hard-outcome evidence is weaker than for Gaucher. Agalsidase beta and agalsidase alfa, intravenous every 2 weeks, clear Gb3 from endothelium and reduce plasma lyso-Gb3. The pivotal trials used histological clearance of Gb3 from renal capillary endothelium as the endpoint, not clinical events. The largest randomised trial of agalsidase beta showed a reduction in a composite clinical endpoint of renal, cardiac and cerebrovascular events and death that was significant only

after adjustment for baseline proteinuria. Cochrane and other systematic reviews conclude the evidence for hard clinical benefit is limited, while registry data suggest slowed decline in renal function when treatment starts early. Migalastat, an oral chaperone, is effective only in the roughly 35 to 50 per cent of patients with amenable mutations†. Established fibrosis, renal, cardiac or cerebral, does not reverse. Early treatment is the whole argument, and it collides with the fact that newborn screening cannot yet predict who will develop disease.

Infantile-onset Pompe disease is the closest thing in the class to a transformation. Untreated, median survival is roughly 6 to 8.7 months and virtually none are alive at 2 years†. With alglucosidase alfa, approved in 2006, roughly 95 per cent of treated infants in the pivotal trial were alive at 18 months of age†. Roughly 92 per cent were alive and free of invasive ventilation†. In an untreated historical cohort roughly 2 per cent were alive and ventilator-free at that age†. Cardiomyopathy reverses substantially. This converted a uniformly fatal infantile disease into a survivable one, one of the largest single-drug survival effects recorded for any disease in this chapter.

It also created a new phenotype. Survivors develop residual myopathy, speech and swallowing difficulty, hearing loss, and in some cases a progressive white matter abnormality, because the enzyme does not reach the brain. The disease is controlled and not cured, and the surviving children have a condition that did not previously exist long enough to be described. CRIM-negative infants require immune tolerance induction (rituximab, methotrexate, immunoglobulin) or they develop neutralising antibodies and lose the benefit. Avalglucosidase alfa (2021) and cipaglucosidase alfa plus miglustat (2023) are next-generation products with better muscle targeting, and both showed modest superiority on respiratory and walking endpoints in late-onset disease.

Late-onset Pompe disease shows a modest measured benefit. The LOTS trial showed a roughly 25 metre improvement in 6-minute walk distance and stabilisation of forced vital capacity against placebo over 78 weeks†. That is small, and set against inexorable decline. Gene therapy is in trials for all three, AAV liver-directed for Fabry and Pompe and lentiviral haematopoietic for Gaucher and Fabry, and nothing is approved. Preliminary results show enzyme expression and substrate reduction.

**Prevention.** Carrier screening in founder populations. Ashkenazi Jewish carrier screening panels include Gaucher disease, carrier frequency roughly 1 in 15 to 18, and have operated for decades alongside Tay-Sachs screening. The Tay-Sachs programme reduced affected births in Ashkenazi communities by roughly 90 per cent†. Gaucher is screened within the same framework, though it raises a different question, because type 1 Gaucher is treatable and compatible with a long life. STRONG for birth prevalence. The ethical case differs from Tay-Sachs because the disease is treatable.

Cascade testing of relatives of an index case has a high yield and shortens the diagnostic delay of 4 to 16 years for the next family member. In Fabry disease, testing the family of one index case typically identifies roughly 5 additional affected relatives†. STRONG. Prenatal and preimplantation genetic diagnosis where available and acceptable: STRONG for birth prevalence.

Newborn screening is CONTESTED and is the central controversy in this class. For infantile-onset Pompe disease the case is strong, because treatment before symptom onset produces markedly better outcomes than treatment after and untreated infantile Pompe is fatal. Taiwan's programme showed that screened infants had better motor and cardiac outcomes than clinically diagnosed ones. STRONG for infantile Pompe. For Fabry disease and late-onset Pompe the case is contested. Screening detects 10 to 50 times more cases than clinical ascertainment, the great majority with later-onset or uncertain-significance genotypes, and nobody knows how many will develop disease or when to start a treatment costing hundreds of thousands of dollars a year. Screening generates patients-in-waiting and their families. CONTESTED. For Gaucher disease newborn screening is generally not recommended, because type 1 is compatible with decades of good health and treatment is started on clinical indication. Pompe, and in some programmes Fabry and MPS I, are included in the United States Recommended Uniform Screening Panel and in programmes in Taiwan, Japan, Italy, Austria and elsewhere.

Prevention of complications once diagnosed. In Fabry disease, ACE inhibitors or ARBs for proteinuria are standard and probably contribute as much to renal outcome as enzyme replace-

ment. Anticoagulation or antiplatelet therapy for stroke risk, statins, avoiding nephrotoxins, hearing and cardiac surveillance and an implantable defibrillator where indicated complete the list. In Gaucher disease, splenectomy is avoided, since it was historically performed and accelerates bone and liver disease, and bisphosphonates and vitamin D protect bone, with monitoring for myeloma and Parkinson disease. In Pompe disease, respiratory surveillance includes supine spirometry, because diaphragmatic weakness is missed on erect spirometry, with non-invasive ventilation, vaccination, physiotherapy and careful anaesthetic management. STRONG for each.

Shortening the diagnostic delay. Targeted screening of high-risk populations has demonstrated yield: enzyme or genetic testing in young stroke patients, unexplained left ventricular hypertrophy and dialysis populations for Fabry disease, in unexplained splenomegaly or thrombocytopenia for Gaucher disease, and in unexplained limb-girdle myopathy or raised creatine kinase for Pompe disease. These yield affected patients in roughly 0.2 to 3 per cent of those tested†. MODERATE.

**Treatment.** Enzyme replacement therapy is an intravenous infusion every 1 to 2 weeks, lifelong. For Gaucher disease the products are imiglucerase, velaglucerase alfa and taliglucerase alfa. For Fabry disease they are agalsidase beta, agalsidase alfa and pegunigalsidase alfa (2023). For Pompe disease they are alglucosidase alfa, avalglucosidase alfa and cipaglucosidase alfa plus miglustat. All are patented in practice. Their listing status on the WHO Essential Medicines List 24th List needs checking†.

Taliglucerase alfa, plant-cell-produced, and velaglucerase entered as competitors to imiglucerase and reduced prices by roughly 25 to 40 per cent in some markets†. This is the only meaningful price competition in the class, and it was created deliberately by payers and by an Israeli and a United States manufacturer and not by patent expiry. Cost is hundreds of thousands of dollars a patient-year, weight-based, so adult and paediatric costs differ severalfold. Alglucosidase alfa costs more than the others for an adult. An infant costs far less, and the cost rises as the child grows, which has produced documented access crises as treated infants reach adolescence.

During the 2009 imiglucerase supply crisis, caused by viral contamination of the manufacturing line, patients worldwide were placed on reduced doses. Outcomes were largely maintained at substantially lower doses. That is evidence that the licensed doses may be higher than necessary, with obvious cost implications, and it has not been followed up systematically with dose-ranging trials.

Oral small molecules. Eliglustat, substrate reduction for Gaucher type 1, is non-inferior to enzyme replacement for maintenance in ENCORE, is taken orally twice daily, and costs hundreds of thousands of dollars a patient-year, oral and not cheaper. Miglustat is less effective with more gastrointestinal toxicity, is off-patent, and still costs tens to hundreds of thousands of dollars a patient-year, with generics at lower prices in some markets. Migalastat for Fabry disease, only for amenable mutations, is taken orally on alternate days at hundreds of thousands of dollars a patient-year. Their listing status needs checking against the 24th List†.

Immune tolerance induction in CRIM-negative infantile Pompe disease uses rituximab, methotrexate and immunoglobulin. Rituximab biosimilars cost thousands of dollars a course, methotrexate pennies, and immunoglobulin is expensive and plasma-constrained. All three of the drugs that make the enzyme work are cheap or moderately priced against it. Rituximab is on the 24th List, for multiple sclerosis in the complementary list and for Burkitt lymphoma, diffuse large B-cell lymphoma, chronic lymphocytic leukaemia and follicular lymphoma, and tolerance induction in Pompe disease is not among the recorded indications.

Haematopoietic stem cell transplant cures Gaucher visceral disease and is used for other lysosomal diseases (MPS I Hurler, metachromatic leukodystrophy, Krabbe disease) where it must be done before neurological damage. Supportive and complication-directed treatment is where most of the cheap benefit lies. In Fabry disease: ACE inhibitors or ARBs for proteinuria, at a few dollars to tens of dollars a patient-year; carbamazepine, gabapentin or pregabalin for neuropathic pain, at tens to hundreds of dollars; antiplatelets or anticoagulants; statins; and dialysis and renal transplantation. Kidney transplant outcomes in Fabry disease are good, at far lower cost than lifelong enzyme replacement plus dialysis. The listing status of these drugs needs checking against the 24th List†.

In Gaucher disease: bisphosphonates and vitamin D at tens of dollars a patient-year, transfusion, analgesia and joint replacement, and not splenectomy. In Pompe disease: non-invasive ventilation, a device costing hundreds to a few thousand dollars one-off plus consumables, which is what prevents death in late-onset disease and is far cheaper than enzyme replacement; physiotherapy; nutritional support; and mobility aids. Genetic counselling serves the family.

**Simple means.** This is the entry in which the simple means are least able to substitute for the expensive treatment, and that is stated directly. What exists still matters.

Non-invasive ventilation in Pompe disease. Respiratory failure from diaphragmatic weakness is what kills in late-onset Pompe, and a bilevel ventilator costing hundreds to a few thousand dollars plus masks prolongs life and relieves symptoms substantially. Against enzyme replacement at hundreds of thousands of dollars a patient-year with a roughly 25-metre walk-distance benefit, it is the highest-value intervention available for that disease. Supine spirometry costs nothing extra and detects diaphragmatic weakness that erect spirometry misses, and in late-onset Pompe it is the test that determines whether ventilation is needed.

ACE inhibitors or ARBs for Fabry proteinuria cost a few dollars to tens of dollars a patient-year, are off-patent, and slow renal decline. Where enzyme replacement is unaffordable, which is most of the world, these plus blood pressure control, statins and antiplatelet therapy are the realistic standard of care, and it is not nothing. Generic neuropathic pain drugs, carbamazepine, gabapentin, pregabalin and amitriptyline, treat the acroparaesthesia that is often the most disabling daily symptom of Fabry disease in young people, at tens to a couple of hundred dollars a year. Avoiding heat, exertion in heat and dehydration in Fabry disease is free and prevents crises, since hypohidrosis prevents normal thermoregulation.

Not performing splenectomy in Gaucher disease is free. Bisphosphonates and vitamin D for Gaucher bone disease cost tens of dollars a patient-year. Kidney transplantation in Fabry disease has good outcomes and is cheaper over a lifetime than dialysis plus enzyme replacement. Family testing is a pedigree and a blood test: one Fabry index case typically identifies roughly five affected relatives, and the diagnostic delay is 13 to 16 years.

A dried blood spot enzyme assay for Gaucher, Fabry and Pompe can be posted to a reference laboratory and costs tens of dollars per disease. It is how diagnosis is achieved in countries with no metabolic laboratory and is the cheapest step in this entry. Corneal verticillata in Fabry disease are visible on slit-lamp examination, cost nothing to look for, and are present in the great majority of classically affected patients of both sexes. Physiotherapy and exercise within tolerance help in Pompe disease, and joint protection in Gaucher disease.

**Gaps.** Newborn screening finds 10 to 50 times more Fabry disease and several times more Pompe disease than clinical ascertainment, and nobody knows what proportion of screen-detected later-onset genotypes will ever develop disease. It is the central unresolved problem in the class, and it makes screening for Fabry and late-onset Pompe genuinely contested while screening for infantile Pompe is clearly beneficial.

The evidence for hard clinical benefit of enzyme replacement in Fabry disease is limited. The pivotal trials used histological endpoints, Cochrane and other systematic reviews conclude the clinical-event evidence is weak, and registries suggest early treatment helps. The sources disagree, and the drug costs hundreds of thousands of dollars a patient-year. Late-onset Pompe enzyme replacement gives roughly a 25-metre improvement in 6-minute walk distance at hundreds of thousands of dollars a patient-year, against non-invasive ventilation at hundreds to a few thousand dollars, and no head-to-head comparison or cost-effectiveness consensus exists.

The 2009 imiglucerase supply crisis showed outcomes maintained at substantially reduced doses, implying licensed doses may be unnecessarily high, and no dose-ranging trials have followed. It is the clearest unexploited cost-reduction opportunity in the class.

Whether any of these drugs is on the WHO Essential Medicines List 24th List needs checking, and essentially none is available in low-income countries. Published outcome data come almost entirely from high-income registries, which are also largely manufacturer-funded. Enzyme replacement is weight-based, so cost rises as a treated child grows, and documented access crises occur when treated infants reach adolescence and the annual cost doubles or triples.

Enzyme replacement does not cross the blood-brain barrier. Neuronopathic Gaucher disease, the neurological features of Fabry disease and the emerging white matter disease in long-surviving treated infantile Pompe patients are untreated. Treated infantile Pompe survivors have a phenotype that did not exist before the drug, and its natural history is being described in real time. Diagnostic delays of 4 to 16 years persist despite cheap dried blood spot assays. Why severity varies at identical genotype is unexplained, and in Fabry females X-inactivation accounts for part of it.

*GBA1*'s role as the largest genetic risk factor for Parkinson disease connects this rare-disease class to a common disease, and the therapeutic implications are being tested now. Combined class incidence estimates, 1 in 4,000 to 1 in 8,000, come from a handful of population studies in the Netherlands, Australia and Italy, and nothing comparable exists from Africa, Asia or Latin America.

---

## Hereditary metabolic disorders screened for at birth

**What it is.** A dried spot of blood taken from a newborn's heel and tested for a panel of inherited disorders. They cause death or permanent disability if untreated, and can be treated if caught in the first days of life. It is the largest genetic screening programme in the world.

**Measured.** Newborn screening reaches roughly two-thirds to three-quarters of the world's births for at least one condition, out of roughly 130 million babies born each year†. Near-universal coverage exists in North America, Europe, Australasia, Japan, Korea, Taiwan, much of Latin America and parts of the Middle East. Coverage is minimal across most of sub-Saharan Africa and parts of South and Central Asia.

Panel size varies enormously by country, and this is the central measured fact.

- United States Recommended Uniform Screening Panel: 38 core conditions plus 26 secondary conditions.
- Italy: roughly 40 to 50 conditions.
- Germany, Austria, the Netherlands, Spain and Portugal: roughly 15 to 30.
- United Kingdom: 9 conditions, which are phenylketonuria, congenital hypothyroidism, sickle cell disease, cystic fibrosis, medium-chain acyl-CoA dehydrogenase deficiency, maple syrup urine disease, isovaleric acidaemia, glutaric aciduria type 1 and homocystinuria.
- France: expanded from 5 to 13 in 2023.
- Finland, Denmark and Sweden: roughly 2 to 25 depending on era.

Two high-income European countries with similar populations can thus differ four-fold in what they screen for, and the difference reflects policy judgement about screening criteria and not differences in disease prevalence. Roughly 1 in 1,500 to 1 in 4,000 newborns has a condition detected by an expanded tandem mass spectrometry (MS/MS) panel, depending on panel breadth and population.

The founding condition is phenylketonuria, roughly 1 in 12,000 births, with Guthrie's test in the early 1960s and Ireland's national programme in February 1966†. The highest-yield conditions on most panels follow.

Congenital hypothyroidism occurs in roughly 1 in 2,000 to 1 in 4,000, the commonest condition on most panels and the commonest preventable cause of intellectual disability. Levothyroxine started within the first two weeks produces normal IQ. Untreated, it causes severe irreversible intellectual disability, with a mean IQ loss of roughly 25 to 40 points, and worse where diagnosis is later†.

Sickle cell disease occurs in roughly 1 in 2,000 births in the United States and far higher in African and Afro-descended populations. Penicillin prophylaxis and pneumococcal vaccination from screening reduce early childhood death substantially, and the PROPS trial showed an 84 per cent reduction in pneumococcal septicaemia†. Cystic fibrosis occurs in roughly 1 in 3,000 in northern European populations. Congenital adrenal hyperplasia occurs in 1 in 14,200 live births and screening prevents neonatal salt-wasting death and incorrect sex assignment.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency occurs in roughly 1 in 10,000 to 20,000†. It is one of the clearest cases for screening. Untreated, roughly 20 to 25 per cent

of undiagnosed children die at the first metabolic crisis and many survivors have brain injury. With screening and avoidance of fasting, mortality falls to near zero. The intervention is an instruction: do not let the child fast, and give glucose during illness.

Severe combined immunodeficiency occurs in 1 in 58,000 by TREC screening†. Galactosaemia occurs in roughly 1 in 40,000 to 60,000†. Untreated it causes neonatal sepsis, liver failure and death, and the treatment is a lactose-free diet. Biotinidase deficiency occurs in roughly 1 in 60,000†. Untreated it causes seizures, developmental delay, hearing loss, optic atrophy and death. The treatment is oral biotin, costing a few dollars a year, and it prevents all of it. It is the highest benefit-to-cost ratio of any condition on any screening panel.

Maple syrup urine disease, homocystinuria, glutaric aciduria type 1, isovaleric acidaemia, propionic and methylmalonic acidaemia, tyrosinaemia type 1, urea cycle disorders, and very-long-chain and long-chain fatty acid oxidation defects each occur in roughly 1 in 50,000 to 1 in 250,000†. Increasingly added are spinal muscular atrophy (SMA), roughly 1 in 10,000, X-linked adrenoleukodystrophy, Pompe disease, mucopolysaccharidosis type I, Fabry disease and, in some programmes, Duchenne muscular dystrophy.

Cost is low. The full MS/MS panel costs tens of dollars per newborn depending on programme and panel breadth, and the dried blood spot card, collection and courier are a large share of it. Cost-effectiveness analyses consistently find expanded newborn screening cost-saving or highly cost-effective, driven by phenylketonuria, congenital hypothyroidism, MCAD deficiency and congenital adrenal hyperplasia, where the averted lifetime care costs greatly exceed programme costs. The heel-prick sample is taken at 24 to 72 hours, in some programmes 2 to 7 days, with a repeat where indicated.

**Where it starts.** The conditions screened are almost all Mendelian, mostly autosomal recessive, so heritability is 1.0 for the genotype, and the parents of an affected child are almost always healthy carriers with no family history. This is the central epidemiological point. These diseases are not predictable from family history in the great majority of cases, which is why population screening and not targeted testing is required.

Consanguinity raises the incidence of recessive conditions substantially. In highly consanguineous populations the combined incidence of screened metabolic disorders can be several-fold higher, and those are where screening coverage is often lowest. Founder effects change what is worth screening for. Tyrosinaemia type 1 occurs in Saguenay-Lac-Saint-Jean (Quebec) at roughly 1 in 1,850. Glutaric aciduria type 1 occurs in Old Order Amish and in the Irish Travelling community. Maple syrup urine disease occurs in Mennonites at roughly 1 in 380. Sickle cell disease occurs in African-descended populations, beta-thalassaemia in Mediterranean, Middle Eastern and South Asian populations, and Gaucher disease and Tay-Sachs disease in Ashkenazi Jewish populations.

Not all conditions on panels are genetic. Congenital hypothyroidism is mostly non-genetic, thyroid dysgenesis in roughly 85 per cent, and in iodine-deficient areas is partly environmental, so iodisation reduces the burden the screen detects. Congenital cytomegalovirus and critical congenital heart disease, detected by pulse oximetry and not blood spot, are also on some panels.

Early treatment works and late treatment does not because a metabolite accumulates or a hormone is absent during a critical developmental window. In phenylketonuria and congenital hypothyroidism the window is the first weeks to months of brain development, and damage is cumulative and irreversible. In MCAD deficiency and other fatty acid oxidation defects the risk is an acute catastrophic crisis precipitated by fasting or illness, which can be prevented indefinitely. In galactosaemia and tyrosinaemia the damage is acute organ injury in the neonatal period. In SMA the window is motor neuron loss, which is largely complete in the first months. This distinction, cumulative developmental damage against preventable acute crisis, determines whether a condition belongs on a panel.

The screening criteria of Wilson and Jungner (1968) and their modern revisions require an important condition, a recognisable latent stage, an available and acceptable test, an effective treatment, and benefit outweighing harm. Technology has outrun the criteria. MS/MS can detect dozens of analytes at no marginal cost per condition, so conditions get added because they are detectable and not because treatment is established. That is the central tension in the field.

*Not known*: for many conditions added in the MS/MS era, what proportion of screen-detected cases would ever have become clinically apparent. Expanded screening detects mild and variant forms. In short-chain acyl-CoA dehydrogenase deficiency, 3-methylcrotonyl-CoA carboxylase (3-MCC) deficiency and mild variants of several organic acidaemias, the screen-detected population is substantially healthier than the clinically ascertained one, and many will never have symptoms. The same problem appears in Fabry disease and late-onset Pompe disease. How to handle this is unresolved, and it is the main harm of expanded screening.

**Cure status.** This is a grouped entry covering a whole screening panel, and the labels differ by condition. The strata are grouped by what the treatment does. Newborn screening exists because the list is dominated by conditions whose treatment must start within days of birth and then continue.

Held by a lifelong diet, cofactor, hormone or emergency regimen: CONTROLLABLE. This covers phenylketonuria, congenital hypothyroidism, biotinidase deficiency, galactosaemia, MCAD deficiency and other fatty acid oxidation defects, maple syrup urine disease, homocystinuria, tyrosinaemia type 1, urea cycle disorders, organic acidaemias and congenital adrenal hyperplasia. The label is CONTROLLABLE and not CURABLE because the treatment continues for life. That does not reduce the value of screening. It is the difference between a normal life on treatment and irreversible damage without it.

Sickle cell disease: CONTROLLABLE, by penicillin prophylaxis plus pneumococcal vaccination plus parental education, which converts a condition that killed in early childhood into one compatible with adult life. Sickle cell disease after successful matched sibling transplant, available to a few: CURABLE. After gene therapy: CONTROLLABLE. Severe combined immunodeficiency, transplanted early: CURABLE. X-linked adrenoleukodystrophy, transplanted or treated with elivaldogene autotemcel before neurological damage: CURABLE. Spinal muscular atrophy treated before symptoms: CONTROLLABLE. Any of these diagnosed after irreversible damage is established: RELIEF ONLY. Krabbe disease and several mild variant forms detected by MS/MS have no established treatment benefit, and no label is assigned.

Phenylketonuria is CONTROLLABLE if caught at birth and RELIEF ONLY if caught late; see phenylketonuria. Congenital hypothyroidism treated with levothyroxine within two weeks gives normal IQ, and untreated gives severe permanent intellectual disability. Biotin, a few dollars a year, prevents seizures, deafness, blindness, developmental delay and death entirely in biotinidase deficiency. In galactosaemia, a lactose- and galactose-free diet prevents neonatal death and liver failure, though learning, speech and ovarian outcomes remain impaired in a substantial minority despite perfect dietary compliance, which is unexplained. In MCAD deficiency, avoidance of fasting plus glucose during illness takes mortality from roughly 20 to 25 per cent at the first crisis to near zero†. The treatment is an instruction and an emergency regimen, not a product.

Maple syrup urine disease, homocystinuria, tyrosinaemia type 1, urea cycle disorders and organic acidaemias are held by specialised diets and cofactors. These are pyridoxine in some homocystinuria, hydroxocobalamin in some methylmalonic acidaemia and biotin in some propionic acidaemia. Nitisinone in tyrosinaemia type 1 transformed it from a liver-transplant disease to a medical one, and nitrogen-scavenging drugs serve urea cycle disorders. Outcomes are good with early treatment and poor with late treatment, and residual neurocognitive morbidity is common even when treated. Congenital adrenal hyperplasia is held by hydrocortisone and fludrocortisone, which prevent salt-wasting death.

For severe combined immunodeficiency, overall survival is roughly 92 to 94 per cent when transplanted before 3.5 months against roughly 50 to 66 per cent later with active infection†. The screen delivers the age advantage.

Spinal muscular atrophy is the transformation case, and it has changed newborn screening policy worldwide. Untreated SMA type 1 reaches median survival or permanent ventilation by roughly 10 to 24 months, and almost none sit unaided†. Nusinersen (2016), onasemnogene abeparvovec (2019, a single AAV9 gene therapy) and risdiplam (2020) are the treatments. The NURTURE study gave nusinersen to presymptomatic infants identified genetically: all 25 were alive without permanent ventilation at a median of roughly 5 years of follow-up, all could sit unaided, and 23 of 25 could walk independently, outcomes essentially unheard of in untreated SMA. Presymptomatic treatment produces outcomes within or close to the normal

range, and symptomatic treatment does not. That contrast is the strongest modern argument for newborn screening of any condition, and SMA has been added to panels in the United States, much of Europe, Australia, Japan and Taiwan within a few years.

Onasemnogene abeparvovec costs roughly two million dollars as a single dose, nusinersen several hundred thousand dollars in the first year and about half that each year after, and risdiplam hundreds of thousands of dollars a patient-year depending on weight and market. These are among the highest-priced medicines in existence, and the condition is detected by a test costing a few dollars.

**Prevention.** Newborn screening is itself the prevention, and the measured effects are set out above. Phenylketonuria gives normal development against severe intellectual disability. Congenital hypothyroidism gives normal IQ against a 25 to 40 point loss. MCAD deficiency gives near-zero against 20 to 25 per cent mortality at first crisis. Severe combined immunodeficiency gives 92 to 94 per cent against 50 to 66 per cent survival. SMA gives walking independently against death or ventilation by 2 years. Sickle cell disease gives an 84 per cent reduction in pneumococcal septicaemia. A full panel costs tens of dollars per newborn. STRONG for the core conditions. CONTESTED for several recent additions.

Extending coverage to the countries without it is the largest remaining preventable burden in this chapter. In populations without screening, phenylketonuria, congenital hypothyroidism, congenital adrenal hyperplasia, galactosaemia and MCAD deficiency cause exactly the deaths and disabilities they caused everywhere before screening existed. Congenital hypothyroidism alone occurs at roughly 1 in 2,000 to 4,000 births. With 130 million annual births that implies roughly 32,000 to 65,000 affected infants a year worldwide†. A large share are unscreened, and each needs a levothyroxine tablet costing a few dollars to a few tens of dollars a year. STRONG.

Premarital and preconception carrier screening in high-incidence and consanguineous populations has been implemented for haemoglobinopathies in Cyprus, Iran, Saudi Arabia and the United Arab Emirates, with large measured reductions in affected births. STRONG for birth prevalence, and socially and ethically variable. Cascade testing after an index case, since a subsequent pregnancy in the same family carries a 1-in-4 recessive risk and prenatal or preimplantation diagnosis is available: STRONG. Universal salt iodisation reduces the congenital hypothyroidism the screen detects: STRONG.

Getting the sample at the right time. Too early, under 24 hours, causes false negatives for congenital hypothyroidism and congenital adrenal hyperplasia, and too late loses the treatment window. Timely sample collection and timely result communication are the operational determinants of whether the programme works. Failures of follow-up, and not of the laboratory, are the documented cause of most preventable harm in established programmes. STRONG.

Preventing the harms of screening: clear protocols for borderline and variant results, genetic counselling, and explicit decisions about which conditions to include based on treatment availability and not detectability. MODERATE, and this is where policy is weakest.

**Treatment.** Treatment is condition-specific, and the striking feature of the list is how cheap most of it is.

Levothyroxine for congenital hypothyroidism is on the WHO Essential Medicines List 24th List, section 18.7, for hypothyroidism. It is off-patent and costs a few dollars to a few tens of dollars a patient-year. It prevents severe intellectual disability and must start within two weeks.

Biotin for biotinidase deficiency is off-patent and costs a few dollars a patient-year. It prevents seizures, deafness, blindness and death completely. Its listing status needs checking against the 24th List†.

Penicillin V and pneumococcal conjugate vaccine for sickle cell disease give an 84 per cent reduction in pneumococcal septicaemia. Penicillin is off-patent and costs a few dollars a patient-year plus the vaccine cost. Their listing status needs checking against the 24th List†. Hydrocortisone and fludrocortisone for congenital adrenal hyperplasia are off-patent at tens to hundreds of dollars a patient-year, and their listing status needs checking against the 24th List†; see adrenal insufficiency.

Dietary treatment for phenylketonuria, galactosaemia, maple syrup urine disease, homocystinuria, tyrosinaemia, organic acidaemias and urea cycle disorders uses specialised amino acid substitutes and low-protein medical foods. They are made by few suppliers and cost thousands to tens of thousands of dollars a patient-year; see phenylketonuria. The diet controls the disease and the formulated products are the expense. Whether any is on the 24th List needs checking†.

Cofactor vitamins are pyridoxine for B6-responsive homocystinuria, hydroxocobalamin for B12-responsive methylmalonic acidaemia, biotin for biotin-responsive propionic acidaemia, riboflavin for multiple acyl-CoA dehydrogenase deficiency and thiamine for thiamine-responsive maple syrup urine disease. All are off-patent and cost a few dollars to a few tens of dollars per patient-year. Identifying a cofactor-responsive variant converts an expensive dietary disease into a vitamin-treated one. Their listing status needs checking against the 24th List†.

Carnitine for fatty acid oxidation defects and organic acidaemias is off-patent and costs hundreds to thousands of dollars a patient-year; its listing status needs checking. Nitisinone for tyrosinaemia type 1 transformed the disease. Generics have entered and prices have fallen substantially in some markets, from tens of thousands of dollars a patient-year to thousands. Its listing status needs checking against the 24th List†.

Nitrogen scavengers for urea cycle disorders are sodium benzoate, cheap and off-patent, sodium phenylbutyrate, off-patent at tens of thousands of dollars a patient-year, and glycerol phenylbutyrate, patented and higher. Intravenous sodium benzoate and arginine, plus haemodialysis, treat hyperammonaemic crisis, cheaply and time-critically. Their listing status needs checking against the 24th List†.

Emergency regimens for MCAD and other fatty acid oxidation defects, organic acidaemias and urea cycle disorders are a written emergency plan, a glucose polymer drink, and immediate intravenous dextrose during illness. This is the treatment that prevents death in these conditions and it costs almost nothing.

Haematopoietic stem cell transplant treats severe combined immunodeficiency, adrenoleukodystrophy, MPS I Hurler, metachromatic leukodystrophy and Krabbe disease. It is time-critical, and screening makes the timing possible. Gene and antisense therapies are onasemnogene abeparvovec at roughly two million dollars a single dose, nusinersen, risdiplam and elivaldogene autotemcel for adrenoleukodystrophy at about three million dollars. All are patented, and their listing status needs checking against the 24th List†. Enzyme replacement for Pompe disease and MPS I where screened costs hundreds of thousands of dollars a patient-year; see lysosomal storage diseases.

**Simple means.** This entry contains the highest-value simple means in the chapter.

The heel-prick dried blood spot is a few drops of blood on a filter paper card, air-dried and posted to a central laboratory. The full panel costs tens of dollars per newborn, and the phenylketonuria assay within it a few dollars. It requires no imaging, no clinic visit and no specialist, and the card survives the post. Against outcomes of normal development versus severe permanent intellectual disability, or life versus death at the first metabolic crisis, it is the highest benefit-to-cost intervention documented in this chapter, and it is unavailable to a large share of the world’s newborns.

Levothyroxine for congenital hypothyroidism costs a few dollars to a few tens of dollars a patient-year, is off-patent, is on the Essential Medicines List, and started within two weeks gives normal IQ instead of severe intellectual disability. At roughly 1 in 2,000 to 4,000 births it is the commonest condition on the panel and the cheapest treatment. Biotin for biotinidase deficiency costs a few dollars a year and prevents seizures, deafness, blindness, developmental delay and death.

For MCAD deficiency and other fatty acid oxidation defects the instruction is: do not let this child fast, and give glucose when ill. That instruction plus an emergency regimen takes mortality from roughly 20 to 25 per cent at first crisis to near zero. The intervention is a piece of paper and a glucose drink.

Penicillin twice a day and the pneumococcal vaccine in sickle cell disease give an 84 per cent reduction in pneumococcal septicaemia for a few dollars a year. A lactose-free diet in galactosaemia is ordinary dietary avoidance that prevents neonatal liver failure and death.

Cofactor vitamins, pyridoxine, hydroxocobalamin, biotin, riboflavin and thiamine, cost a few dollars to a few tens of dollars a year, and in the responsive variants replace the entire expensive apparatus of dietary management. Salt and hydrocortisone serve congenital adrenal hyperplasia, and salt costs nothing.

A written emergency letter carried by the family, naming the condition and the intravenous dextrose or ammonia-scavenging regimen needed on arrival at hospital, is free. It prevents death in a metabolic crisis when the family reaches a hospital that has never heard of the condition. Getting the sample at 24 to 72 hours and chasing the result is operational and free, and failures of follow-up and not of the laboratory cause most preventable harm in working programmes. Iodised salt reduces the congenital hypothyroidism burden upstream of the screen. Telling the family that a subsequent pregnancy carries a 1-in-4 risk, and that testing is available, costs nothing.

**Gaps.** Panel composition differs four-fold or more between comparable high-income countries, UK 9 conditions, United States 38 core plus 26 secondary, Italy roughly 40 to 50, for reasons of policy judgement and not disease prevalence. There is no international consensus on what should be screened. Technology has outrun the Wilson and Jungner criteria. MS/MS detects dozens of analytes at near-zero marginal cost, so conditions are added because they are detectable, and the requirement for an established effective treatment has weakened.

For several MS/MS-detected conditions, nobody knows what proportion of screen-detected cases would ever have become symptomatic. Expanded screening finds mild variants of short-chain acyl-CoA dehydrogenase deficiency, 3-MCC deficiency and several organic acidaemias whose clinical significance is unknown, creating patients-in-waiting. It is the main harm of expanded screening and it is unquantified. Krabbe disease screening has been implemented in some United States states despite uncertain benefit and a very narrow transplant window, and sources disagree sharply on whether it should be screened.

Coverage is minimal across most of sub-Saharan Africa and parts of South and Central Asia, and no systematic global figure exists for how many newborns are screened for what. The two-thirds to three-quarters figure for at least one condition is an estimate. Galactosaemia outcomes remain impaired in a substantial minority despite perfect dietary compliance, in learning, speech and ovarian function, and this is unexplained, which means the dietary control is incomplete for reasons nobody understands. Residual neurocognitive morbidity is common in treated organic acidaemias, urea cycle disorders and maple syrup urine disease even with early diagnosis, so screening prevents death and crisis more reliably than it prevents disability.

Expanded panels generate roughly 10 to 100 false positives per true positive depending on condition and cut-off, with documented parental anxiety and medicalisation of healthy infants. Second-tier molecular testing reduces this and is not universally implemented. Follow-up failure, and not laboratory failure, causes most preventable harm in established programmes, and the data on this are from incident reports and not systematic measurement.

The price contrast is extreme and unreconciled. SMA is detected by a test costing a few dollars and treated with a medicine costing about two million dollars. Congenital hypothyroidism is detected by the same test and treated for a few dollars to a few tens of dollars a year. No framework reconciles these within a single screening programme’s budget. Specialised medical foods and amino acid substitutes have no generic pathway and cost thousands to tens of thousands of dollars a patient-year, so the dietary control that newborn screening makes possible is among the least affordable treatments in the chapter relative to its simplicity. Whether genomic sequencing should replace or supplement biochemical newborn screening is under active trial, in the UK Generation Study, BabySeq and others, and the evidence is not yet in.

---

*End of chapter.*

# Chapter 13 — Mental, Sleep-Wake and Nervous System Conditions

**ICD-11 Chapter 06 — Mental, behavioural or neurodevelopmental disorders. Chapter 07 — Sleep-wake disorders. Chapter 08 — Diseases of the nervous system.**

---

This chapter covers fifty-one conditions across three ICD-11 chapters. They are taken together because the three chapters cut one territory three ways, and because several conditions are coded in two of them at once. Dementia is a Chapter 06 neurocognitive disorder whose causes are Chapter 08 diseases, so Alzheimer disease appears twice: once as a disease of the nervous system, once as the syndrome it produces. Sleep-wake disorders were a chapter of their own for the first time in ICD-11, having previously been distributed between the other two.

The burden is large. Depressive disorders and anxiety disorders rank second and third among all causes of years lived with disability worldwide, at 56.0 million (95 per cent UI 38.2 to 80.3) and 55.4 million (36.4 to 81.3). Headache disorders rank sixth at 45.5 million (31.4 to 62.0). Stroke ranks third among all causes of disability-adjusted life years at 157 million (141 to 172). Nervous system conditions as a group were the leading cause of illness and disability worldwide on the GBD 2021 analysis, with about 3.4 billion people affected and 443 million DALYs. The nervous-system figure covers Chapter 08 only, Chapter 07 has no stand-alone estimate, and no sum of the three chapters is printed.

In this chapter a simple means sometimes matches or beats the drug, and the figures are good ones. Exercise for depression was tested in a network meta-analysis of 218 studies, 495 arms and 14,170 participants. Against active controls, walking or jogging gave Hedges' g −0.62 (95 per cent CI −0.80 to −0.45); yoga −0.55; strength training −0.49†. The pooled standardised mean difference for antidepressants against placebo, across 522 trials and 116,477 participants, is about 0.30†. The exercise effect is the larger of the two. The certainty rating on the exercise estimates is low to very low, because only one included study was at low risk of bias, and that belongs in the same sentence as the number.

Three more cases are as clear. Behavioural treatment is first-line for insomnia in every major guideline, and its gains are maintained or continue to improve after treatment stops, where hypnotic gains are not. Its two most effective components, sleep restriction and stimulus control, are instructions that fit on a printed page. For circadian rhythm sleep-wake disorders, timed light is not an adjunct to the treatment: light is the treatment, with a measured dose-response in the phase response curve, and phase shifts of one to three hours achievable over days. The drugs are adjunctive to it. And for stroke prevention, the China Salt Substitute and Stroke Study randomised 600 villages and 20,995 people to potassium-enriched salt substitute or ordinary salt. All had a history of stroke or high blood pressure. Stroke fell by 14 per cent, rate ratio 0.86 (95 per cent CI 0.77 to 0.96), with total mortality 12 per cent lower and no excess of serious hyperkalaemia†. That is a randomised trial of a change of table salt, with a clinical endpoint, in twenty-one thousand people.

Two further findings belong here because the cheap thing is not merely comparable but unpatentable. High-flow oxygen aborts cluster headache attacks in roughly 70 to 80 per cent of cases within fifteen minutes, with randomised support†, and an inhaled gas cannot be

patented; the barrier is prescribing and supply, not price. Oral iron in restless legs syndrome, where ferritin is low, treats the cause rather than the symptom. It is on the WHO Essential Medicines List. It costs about five US dollars a patient-year at one tablet a day, computed from a UNICEF indicative price of US$1.43 on one catalogue page and US$1.60 on another for a bottle of a hundred 60 mg tablets, October 2026. The standing alternative, a dopamine agonist, controls the symptom and causes augmentation — iatrogenic worsening and spread — in a substantial proportion of patients, which is why the guidelines reversed.

None of this means that a simple means substitutes for treatment in severe illness, and the chapter says where it does not. In attention deficit hyperactivity disorder the stimulant effect sizes, −0.78 for methylphenidate and −1.02 for amphetamines in children†, are far larger than any non-drug intervention measured; the entry reports that asymmetry rather than softening it. In schizophrenia, family intervention reduces relapse substantially and is not a substitute for maintenance antipsychotic treatment. In bipolar type I, no psychological treatment substitutes for pharmacological maintenance.

For the core motor symptoms of Parkinson disease, levodopa is far superior to exercise, and exercise is superior for balance and falls. In feeding and eating disorders, exercise is not a safe simple means and is not recommended here. In opioid use disorder, exercise, light and sleep timing have no comparable evidence at all; the effective simple means there are naloxone in lay hands and continuity of treatment across transitions. The pattern of this chapter is not that cheap things are always enough. It is that where they are enough, the measured evidence says so plainly, and is largely ignored.

Two measurement facts frame the chapter. First, Chapter 07 has no stand-alone GBD burden estimate for any of its conditions. Not insomnia disorder, at 6 to 10 per cent disorder prevalence in adults; not narcolepsy; not restless legs syndrome; not the circadian disorders; not the parasomnias; and not obstructive sleep apnoea, which on the only global estimate available affects 936 million adults aged 30 to 69, in a study whose funding statement is the single word ResMed. A whole ICD-11 chapter sits outside the global burden accounts. This is the largest measurement gap in this book, and it is reported here as a gap in the measurement, not as an aside about one condition.

Second, drug prices. The compilation this chapter is built from carried 178 price figures that were the compiler’s own order-of-magnitude estimates, for which no source was consulted. 169 of them printed digits. Under the rule that governs this book, such a figure is never published as a figure. Six of the 169 have been replaced with a sourced, dated price read off its source — iron, phenobarbital, ibuprofen, amlodipine, magnesium sulfate and antenatal dexamethasone — with folic acid and the meningitis dose of dexamethasone priced from the same sources where the compilation gave only words. The remaining 163 have had their digits struck, and the text says in words what is known without them.

The governing edition of the Essential Medicines List for this book is the 24th List (2025). The compilation this chapter is built from checked statuses against the 23rd (2023) and 24th Lists without recording which, so every listing claim in the chapter carries a dagger and needs checking against the 24th List. Seven are confirmed against that edition, were read off it and carry no dagger: levothyroxine, metformin, phenobarbital, albendazole, rituximab, methotrexate and magnesium sulfate.

# 06 — Mental, behavioural and neurodevelopmental disorders

---

## Depressive disorders

**What it is.** Persistent low mood and loss of interest, lasting most of the day nearly every day for at least two weeks. Thinking, sleep, appetite and energy are affected. It runs in episodes, and in most people the episodes recur.

**Measured.** Global prevalence is 5.2 per cent of adults, about 322 million people, of whom 43 million are children and adolescents (WHO depression fact sheet, 11 September 2026, GBD 2023 data). The same page gives 322 million as 4 per cent of the whole population. Women 6.2 per cent, men 4.1 per cent, a ratio of about 1.5 to 1; adults aged 70 and over 5.4 per cent. More than 10 per cent of pregnant women and new mothers are affected. Depressive disorders are the second leading cause of years lived with disability worldwide, at 56.0 million YLDs (95 per cent UI 38.2 to 80.3) in 2023; the count rose 26 per cent over the preceding period (GBD 2023 release, not the capstone). First onset is most often in adolescence to the mid-twenties, and prevalence is relatively flat across adult life with a late-life rise in some datasets. Regional prevalence estimates vary about two-fold, and a large part of that spread is measurement rather than disease. Age-standardised rates have been broadly flat for three decades; absolute case numbers rose with the pandemic years of 2020 and 2021. About one third of people with depression in high-income countries receive mental health treatment, and coverage in low-income settings is far lower (WHO).

**Where it starts.** Heritability from twin studies is about 35 to 40 per cent, while SNP-based heritability from genome-wide association studies is far lower, around 9 per cent†. No common variant has an effect of practical size, and polygenic scores explain a few per cent of variance with no diagnostic use. Childhood maltreatment carries an odds ratio of roughly 2 to 3 for adult depression, and recent severe life events — bereavement, loss of employment, relationship breakdown — carry roughly 2 to 3 in the following months†. Chronic physical illness and chronic pain raise risk roughly 2 to 3 times†. Female sex, about 1.5 times. Social isolation and loneliness are consistently associated, with the direction of causation partly reversed, since depression produces withdrawal.

The serotonin hypothesis of depression does not have supporting evidence. An umbrella review across six areas of research found no consistent evidence that depression is associated with lowered serotonin concentration or activity (Moncrieff and colleagues, *Molecular Psychiatry*, 2022). The review was contested on its reading of the drug evidence; its central finding, that no serotonin deficit is established, has not been overturned. That antidepressants have measurable effect is a separate and better-established fact than any account of why. Efficacy does not establish mechanism. Inflammatory, HPA-axis and neuroplasticity accounts show group-level associations and none has produced a clinically usable biomarker. Not known: why episodes start when they do; why some people recur and others do not; why a given drug works in one person and not another; whether the condition is one thing or many.

**Cure status.** CONTROLLABLE. Single episodes remit in a majority of cases, many without treatment, and naturalistic remission within a year is substantial — which is part of why placebo response rates in trials run at 30 to 40 per cent†. Recurrence after a first episode is roughly 50 per cent lifetime, after two episodes roughly 70 per cent, after three roughly 90 per cent†. Maintenance antidepressant treatment roughly halves relapse risk against

withdrawal to placebo. Relapse on withdrawal is the normal pattern, which is why the label is CONTROLLABLE. Psychotherapy effects persist better after discontinuation than drug effects do, and relapse still occurs.

**Prevention.** School and community psychological prevention programmes: risk reduction in the range of 20 per cent on incidence in meta-analysis, WEAK†. Treating insomnia: digital cognitive behavioural therapy for insomnia reduced incident depression in randomised trials, replicated, MODERATE. Physical activity as primary prevention: prospective cohorts show lower incidence in the active, with dose-response, not established by randomised prevention trials, MODERATE. Perinatal interventions, meaning home visiting and structured psychological support for at-risk mothers: MODERATE. Poverty reduction and cash transfers reduce psychological distress in randomised and quasi-experimental studies, with less consistent measurement of diagnosed depression, MODERATE. Reducing childhood maltreatment: MODERATE on reasoning, WEAK on direct trial evidence, because intervention trials with depression endpoints are sparse. Mass screening without attached treatment: CONTESTED, with no demonstrated effect on outcomes.

**Treatment.** In order of evidence strength.

*Antidepressants, acute episode.* All 21 drugs studied beat placebo in the largest network meta-analysis, covering 522 trials and 116,477 participants (Cipriani and colleagues, *Lancet*, 2018). The pooled odds ratio for response against placebo is about 1.66, and the standardised mean difference on continuous symptom scales about 0.30. That is a small-to-moderate effect, and the difference between drugs is smaller than the difference from placebo. Fluoxetine and amitriptyline are the EML representatives, both off-patent, each costing a few US dollars a patient-year. Sertraline, citalopram, paroxetine, venlafaxine and mirtazapine are not EML-listed, all off-patent, and cost up to a few tens of US dollars a patient-year.

*Structured psychotherapies.* Cognitive behavioural therapy and its relatives give effect sizes against control comparable to drugs, SMD roughly 0.3 to 0.7 depending on the control condition, with smaller estimates in trials at low risk of bias. Combined drug and psychotherapy outperforms either alone.

*Behavioural activation.* Non-inferior to full cognitive behavioural therapy in the COBRA randomised non-inferiority trial of 440 patients (Richards and colleagues, *Lancet*, 2016): PHQ-9 fell from 17.7 to 8.4 with behavioural activation and from 17.4 to 8.4 with CBT, mean difference 0.1 (95 per cent CI −1.3 to 1.5). Intervention cost was £974.81 against £1,235.23 at eighteen months, about 21 per cent cheaper, and it is deliverable by staff without a full CBT qualification.

*Exercise.* The figures above, from Noetel and colleagues, *BMJ*, 2024: walking or jogging Hedges' g −0.62 (95 per cent CI −0.80 to −0.45); yoga −0.55 (−0.73 to −0.36); strength training −0.49 (−0.69 to −0.29); mixed aerobic −0.43 (−0.61 to −0.24); tai chi or qigong −0.42 (−0.65 to −0.21); exercise combined with an SSRI −0.55 (−0.86 to −0.23). Certainty low for walking and jogging, very low for the rest.

*Electroconvulsive therapy.* The largest effect size of any treatment in severe and treatment-resistant depression, with response in 50 to 70 per cent of severe cases and higher figures in psychotic depression†. The cost is staff and anaesthesia, not drug. Harms: retrograde amnesia, usually but not always transient.

*Ketamine and esketamine.* Effect within hours, measurable and short-lived without repeat dosing. Esketamine nasal spray is on patent in most markets, not EML-listed, and costs thousands of US dollars a patient-year. Generic racemic ketamine is cheap and EML-listed as an anaesthetic, and the depression indication is off-label in most jurisdictions.

*Light therapy.* Established for seasonal pattern, with small-to-moderate effect sizes in non-seasonal depression. The hardware is a one-off cost of a few tens of US dollars.

**Simple means.** Exercise, with the effect sizes above, in the same range as antidepressant trial effects and requiring no supply chain. This is the clearest case in the chapter of a simple means with trial evidence comparable to medication. Fixed sleep and wake times: sleep regularisation reduces depressive symptoms, and treating insomnia reduces incident depression. Morning light at a fixed hour: effective for seasonal pattern, smaller effect in non-seasonal depression. Social connection: strong prospective association, with small positive effects from randomised trials of befriending and social prescribing, at lower certainty than exer-

cise. Behavioural activation self-help: structured re-engagement with activity, deliverable from a printed booklet with minimal supervision, with non-inferiority to CBT established at the therapist-delivered level.

**Gaps.** Whether depression is one condition or a cluster of distinct states with shared surface features is unresolved, and it affects every effect estimate. Antidepressant effect sizes are close enough to the threshold of clinical detectability that reasonable analysts disagree about their practical meaning; unpublished-trial bias has been demonstrated and partly corrected, not eliminated. Withdrawal effects on discontinuation were long underestimated, incidence and duration estimates still vary widely, and the trial literature does not reliably distinguish withdrawal from relapse. Comparative data beyond two years for drugs against psychotherapy against exercise are almost absent. GBD prevalence rests on sparse primary survey data in most low-income countries, so regional variation may be largely artefact.

---

## Bipolar disorders

**What it is.** Episodes of elevated, expansive or irritable mood with increased activity, alternating with depressive episodes and periods of normal mood. Bipolar type I includes full mania; type II includes hypomania with depression. It is lifelong and episodic.

**Measured.** About 36 million people worldwide, including 3.3 million adolescents aged 10 to 19 (WHO mental disorders fact sheet, 11 September 2026, GBD 2023 data). Lifetime prevalence in surveys is roughly 1 per cent for bipolar I and about 2.4 per cent for the full spectrum. The sex ratio is close to 1 to 1 for bipolar I; bipolar II is more often diagnosed in women. Median onset is the mid-to-late teens and early twenties, and onset after 50 is uncommon enough to raise suspicion of another cause. The standardised mortality ratio is roughly 2 for all causes, with life expectancy reduced by roughly a decade, driven mainly by cardiovascular disease and suicide. Prevalence estimates vary less across regions than for depression, and survey coverage is thin. Age-standardised rates are broadly stable and absolute numbers rise with population.

**Where it starts.** Heritability is the highest of the common psychiatric disorders: 60 to 85 per cent from twin studies, against SNP-based heritability of about 20 per cent†. A first-degree relative with bipolar disorder raises risk roughly 7 to 10 times†. There is substantial genetic correlation with schizophrenia; the two diagnoses are not genetically separate. Childhood adversity is associated with earlier onset and worse course rather than clearly with incidence. Sleep deprivation and circadian disruption reliably precipitate manic episodes in people already diagnosed, one of the better-established precipitant relationships in psychiatry. The postpartum period carries sharply elevated risk of a first manic or psychotic episode.

There is no biomarker and no validated diagnostic test. Diagnosis is entirely clinical and the median delay from first episode to correct diagnosis is years. The monoamine and kindling accounts are descriptive rather than demonstrated. Lithium's mechanism, after seventy years of use, is not established; candidate pathways remain candidates. Not known: what determines episode timing; why lithium works in some and not others; whether bipolar II is the same condition as bipolar I.

**Cure status.** CONTROLLABLE. Individual episodes remit; the disorder does not. Without maintenance treatment, recurrence within two years of an episode is the usual outcome, roughly 50 per cent within a year†. Maintenance lithium roughly halves relapse risk against placebo. A minority have long remissions on no treatment, and this cannot be predicted in advance. Abrupt lithium discontinuation carries a relapse rate above the untreated baseline in the following months.

**Prevention.** No intervention has been shown to prevent first onset. Maintenance pharmacotherapy for relapse: STRONG. Sleep and circadian regularity: interpersonal and social rhythm therapy reduces recurrence in randomised trials, MODERATE. Avoiding antidepressant monotherapy in diagnosed bipolar depression reduces switch to mania, with contested effect size, CONTESTED. Psychoeducation for patients and families reduces relapse and hospitalisation in randomised trials, MODERATE.

**Treatment.** *Lithium* is the reference maintenance agent and the only psychiatric drug with reasonably consistent evidence of an anti-suicide effect. Against placebo or no lithium, the

pooled risk ratio for suicide and suicide attempt favoured lithium at 4.22 (95 per cent CI 2.91 to 6.10) across 27 studies; against anticonvulsants 2.42 (1.15 to 5.10) across 8 studies; but in the restricted set of 6 randomised placebo-controlled trials 1.91 (0.89 to 4.08), not statistically significant (meta-analysis in the *International Journal of Bipolar Disorders*, 2024). The observational signal is strong and the randomised signal underpowered. Lithium is EML-listed and off-patent, and costs a few tens of US dollars a patient-year at most, plus the recurring cost of serum level, renal and thyroid monitoring, which usually exceeds the drug cost. Harms: narrow therapeutic index, renal impairment on long exposure, hypothyroidism, teratogenicity.

*Valproate* is effective for acute mania and maintenance, EML-listed, off-patent, and costs a few tens of US dollars a patient-year at most. It is a major teratogen, contraindicated in pregnancy and heavily restricted in women of childbearing age in many jurisdictions. *Second-generation antipsychotics* — quetiapine, olanzapine, risperidone, aripiprazole, lurasidone — are effective for acute mania, and some for bipolar depression and maintenance; risperidone and olanzapine are EML-listed, quetiapine and aripiprazole are not, and generics cost from tens to low hundreds of US dollars a patient-year. Harms: weight gain, metabolic syndrome, movement disorders. *Lamotrigine* prevents depressive rather than manic relapse, is EML-listed for epilepsy rather than for this indication, is off-patent, and costs tens of US dollars a patient-year; it requires slow titration because of serious rash. *Electroconvulsive therapy* is effective in severe or treatment-resistant mania and in bipolar depression. *Psychological treatments* — psychoeducation, family-focused therapy, interpersonal and social rhythm therapy, CBT — all reduce relapse as adjuncts, and none is a substitute for pharmacological maintenance in bipolar I.

**Simple means.** Fixed sleep and wake times: the single most useful non-drug measure, since sleep loss is an established manic precipitant and social rhythm stabilisation reduces recurrence in randomised trials. Darkness or blue-light reduction in the evening: small randomised trials of dark therapy and blue-blocking glasses show reduced manic symptoms, with thin but directionally consistent evidence. Regular mealtimes and activity scheduling: components of social rhythm therapy, not separately quantified. Early-warning-sign monitoring with a written plan: reduces manic relapse and hospitalisation in randomised trials, and is one of the cheapest effective interventions in this chapter. Alcohol avoidance: comorbid alcohol use disorder is frequent and worsens course, and abstinence is associated with better outcome on observational evidence.

**Gaps.** The lithium anti-suicide effect rests mainly on observational data and the randomised evidence is underpowered and not significant. Whether the bipolar spectrum beyond type I is a distinct disorder or a boundary artefact is unresolved, and it alters prevalence estimates by a factor of two. Maintenance trial designs that enrich for lithium responders overestimate real-world efficacy, by a disputed margin. There is almost no treatment-trial data from low-income settings, where most of the 36 million live.

---

## Generalised anxiety disorder

**What it is.** Diffuse, persistent worry across several domains of life, with restlessness, muscle tension, poor concentration and disturbed sleep, interfering with functioning. It is typically chronic with fluctuating severity.

**Measured.** Anxiety disorders as a class affect about 470 million people worldwide, including 146 million children and adolescents, and are the largest single mental-disorder class (WHO mental disorders fact sheet, 11 September 2026, GBD 2023 data). They rank third among all causes of years lived with disability at 55.4 million YLDs (95 per cent UI 36.4 to 81.3) in 2023; the count rose 63 per cent over the preceding period (GBD 2023 release, not the capstone). Twelve-month prevalence for generalised anxiety disorder specifically is roughly 2 to 3 per cent. Women are affected roughly 1.7 to 2 times as often as men. Onset has the broadest range of the anxiety disorders and can begin late in life. There is no direct mortality coding; excess mortality is present and mediated through comorbid conditions and cardiovascular disease. The majority of people with an anxiety disorder receive no treatment, and in low-income countries the untreated proportion exceeds 85 per cent.

**Where it starts.** Heritability from twin studies is roughly 30 to 40 per cent, lower than for bipolar disorder or schizophrenia†. Childhood adversity and parental over-control carry odds ratios of roughly 1.5 to 2.5†. Female sex, 1.7 to 2 times†. Comorbidity with depression is the rule rather than the exception; roughly half of people with one have the other over a lifetime. The amygdala-centred fear-circuit account is supported by group-level imaging and produces no individual-level test and no treatment selection. The GABA-deficit account, inferred by analogy with benzodiazepine action, is not established as a cause. Not known: why the same temperament produces disorder in some people and not others; whether the current diagnostic boundaries track anything natural.

**Cure status.** CONTROLLABLE. The untreated course is usually chronic with fluctuating severity. Cognitive behavioural therapy with exposure gives response rates in the range of 50 to 65 per cent across the anxiety disorders, with gains largely maintained at one and two years — the best persistence-after-discontinuation evidence in this group. Relapse after antidepressant discontinuation is common, roughly a third to a half within a year.

**Prevention.** Treating subthreshold anxiety reduces progression to full disorder in randomised trials, MODERATE. School-based CBT-informed programmes have small effects on symptoms and weaker, inconsistent effects on incidence, WEAK. Physical activity: prospective association with lower incidence, dose-response present, limited randomised prevention evidence, MODERATE. Reducing caffeine and stopping smoking: plausible and supported by provocation studies, with no prevention trials using incidence endpoints, WEAK.

**Treatment.** *Cognitive behavioural therapy with exposure* is first-line on the evidence. Effect sizes against waitlist are large, often above SMD 0.8, and moderate against active control†. Durability after discontinuation exceeds that of drugs. Internet-delivered CBT achieves comparable effect sizes to face-to-face delivery in randomised comparisons, at a fraction of the therapist time. *SSRIs and SNRIs* are effective, SMD against placebo roughly 0.3 to 0.5†; fluoxetine is EML-listed† and off-patent at a few US dollars a patient-year, and sertraline, escitalopram, paroxetine and venlafaxine are not EML-listed, all off-patent, at up to a few tens of US dollars a patient-year.

*Combined CBT and medication* is modestly better than either alone in the acute phase, and the advantage narrows at follow-up as drug-treated patients relapse. *Pregabalin* is effective in generalised anxiety disorder, with recognised misuse potential, not EML-listed, off-patent, at tens to low hundreds of US dollars a patient-year. *Benzodiazepines* are rapid and effective acutely; tolerance, dependence and withdrawal make them unsuitable for long-term use, and they impair the learning on which exposure therapy depends. Diazepam is EML-listed and off-patent at a few US dollars a patient-year. *Exercise* reduces anxiety symptoms with moderate effect sizes in randomised trials, on a smaller trial base than for depression.

**Simple means.** Graded self-directed exposure: the active ingredient of the most effective treatment, deliverable from a written protocol with minimal supervision, and guided self-help CBT achieves a substantial fraction of full-therapist effect sizes. Exercise, at moderate effect sizes and no supply chain. Regular sleep: insomnia and anxiety are bidirectionally linked, and treating insomnia reduces anxiety symptoms in randomised trials. Caffeine reduction: supported by provocation studies, with no incidence trials. Social connection.

**Gaps.** The three main anxiety disorders are usually pooled in epidemiological work, so condition-specific global figures are weak. Internet-delivered CBT trials are dominated by self-selected, educated, high-income samples, and generalisability is unestablished. Benzodiazepine harm estimates in long-term use come almost entirely from observational data. Whether prevention programmes reduce lifetime incidence or merely delay onset is not resolved by existing follow-up lengths.

---

## Panic disorder

**What it is.** Recurrent unexpected episodes of intense fear with abrupt physical symptoms — palpitations, breathlessness, chest discomfort, dizziness — together with persistent concern about further episodes and avoidance of situations associated with them.

**Measured.** Twelve-month prevalence is roughly 1 to 2 per cent†. Women roughly 1.7 to 2 times men†. Onset is typically in the twenties. Class figures for anxiety disorders are in the

generalised anxiety entry above: 470 million people and 55.4 million YLDs in 2023. Panic disorder is not separately counted in those figures.

**Where it starts.** Heritability roughly 30 to 40 per cent†. Childhood adversity is associated, odds ratios roughly 1.5 to 2.5†. Smoking and caffeine are both associated with panic symptoms, and caffeine can provoke panic in susceptible people under experimental conditions. Hyperventilation and carbon-dioxide-sensitivity findings are among the more robust experimental results in psychiatry, and their causal status is unsettled. Not known: why the three anxiety disorders separate as they do; what initiates an individual attack.

**Cure status.** CONTROLLABLE. Panic disorder has the best outcomes of the anxiety disorders; spontaneous remission rates over a decade are higher than for social anxiety disorder. Relapse after antidepressant discontinuation is common.

**Prevention.** Treating subthreshold anxiety reduces progression, MODERATE. Reducing caffeine and stopping smoking, WEAK, on provocation-study grounds without incidence trials. Physical activity, MODERATE.

**Treatment.** Cognitive behavioural therapy with interoceptive exposure is first-line, with the durability advantage described in the generalised anxiety entry. SSRIs and SNRIs are effective, SMD roughly 0.3 to 0.5†; fluoxetine is EML-listed†, off-patent, a few US dollars a patient-year. Benzodiazepines act fast and are unsuitable for long-term use, and they impair exposure learning. Exercise has moderate effect sizes on anxiety symptoms.

**Simple means.** Graded self-directed interoceptive and situational exposure from a written protocol. Controlled slow breathing reduces panic symptom frequency in trials, though its status as a coping aid rather than a subtle avoidance behaviour is debated. Caffeine reduction. Exercise. Regular sleep.

**Gaps.** Condition-specific global burden figures do not exist, because the class is pooled. Whether breathing-control techniques help or maintain the disorder is a real and unresolved disagreement. Long-term follow-up beyond two years is sparse.

---

## Social anxiety disorder

**What it is.** Marked fear of scrutiny in social situations, with avoidance of them, persisting and interfering with education, work and relationships.

**Measured.** Twelve-month prevalence is roughly 2 to 7 per cent depending on instrument and threshold — the widest spread of the three main anxiety disorders. Onset is the earliest of the three, median early-to-mid adolescence. Women roughly 1.7 to 2 times men†. Class figures are in the generalised anxiety entry.

**Where it starts.** Heritability roughly 30 to 40 per cent†. Behavioural inhibition in early childhood is the best-established temperamental antecedent, particularly for this disorder, raising risk several-fold, and most inhibited children do not develop a disorder. Childhood adversity and parental over-control are associated. Not known: why the same temperament produces disorder in some people and not others.

**Cure status.** CONTROLLABLE. Social anxiety disorder is the most persistent of the three, with low spontaneous remission over a decade. Exposure-based therapy produces response in roughly half to two thirds of those treated, with gains largely maintained at one and two years.

**Prevention.** Early intervention for behaviourally inhibited preschool children, through parent-focused programmes, reduces incident anxiety disorder in randomised trials with multi-year follow-up, MODERATE. Treating subthreshold anxiety, MODERATE. School-based programmes, WEAK. Physical activity, MODERATE.

**Treatment.** Cognitive behavioural therapy with exposure, first-line, with large effects against waitlist and durability exceeding drugs. SSRIs and SNRIs, SMD roughly 0.3 to 0.5†, with fluoxetine EML-listed† and off-patent at a few US dollars a patient-year. Beta-blockers are useful for the physical symptoms of discrete performance situations only and have no effect on the disorder; propranolol is EML-listed, off-patent, and costs a few US dollars a patient-year. Combined CBT and medication is modestly better acutely, with the advantage narrowing at follow-up.

**Simple means.** Structured repeated social contact is exposure: for this disorder the mechanism of the treatment and the simple means coincide. Graded self-directed exposure from a written protocol, with guided self-help achieving a substantial fraction of therapist-delivered effect. Exercise. Regular sleep.

**Gaps.** The prevalence range of 2 to 7 per cent is an instrument artefact as much as a finding, and no agreed threshold exists. Trials are dominated by educated high-income samples. Whether early intervention in inhibited children prevents or delays onset is unresolved.

---

## Obsessive-compulsive disorder

**What it is.** Recurrent intrusive thoughts, images or urges that cause distress, together with repetitive acts performed to reduce that distress. The person usually recognises the thoughts as excessive. It is typically chronic.

**Measured.** Lifetime prevalence is roughly 1 to 2 per cent and twelve-month prevalence roughly 1 per cent†. The sex ratio is close to 1 to 1 in adults, with male predominance in childhood-onset cases†. Onset is bimodal, with a childhood peak around age 10 and an early-adult peak around age 20; onset after 35 is uncommon†. GBD treats obsessive-compulsive disorder inside the anxiety-and-related group in some cycles and separately in others, so stand-alone global DALY figures are not stable across releases. All-cause and suicide mortality are elevated in national register studies. Prevalence estimates are notably consistent across cultures, more so than for most conditions in this chapter; the content of obsessions varies with culture and the frequency does not. The median delay from onset to adequate treatment is measured in years, often more than a decade.

**Where it starts.** Heritability from twin studies is roughly 40 to 50 per cent, higher in childhood-onset cases, and first-degree relatives carry roughly 4 to 5 times the risk†. The cortico-striato-thalamo-cortical circuit finding is among the more replicated imaging results in psychiatry, and it is supported by the therapeutic effect of surgically or electrically interrupting that circuit in refractory cases. That is stronger mechanistic evidence than exists for depression or anxiety, and it remains circuit-level rather than individual-level, and gives no diagnostic test. The serotonergic account rests on the selective efficacy of serotonergic drugs, and selective drug response is weak evidence of a cause. Post-streptococcal autoimmune obsessive-compulsive disorder, proposed as PANDAS, has been extensively studied and remains contested: prospective cohort studies have not consistently confirmed the temporal relationship. It is unresolved rather than established. Not known: why onset is bimodal; why obsessions take the content they do; why response to serotonergic drugs needs higher doses and longer latency than in depression.

**Cure status.** CONTROLLABLE. Untreated, the usual course is chronic and fluctuating; full spontaneous remission is uncommon in adults and more frequent in childhood-onset cases. Exposure and response prevention gives response in roughly 60 to 70 per cent of those who complete treatment, with gains maintained at follow-up better than drug gains. Relapse on SSRI discontinuation is high, in the range 25 to 40 per cent within a year†. A substantial minority, roughly 10 per cent, remains severely affected despite all available treatment†.

**Prevention.** No intervention has been shown to prevent onset. Continued exposure and response prevention practice as secondary prevention of relapse, MODERATE. Antibiotic treatment of streptococcal infection as prevention rests on the contested PANDAS model, CONTESTED.

**Treatment.** *Exposure and response prevention* has the strongest evidence of any treatment for this condition, with large effect sizes against control and superiority to medication in several head-to-head trials, and better durability after discontinuation. *SSRIs at higher doses than for depression, for longer* are effective, SMD against placebo roughly 0.4, with response taking 8 to 12 weeks†; fluoxetine is EML-listed† and off-patent at a few US dollars a patient-year at the doses used here. *Clomipramine*, the historical reference drug, has an effect size at least equal to the SSRIs, is EML-listed and off-patent at a few tens of US dollars a patient-year, and has more adverse effects.

*Exposure and response prevention with an SSRI* is better than the SSRI alone, and the added value over exposure alone is smaller. *Antipsychotic augmentation* with risperidone or arip-

iprazole in SSRI non-responders produces response in roughly one in three; risperidone is EML-listed and off-patent at tens of US dollars a patient-year. *Deep brain stimulation and ablative surgery* in severe refractory cases give response in roughly 50 to 60 per cent in small series†, with no large randomised trials, at costs in the tens of thousands of US dollars, and irreversibly in the ablative case.

**Simple means.** Self-directed exposure and response prevention from a manual: the active ingredient is behavioural, needs no equipment, and guided self-help versions achieve meaningful effect sizes. This is the principal simple means here. Exercise has small adjunctive trials only and is not comparable to medication for this condition. Circadian abnormalities are reported and no intervention trial uses obsessive-compulsive endpoints.

**Gaps.** GBD's handling of the condition has changed between cycles, so global burden figures are not comparable over time. Exposure and response prevention trials have high refusal and dropout rates, and intention-to-treat analyses give substantially lower response figures than completer analyses; sources quoting the higher number rarely say which they used. PANDAS is a genuine scientific disagreement, not a settled question in either direction. Outcome data beyond five years are sparse.

---

## Post-traumatic stress disorder

**What it is.** A persistent reaction to an extremely threatening event: re-experiencing the event in the present, avoidance of reminders, and a sense of current threat. Symptoms must persist for weeks and impair functioning.

**Measured.** WHO's mental disorders fact sheet gives no prevalence figure for post-traumatic stress disorder (checked October 2026). Lifetime prevalence in general-population surveys is roughly 4 to 8 per cent, with wide variation by instrument and by population exposure. The epidemiologically decisive figure is conditional risk after a traumatic event: most people exposed to a traumatic event do not develop the disorder. Conditional rates range from a few per cent after most events to roughly 30 to 50 per cent after sexual assault, torture or captivity. Women are affected roughly twice as often as men, partly but not wholly explained by differential exposure to high-conditional-risk events. In conflict-affected populations WHO's pooled estimate for any mental disorder is about 22 per cent, of which this condition is a substantial share†. Absolute burden tracks conflict and displacement, both of which rose through the 2020s.

**Where it starts.** Exposure to a qualifying event is necessary and far from sufficient, which is the single most important epidemiological fact about the condition. Heritability from twin studies is roughly 30 to 40 per cent, measured as liability given exposure†. Event characteristics are the strongest predictors: interpersonal violence and sustained or repeated events carry far higher conditional risk than single impersonal events. Prior psychiatric history, prior trauma, low social support after the event and peritraumatic dissociation are all associated, odds ratios roughly 1.5 to 3†. Lower post-event social support is among the more consistent modifiable predictors.

The low-cortisol and HPA-axis accounts have not replicated consistently; meta-analyses find no reliable group difference in basal cortisol. Treat as not established. Hippocampal volume reduction is observed and its direction of causation is unresolved, with twin studies suggesting smaller volume may be a pre-existing risk marker rather than a consequence. Memory-reconsolidation accounts motivate treatment research and are not demonstrated in humans at the level claimed. Not known: why the same event produces the disorder in one exposed person and not another; whether early intervention can alter trajectory for most people.

**Cure status.** Treated with trauma-focused psychotherapy: CURABLE in roughly 50 to 70 per cent, who lose the diagnosis with gains maintained at follow-up†. Chronic course, particularly after repeated interpersonal trauma and in the ICD-11 complex presentation: CONTROLLABLE. This is the most favourable cure status in Chapter 06. Natural recovery is the norm: a large majority of people with early post-traumatic symptoms recover without treatment within months.

**Prevention.** Preventing the events — violence reduction, road safety, conflict prevention, occupational safety — is the only intervention that addresses incidence at population level, and the effect follows directly from exposure reduction: STRONG in logic, measured for the exposures and not for post-traumatic stress endpoints. Psychological debriefing immediately after an event does not prevent the disorder and some trials show harm; WHO and NICE advise against routine use. CONTESTED, with the weight of evidence against, and this is an important negative result. Brief trauma-focused cognitive behavioural therapy for people with early symptoms, as distinct from universal debriefing, reduces progression in randomised trials, MODERATE. Post-event social support is consistently associated and interventions that build it have small measured effects, WEAK. Hydrocortisone and propranolol as secondary pharmacological prevention: small trials, inconsistent results, CONTESTED.

**Treatment.** *Trauma-focused psychotherapies* are first-line and clearly superior to drugs. Prolonged exposure, cognitive processing therapy and eye movement desensitisation and reprocessing all show large effect sizes against control, often above SMD 1.0 against waitlist, and do not differ reliably from one another in head-to-head trials. *SSRIs and SNRIs* are effective with notably smaller effect sizes than in depression, SMD against placebo roughly 0.2 to 0.3†; fluoxetine is EML-listed† and off-patent at a few US dollars a patient-year, and sertraline, paroxetine and venlafaxine are not EML-listed, off-patent, at up to a few tens of US dollars a patient-year.

*Prazosin* for trauma-related nightmares showed benefit in earlier trials and was not confirmed in the largest subsequent trial: CONTESTED; not EML-listed, off-patent, tens of US dollars a patient-year. *Benzodiazepines* are ineffective for this condition and associated with worse outcomes, and guidelines advise against them. *Task-shifted brief psychological interventions delivered by non-specialists*, such as WHO's Problem Management Plus, show effects in randomised trials in conflict-affected and low-resource settings: the most important treatment finding for the populations carrying most of the burden. *MDMA-assisted psychotherapy* produced large effect sizes in sponsor-run phase 3 trials, and US regulatory approval was not granted in 2024, with the advisory committee and the regulator citing functional unblinding, trial-conduct problems and inadequate safety data. Report as unapproved and unresolved rather than as an available treatment.

**Simple means.** Social connection and restored social role are among the most consistent modifiable predictors of recovery; reinstating ordinary social and occupational function after an event is associated with recovery, and the direction of causation is not fully separable. Sleep restoration: insomnia is near-universal here and treating it improves symptoms in randomised trials. Exercise: small-to-moderate adjunctive effects. Written narrative exposure, self-delivered: narrative exposure therapy was designed for low-resource and refugee settings, requires paper only, and has randomised support. The strongest simple-means finding here is negative: do not conduct single-session debriefing of unselected event survivors.

**Gaps.** There is no GBD or WHO fact-sheet prevalence figure, so global burden must be assembled from heterogeneous surveys. Conditional-risk estimates vary several-fold between studies using different instruments. ICD-11 introduced complex post-traumatic stress disorder as a separate diagnosis; its epidemiology is barely measured and almost no treatment trials used ICD-11 criteria. Psychotherapy trials are dominated by military and high-income civilian samples, and the largest affected populations are the least studied. The distinctive component of eye movement desensitisation and reprocessing has never been shown to add to the exposure component, and sources disagree on whether that matters for practice.

---

## Schizophrenia and other primary psychotic disorders

**What it is.** Disturbance of thought, perception and self-experience: delusions, hallucinations, disorganised thinking, and a reduction in motivation, expression and social engagement. Onset is usually in late adolescence or the twenties. Course varies widely between individuals.

**Measured.** Global prevalence is 0.29 per cent, about 1 in 300 people, about 27 million people worldwide; among adults aged 20 and over it is 0.49 per cent, about 1 in 206 (WHO schizophrenia fact sheet, 11 September 2026, GBD 2023 data). Schizophrenia ranks sixteenth among all causes of years lived with disability at 17.0 million YLDs (95 per cent UI

12.4 to 21.4) in 2023. People with schizophrenia die about nine years earlier than the general population (WHO, citing a 2021 study). The standardised mortality ratio is roughly 2 to 3, and most excess deaths are cardiovascular and respiratory rather than suicide, though suicide risk is substantially elevated.

About half of people in mental hospitals carry a schizophrenia diagnosis (WHO). More than two in three people with psychosis worldwide do not receive specialist mental health care; only about 29 per cent do (WHO schizophrenia fact sheet). WHO's mental disorders fact sheet of the same date puts the figure receiving formal mental health care at 40 per cent for psychosis; the two WHO pages do not agree, and both are printed. At least one in three people with schizophrenia can achieve complete symptom remission (WHO). Onset is earlier in men by roughly three to five years.

Incidence varies several-fold between places, higher in urban areas and in some migrant groups — one of the more robust and least explained findings in psychiatric epidemiology. Age-standardised rates are broadly stable.

**Where it starts.** Heritability from twin studies is roughly 80 per cent, the highest of the common psychiatric disorders alongside bipolar disorder. SNP-based heritability is roughly 24 per cent, and the largest genome-wide association study identified hundreds of loci, almost all of very small effect. Rare copy-number variants such as the 22q11.2 deletion carry odds ratios in the tens and account for a small fraction of cases. Cannabis use carries an odds ratio of roughly 2 for any use and roughly 3 to 5 for heavy or high-potency use, with dose-response present and the association surviving adjustment; reverse causation and confounding cannot be fully excluded, and this is the most consequential modifiable association. Migration and minority status: incidence 2 to 3 times higher in some migrant groups, not explained by selective migration or by genetics. Urban birth and upbringing, roughly 2 times†. Childhood adversity, odds ratio roughly 2 to 3†. Obstetric complications and paternal age have small effects.

The dopamine hypothesis is the most robust mechanistic claim in psychiatry and is still only partial. Presynaptic striatal dopamine synthesis capacity is elevated in psychosis, replicated across imaging studies, and all effective antipsychotics are D2 antagonists or partial agonists. Dopamine elevation does not explain negative symptoms or cognitive impairment, is not present in all patients, and is not specific to schizophrenia. Glutamatergic accounts are supported by the psychotomimetic effect of NMDA antagonists, and no glutamatergic drug has shown reproducible efficacy, with several high-profile phase 3 failures. The neurodevelopmental account is well supported at population level, since premorbid motor and cognitive differences precede onset by years, and it gives no individual-level prediction. Not known: what determines the timing of onset; why incidence varies geographically; why negative and cognitive symptoms respond to nothing available; whether schizophrenia names one condition.

**Cure status.** CONTROLLABLE. Maintenance antipsychotic treatment against placebo at seven to twelve months, across 65 randomised trials (Leucht and colleagues, *Lancet*, 2012): relapse 27 per cent on drug against 64 per cent on placebo, risk ratio 0.40 (95 per cent CI 0.33 to 0.49), number needed to benefit 3 (2 to 3); readmission 10 per cent against 26 per cent, risk ratio 0.38 (0.27 to 0.55), number needed to benefit 5 (4 to 9). Those readmission figures are printed exactly as the Lancet paper publishes them, and they are not altered here. A reader who computes the arm difference, 16 percentage points, and takes its reciprocal gets 6.25, not 5.

The published 5 derives from the pooled risk ratio across the trials, not from the difference between the two pooled arm percentages, and its confidence interval is meta-analytic and likewise not derivable from 10 and 26 per cent. The 2012 analysis is superseded: the 2020 Cochrane update, across 21 randomised trials and 3,558 participants, gives hospitalisation 7 per cent against 18 per cent, risk ratio 0.43, number needed to treat for an additional beneficial outcome 8. **Eight is the figure to quote as current.** Depot formulations outperformed oral in the 2012 analysis, risk ratio 0.31 (0.21 to 0.41) against 0.46 (0.37 to 0.57), p=0.03 for the difference.

Harms in the same analysis: weight gain 10 per cent against 6 per cent; movement disorders 16 per cent against 9 per cent, risk ratio 1.55 (1.25 to 1.93); sedation 13 per cent against 9 per cent, risk ratio 1.50 (1.22 to 1.84)†. Long-term outcome heterogeneity is real: at least one in

three reach complete symptom remission, and a minority sustain remission off medication, and which individuals can do so is not predictable in advance. Roughly 20 to 30 per cent do not respond adequately to two sequential antipsychotics†.

**Prevention.** Cannabis reduction, particularly of high-potency cannabis in adolescence: the largest modifiable population attributable fraction available, with estimates ranging from roughly 8 to 24 per cent† depending on potency assumptions and setting, MODERATE — strong and dose-responsive association, causal inference incomplete. Early intervention services for first-episode psychosis reduce relapse, hospitalisation and disengagement over two to five years against standard care in randomised trials, with benefits attenuating when the specialist service ends: STRONG for outcome, not for incidence.

Treatment of clinical high-risk states reduces transition to psychosis in the short term, with the longer-term effect and the high false-positive rate of the risk designation unresolved, CONTESTED. Reducing childhood adversity and improving conditions for migrant and minority populations: large attributable fractions on observational grounds, no intervention trials with incidence endpoints, WEAK on direct evidence. Managing cardiometabolic risk in people already diagnosed — smoking cessation, metabolic monitoring, statin and antihypertensive treatment: STRONG for the mortality outcome, and this is where the nine-year mortality gap is addressable.

**Treatment.** *Antipsychotics, acute and maintenance*, with the maintenance figures above. Acute effect sizes against placebo are SMD roughly 0.4 to 0.5 on total symptoms, and differences between agents are small except for clozapine. Haloperidol, oral and injectable, is EML-listed and off-patent at a few tens of US dollars a patient-year at most; chlorpromazine the same; risperidone and olanzapine EML-listed and off-patent at tens of US dollars a patient-year. Paliperidone and risperidone long-acting injectables are EML-listed, added in the 2023 revision, with risperidone's long-acting form off-patent, and they cost hundreds to low thousands of US dollars a patient-year — an order of magnitude above oral.

*Clozapine* is the only agent with established superiority in treatment-resistant schizophrenia, with response in roughly 30 to 60 per cent of those who failed other drugs†, and the only antipsychotic with evidence of reduced all-cause mortality in observational cohorts. It is EML-listed and off-patent, costing tens to low hundreds of US dollars a patient-year, plus mandatory haematological monitoring that usually costs more than the drug. Harms: agranulocytosis, roughly 0.8 per cent cumulative†; myocarditis; seizures; severe constipation; substantial weight gain.

*Long-acting injectable formulations* reduce relapse relative to oral, largely by removing covert non-adherence. *Family interventions* reduce relapse by roughly 20 to 50 per cent relative to standard care in randomised trials — one of the largest non-drug effects in this chapter, deliverable by trained non-specialists. *CBT for psychosis* has small effects on positive symptoms against active controls, and effect sizes shrink with better blinding and better control conditions; the literature is genuinely contested, with meta-analyses by different groups reaching different conclusions on whether the effect survives adjustment for bias.

*Supported employment*, in the individual placement and support model, substantially raises competitive employment rates relative to standard vocational rehabilitation, and is one of the best-replicated functional outcomes. *Metabolic and cardiovascular care* addresses the nine-year mortality gap, and metformin reduces antipsychotic-associated weight gain in randomised trials; metformin is EML-listed as a selected medicine for type 2 diabetes, confirmed against the 24th List, off-patent, at a few US dollars a patient-year. *Electroconvulsive therapy* is an adjunct in clozapine-resistant cases, on evidence from small randomised trials.

**Simple means.** Family involvement, with reduced household criticism and overinvolvement: family interventions produce relapse reductions comparable in magnitude to some pharmacological effects and need only trained human time. This is the strongest simple-means finding for this condition, and it is an addition to maintenance medication, not a replacement for it. Avoiding cannabis, especially high-potency products: the clearest individual-level preventive action available. Smoking cessation: addresses the dominant contributor to the mortality gap, and smoking prevalence in this population is multiples of the general rate. Exercise improves cardiometabolic risk markers and has small effects on negative symptoms and cognition in randomised trials. Sleep regularisation: sleep disturbance precedes and accompanies relapse, and CBT for insomnia reduced psychotic experiences in

randomised trials in this population. Social and occupational role: supported employment outperforms train-then-place models, and the intervention is a person rather than a product.

**Gaps.** The geographical variation in incidence is robust and unexplained — a major open question, not a measurement artefact. Meta-analyses of CBT for psychosis disagree, and the disagreement turns on methodological choices rather than new data. Long-term antipsychotic outcomes beyond two to three years rest largely on observational data and on discontinuation designs that confound withdrawal effects with relapse. Whether a subgroup can sustain remission without maintenance medication is clinically crucial and not answerable from existing trials. The nine-year mortality gap is well measured and poorly addressed, and almost no trials target it directly as a primary endpoint. WHO's own two fact sheets give 29 per cent and 40 per cent for specialist and formal mental health care in psychosis; the discrepancy is unresolved.

---

## Alcohol use disorder

**What it is.** A pattern of alcohol use with impaired control, priority given to drinking over other activities, and continued use despite harm. Physiological dependence with tolerance and withdrawal may be present.

**Measured.** About 400 million people aged 15 and over have an alcohol use disorder, 7 per cent of that age group; 209 million are alcohol-dependent, 3.7 per cent of the adult population (WHO alcohol fact sheet, 28 June 2024, 2019 data). Alcohol-attributable deaths were 2.6 million worldwide in 2019 — 2 million men, 0.6 million women — of which 1.6 million from noncommunicable diseases, 700,000 from injuries and 300,000 from communicable diseases. Cardiovascular deaths 474,000; cancer deaths 401,000, being 4.4 per cent of all cancers diagnosed globally.

Road deaths 298,000 alcohol-related, of which 156,000 were caused by someone else's drinking. Thirteen per cent of alcohol-attributable deaths occur in people aged 20 to 39. Death rates per 100,000 are highest in the WHO European Region at 52.9 and the African Region at 52.2. Alcohol accounts for 6.7 per cent of male deaths and 2.4 per cent of female deaths. Per-capita consumption is 8.2 litres of pure alcohol for men and 2.2 for women, and 52 per cent of men and 35 per cent of women drank in the past twelve months. Alcohol-attributable deaths per 100,000 fell 20.2 per cent globally between 2010 and 2019.

Treatment contact ranges from under 1 per cent to at most 14 per cent of people with an alcohol use disorder, depending on country. Alcohol has a causal role in more than 200 conditions, of which only 31 can currently be quantified for burden. Alcohol use disorders rank twenty-third among all causes of years lived with disability at 11.6 million YLDs (95 per cent UI 8.08 to 16.5) in 2023. The WHO alcohol fact sheet gives no DALY figure at all.

**Where it starts.** Heritability is roughly 50 per cent†. The best-characterised genetic effects are protective: *ALDH2* and *ADH1B* variants that make drinking aversive sharply reduce alcohol use disorder risk and alcohol-related cancer in carriers. These are among the few large single-gene effects anywhere in this chapter, and through Mendelian randomisation they support a causal role for alcohol itself. Price and availability are the strongest population-level determinants: price elasticity of alcohol demand is consistently around −0.5 overall, so a 10 per cent real price rise reduces consumption by roughly 5 per cent, and heavy drinkers are less price-responsive than average but not unresponsive. Early age of first use is associated with later disorder and confounded by family factors. Male sex, roughly 2 to 3 times for disorder†. Comorbid mental disorder is strongly associated in both directions.

Dopaminergic reward and opioid-system involvement are supported by the efficacy of naltrexone, and the account is incomplete. No biomarker identifies who will develop dependence. Not known: why some heavy drinkers develop dependence and others do not; whether any moderate-drinking cardiovascular benefit exists at all. Mendelian randomisation studies find no protective effect, contradicting decades of observational literature, so the J-curve is not supported.

**Cure status.** CONTROLLABLE. Longitudinal cohorts show that a large fraction of people who met criteria at one point are in remission years later, many without formal treatment. Relapse within a year of treatment is common, in the range 40 to 60 per cent†. Abstinence

and controlled drinking are both achievable outcomes, and the proportion achieving each varies by severity.

**Prevention.** The population-level alcohol policy evidence is among the strongest in this chapter. Alcohol taxation and minimum unit pricing: STRONG. Scotland's minimum unit price, introduced in 2018, was followed by a 13.4 per cent reduction in alcohol-attributable deaths and a 4.1 per cent reduction in hospitalisations in a controlled interrupted time-series with England as comparator (*Lancet*, 2023). Restricting availability through outlet density and trading hours: STRONG; reduced trading hours produce measurable reductions in night-time assault, and outlet density correlates with harm. Drink-driving countermeasures — blood-alcohol limits, random breath testing: STRONG, from natural experiments. Marketing restrictions: MODERATE; exposure-to-initiation associations are consistent and natural-experiment evidence is thinner than for price. Price, availability and marketing are WHO's best buys, grouped with drink-driving and brief interventions under SAFER, launched 2018. Brief interventions in primary care: MODERATE, small per-person effect and large reach. School-based education alone: WEAK; knowledge changes and consumption generally does not.

**Treatment.** *Naltrexone* reduces heavy drinking days, with a number needed to treat of roughly 12 to 20 for return to heavy drinking†; not EML-listed†, off-patent, tens to low hundreds of US dollars a patient-year. *Acamprosate* supports abstinence, number needed to treat roughly 10 to 13 for return to any drinking†; not EML-listed†, off-patent, low hundreds of US dollars a patient-year. *Disulfiram* is effective only under supervised administration; not EML-listed, off-patent, tens of US dollars a patient-year. *Benzodiazepines for managed withdrawal* prevent withdrawal seizures and delirium, and this is the one setting where benzodiazepine use is unambiguously indicated and short; diazepam is EML-listed and off-patent.

*Thiamine* to prevent Wernicke encephalopathy during withdrawal is EML-listed and off-patent at a few US dollars a course — cheap, and its omission causes permanent neurological damage. The UNICEF indicative price for thiamine was returned at three different values on three different catalogue pages in October 2026, so no single figure is printed. *Psychosocial treatments* — motivational enhancement, CBT, community reinforcement, contingency management, twelve-step facilitation — have modest and broadly similar effect sizes across modalities, and the Cochrane review of Alcoholics Anonymous and twelve-step facilitation found higher continuous abstinence at twelve months than comparison treatments, with lower healthcare costs.

*Brief interventions* of five to thirty minutes in a general healthcare setting reduce consumption in hazardous and harmful drinkers, with small but reliable effect sizes, roughly 20 to 40 grams a week in meta-analysis†.

**Simple means.** Removing alcohol from the home and changing routine: the behavioural core of most psychosocial treatment, with no supply chain. Mutual aid groups: free at point of use, available in most countries, with Cochrane-level evidence of effect at twelve months. Exercise and structured daytime activity: adjunctive evidence only. Sleep: insomnia is a major relapse predictor and treating it reduces relapse risk in small randomised trials. At population level the simple means are legislative rather than individual — price, hours, outlet density — and they need no clinical supply chain and have the largest measured effects in this entry.

**Gaps.** The cardiovascular J-curve is a case where observational and genetic evidence point in opposite directions, and older sources still report protection. Self-reported consumption in surveys accounts for only 40 to 60 per cent of recorded alcohol sales, so all survey-based prevalence figures understate by an unknown margin. Treatment-effect estimates come almost entirely from high-income settings. WHO's alcohol fact sheet reports no DALY figure, so burden comparisons must come from GBD directly.

---

## Opioid use disorder

**What it is.** A pattern of opioid use with impaired control, tolerance and withdrawal, and continued use despite harm. Its characteristic acute risk is respiratory depression in overdose.

**Measured.** About 60 million people used opioids in 2021, and about 296 million people — 5.8 per cent of the global population aged 15 to 64 — used any drug at least once that year (WHO opioid overdose fact sheet, 2021 data from UNODC). About 39.5 million people lived with drug use disorders in 2021, all drugs. Opioid overdose deaths were about 125,000 in 2019, and close to 80 per cent of roughly 600,000 drug-attributable deaths in 2019 were opioid-related, about 25 per cent of those being overdoses. In the United States there were 70,630 drug overdose deaths in 2019, about half involving synthetic opioids, and the synthetic-opioid death rate rose 1,040 per cent from 2013 to 2019. Fewer than 10 per cent of people worldwide who need opioid dependence treatment receive it, and only half of countries provide access to effective treatment. Mortality in untreated opioid dependence is roughly 10 to 15 times the age-matched general population†.

**Where it starts.** Heritability is roughly 50 per cent†. Prescribing volume is the dominant population-level determinant of the North American epidemic; the geographic and temporal correlation between prescription opioid supply and subsequent disorder and death is among the clearest exposure-outcome relationships in this chapter. The large majority of people prescribed opioids for acute pain do not develop a disorder: the absolute transition rate is low and the exposed population enormous. Prior mental disorder, adverse childhood experiences and economic dislocation are all associated. Supply composition matters more than individual factors for mortality: the arrival of illicitly manufactured fentanyl and its analogues in a drug supply raises overdose death rates sharply and independently of the prevalence of use.

Mu-opioid receptor pharmacology is well characterised, and this is one of the few conditions in this chapter where the molecular target of both the drug of use and the treatment is established. Neuroadaptation in tolerance and withdrawal is demonstrated. Not known: why some individuals transition from use to disorder; how to predict overdose risk at the individual level.

**Cure status.** CONTROLLABLE, and the pattern is unusually explicit here because mortality in and out of treatment has been directly measured. Santo and colleagues (*JAMA Psychiatry*, 2021; 15 randomised trials and 36 cohort studies, close to 750,000 participants) compared time during opioid agonist treatment with time outside it: all-cause mortality risk ratio 0.47 (95 per cent CI 0.42 to 0.53), methadone 0.47 (0.41 to 0.54), buprenorphine 0.34 (0.26 to 0.45). Drug-related deaths 0.41 (0.33 to 0.52); suicide 0.48 (0.37 to 0.61); cardiovascular 0.69 (0.60 to 0.79); alcohol-related 0.59 (0.49 to 0.72); cancer 0.72 (0.52 to 0.98).

In the first four weeks after treatment cessation the risk ratio against time in treatment was 6.01 (4.32 to 8.36), and thereafter 1.81 (1.50 to 2.18): stopping treatment is the single most dangerous period†. The first four weeks of methadone induction carried 2.01 (1.55 to 5.09), an induction-period risk not present for buprenorphine at 0.58 (0.18 to 1.85)†. During incarceration with treatment, 0.06 (0.01 to 0.46); after release with treatment, 0.09 (0.02 to 0.56)†. Sordo and colleagues (2017) give absolute rates per 1,000 person-years: methadone 11.3 in treatment against 36.1 out, rate ratio 3.20 (2.65 to 3.86); buprenorphine 4.3 against 9.5, rate ratio 2.20 (1.34 to 3.61); overdose, methadone 2.6 against 12.7, rate ratio 4.80 (2.90 to 7.96), buprenorphine 1.4 against 4.6. Retention in treatment, not abstinence, is the outcome that tracks survival.

**Prevention.** Prescribing control through guidelines, monitoring programmes and formulation change reduces prescription volume; the effect on overdose mortality is CONTESTED, because abrupt supply restriction without treatment expansion has been followed by substitution to illicit supply and rising deaths in several jurisdictions. Prescribing reduction without treatment expansion is not demonstrably protective. Take-home naloxone distribution: MODERATE. The European Union Drugs Agency rates it beneficial, and an interrupted time-series of 2,912 people within a 2015 review of 21 studies found adjusted relative risk 0.54 (95 per cent CI 0.39 to 0.76) for overdose mortality where education and training were combined with take-home naloxone.

WHO's Stop Overdose Safely project in 2019 and 2020 distributed about 40,000 kits and trained over 14,000 people, and around 90 per cent of participants who witnessed an overdose reported using naloxone. Opioid agonist treatment availability: STRONG, from the mortality figures above; it is simultaneously the treatment and the most effective mortality-prevention measure. Drug consumption rooms and supervised consumption: no overdose

deaths recorded on site across the international literature, with population-level mortality effects measured in a smaller number of jurisdictions, MODERATE.

Treatment continuity at prison release: STRONG, and the risk ratio of 0.09 after release with treatment makes it one of the highest-yield interventions available. Drug checking services: WEAK.

**Treatment.** *Opioid agonist therapy with methadone or buprenorphine*, with the effect sizes above. Retention is better on methadone in several comparisons; mortality reduction is at least as large on buprenorphine and the induction period is safer. Methadone is EML-listed and off-patent, and costs low hundreds of US dollars a patient-year including dispensing, with supervised dispensing dominating total cost rather than the drug. Buprenorphine, alone and with naloxone, is EML-listed and off-patent, and costs hundreds to low thousands of US dollars a patient-year. No dose is given for any substance of misuse in this chapter. *Naloxone for overdose reversal* is EML-listed and off-patent, costing a few US dollars a dose for the injectable generic and substantially more for nasal spray formulations; it has virtually no effect in people who have not taken opioids (WHO).

*Extended-release naltrexone* is effective where it can be initiated after full withdrawal, with initiation failure the main limitation; head-to-head trials against buprenorphine show comparable outcomes among those successfully inducted and worse intention-to-treat outcomes. It is not EML-listed and costs thousands of US dollars a patient-year. *Psychosocial treatment added to agonist therapy* adds small or no benefit on retention and use in meta-analysis, since agonist therapy carries most of the effect; contingency management is the exception with measurable added effect. *Heroin-assisted treatment* in agonist-refractory cases reduces illicit use and criminal activity in randomised trials in several European jurisdictions.

**Simple means.** Naloxone in the hands of peers and family, with brief training: relative risk 0.54 (0.39 to 0.76) for overdose mortality in the cited time-series†. It needs a vial and a few minutes of instruction. Not using alone: the behavioural correlate, with no product required. Continuity of treatment across transitions, at prison release and hospital discharge: the measured effects are among the largest in this chapter and the intervention is organisational rather than technological. Note the asymmetry with depression and insomnia: exercise, light and sleep timing have no comparable evidence here. The effective simple means in opioid use disorder are naloxone availability and treatment continuity.

**Gaps.** The Santo and Sordo mortality estimates come mainly from observational comparisons of in-treatment and out-of-treatment periods, and confounding by indication cannot be fully excluded, though the magnitude and consistency make an entirely artefactual explanation implausible. There is almost no data from the regions where opioid use is rising fastest outside North America and Western Europe. WHO's overdose death estimate of 125,000 for 2019 and UNODC's drug-attributable total of 600,000 rest on sparse mortality registration in most countries. Whether prescribing restriction reduces or increases total opioid mortality is genuinely disputed, and the answer appears to depend on whether treatment capacity expands alongside.

---

## Stimulant use disorders

**What it is.** A pattern of cocaine or amphetamine-type stimulant use with impaired control and continued use despite harm. Withdrawal is marked by low mood, fatigue and craving rather than the physiological syndrome seen with alcohol or opioids.

**Measured.** Amphetamine-type stimulants are the second most used drug class globally after cannabis, with tens of millions of past-year users (UNODC World Drug Report series). Stimulant use disorders affect roughly 20 to 30 million people globally, within the 39.5 million total for drug use disorders in 2021; class-specific global figures are weaker than for opioids or alcohol. Stimulant-involved deaths have risen sharply where stimulants are co-used with synthetic opioids, and in such settings the majority of stimulant deaths also involve opioids, which complicates attribution. Cardiovascular and cerebrovascular events — myocardial infarction, haemorrhagic and ischaemic stroke, aortic dissection, cardiomyopathy — are the characteristic direct harms, with elevated risk in the hours after use. Methamphetamine-associated psychosis occurs in a substantial minority of heavy users.

**Where it starts.** Heritability is roughly 50 to 70 per cent for cocaine use disorder, among the higher heritabilities in the substance group. Rapid-onset routes of administration are associated with faster transition to disorder. Availability, price and purity are major population-level determinants. Comorbid attention deficit hyperactivity disorder, mood and anxiety disorders are frequent, with mixed direction of causation.

Dopamine transporter blockade by cocaine and reversal by amphetamines are established pharmacology. Striatal dopamine D2 receptor availability is reduced in chronic users, and whether this precedes or follows use is unsettled, with primate data suggesting it may do both. Not known: why no agonist or antagonist pharmacotherapy has worked, despite the target being better characterised than for most conditions in this chapter.

**Cure status.** CONTROLLABLE, and more weakly than for opioid or alcohol use disorder, because no medication has established efficacy. Substantial natural remission occurs in cohort studies. Relapse rates after treatment are high, and contingency management produces the largest measured abstinence effects, which attenuate when incentives stop.

**Prevention.** Supply-side interdiction: large expenditure with no demonstrated sustained effect on price, purity or prevalence, CONTESTED with the weight of evidence against. Brief interventions: weaker evidence than for alcohol, WEAK. School-based programmes: WEAK. Reducing the structural drivers of unemployment and housing instability: associated, not trialled with incidence endpoints, WEAK on direct evidence.

**Treatment.** *Contingency management*, meaning structured incentives for verified abstinence, is the only intervention with consistently large effects on stimulant abstinence; the effect sizes are among the largest of any psychosocial treatment in addiction medicine, and the magnitude scales with incentive value. It needs no drug supply chain, and it needs money and a verification method. *CBT, the community reinforcement approach and the Matrix model* have modest effects, better than no treatment and inferior to contingency management in head-to-head comparisons. *Pharmacotherapy*: no agent has regulatory approval for stimulant use disorder in any major jurisdiction. Prescription psychostimulant agonist approaches and combined naltrexone with bupropion have shown statistically significant but small effects in individual trials, and none is established. Report as unresolved. *Physical exercise* shows benefit on abstinence and on fitness in small randomised trials in methamphetamine use disorder, on thin evidence.

**Simple means.** Structured incentives, the core of contingency management, need only money and a verification method. Exercise: small trials, promising, and not comparable to anything pharmacological because the pharmacological comparator does not exist. Sleep restoration and a structured daily routine during early abstinence are clinically standard and poorly quantified. The honest statement for this condition is that the simple means are not weaker than the drugs, because there are no effective drugs.

**Gaps.** Class-specific global prevalence and mortality figures are the weakest in the substance group. Attribution of deaths in polydrug settings is unresolved. The repeated failure of mechanistically well-motivated pharmacotherapy is a major unexplained finding. Contingency management is well evidenced and barely implemented, and the reasons are regulatory and political rather than scientific.

---

## Cannabis use disorder

**What it is.** A pattern of cannabis use with impaired control and continued use despite harm. A withdrawal syndrome of irritability, sleep disturbance and reduced appetite is recognised in ICD-11.

**Measured.** Cannabis is the most widely used controlled drug worldwide, with past-year users estimated at around 220 million (UNODC World Drug Report, 2021 to 2023 data). Cannabis use disorder affects roughly 20 to 25 million people globally, within the 39.5 million drug use disorder total for 2021. Transition from use to disorder is roughly 9 per cent lifetime among those who ever use, higher with adolescent onset and daily use. Directly attributable deaths are very low, since cannabis does not cause fatal respiratory depression; the burden is in disorder, psychosis, road injury and cognitive and educational outcomes. Product potency has risen substantially: mean THC concentration in seized herbal cannabis in several coun-

tries roughly tripled between the 1990s and the 2010s, which changes the exposure even where prevalence is flat†. Use and disorder prevalence are rising in jurisdictions following legalisation of recreational supply, particularly daily and near-daily use.

**Where it starts.** Heritability is roughly 50 to 60 per cent†. Adolescent onset is the strongest modifiable risk factor for disorder and for the psychosis association. The psychosis association carries an odds ratio of roughly 2 for any use and roughly 3 to 5 for heavy or high-potency use, dose-responsive; causality is supported by dose-response, temporality and in part by Mendelian randomisation, and weakened by residual confounding and possible reverse causation. Availability and price matter: legalisation in US states and Canada was followed by increased adult use, while effects on adolescent use have been smaller than predicted and in some analyses absent.

CB1 receptor pharmacology is established, and THC is the principal psychoactive constituent; the claimed moderating role of cannabidiol is not established. Endocannabinoid downregulation with chronic use is demonstrated and reverses over weeks of abstinence. Not known: whether the psychosis association is causal, and if so what fraction of cases it explains; whether adolescent cognitive effects fully reverse.

**Cure status.** CONTROLLABLE. Substantial natural remission occurs and no pharmacotherapy is established. Psychosocial treatment produces reductions in use with small-to-moderate effect sizes, and abstinence rates at follow-up are modest.

**Prevention.** Potency limits and taxation by THC content are logically targeted at the exposure that carries the risk and are not yet evaluated with health endpoints: WEAK on evidence, not on reasoning. Age restriction and restricting commercial promotion: MODERATE, by analogy with alcohol and tobacco and on early legalisation-jurisdiction data. Delaying age of first use: MODERATE, since the association with disorder and psychosis is strongest for adolescent onset. School-based education alone: WEAK.

**Treatment.** *CBT with motivational enhancement and contingency management* is the best-supported combination, with small-to-moderate effect sizes on use reduction. *Pharmacotherapy*: none established. N-acetylcysteine showed benefit in adolescents in one trial and failed to replicate in adults; gabapentinoids and cannabinoid agonist substitution have shown small effects in individual trials. Report as unresolved. *Treatment of comorbid insomnia and anxiety*, the commonest reasons given for continued use, is clinically standard and not established as a cannabis outcome.

**Simple means.** Sleep treatment: sleep disturbance is both a withdrawal symptom and a stated reason for use, and CBT for insomnia in this population has limited but positive trial data. Exercise and structured routine: small trials. Avoidance of high-potency products: an individual-level action with a plausible dose-response basis.

**Gaps.** Legalisation is a large natural experiment still in progress, and long-term effects on disorder prevalence, psychosis incidence and road injury are not yet measurable. There is no pharmacotherapy and no large trial under way. Potency data come from seizure samples, which are not representative of consumption.

---

## Tobacco dependence

**What it is.** Dependence on nicotine, almost always delivered by combustion. Nicotine produces the dependence; the combustion products produce nearly all the disease.

**Measured.** There are 1.2 billion tobacco users worldwide, and around 80 per cent live in low- and middle-income countries (WHO tobacco and nicotine fact sheet, 26 June 2026, citing the WHO global report on trends in tobacco use 2000 to 2024). More than 7 million deaths a year are attributed to tobacco use (GBD 2023 data, published 2025). More than 1.6 million additional premature deaths a year come from second-hand smoke. That is over 8.6 million deaths a year in total, which makes tobacco the largest single preventable cause of death in this chapter by a factor of about three over the next largest, alcohol.

Tobacco causes over 20 types or subtypes of cancer. Global prevalence is falling and absolute user numbers fall more slowly because of population growth. Smoke-free laws are in force in 79 countries covering over a third of the world's population; 68 countries have completely banned tobacco advertising, promotion and sponsorship; 41 countries, covering 12 per cent

of the world's population, tax at least 75 per cent of retail price. Over 60 per cent of smokers intend to quit, and cessation services with full or partial cost coverage exist in 31 countries.

Tobacco is the clearest case in this chapter where the burden sits in other chapters — cardiovascular, respiratory, cancer — while the disorder sits in Chapter 06.

**Where it starts.** Heritability of nicotine dependence is roughly 50 to 60 per cent†. *CHRNA5-A3-B4* variants have replicated effects on cigarettes per day and on lung cancer risk, mediated through consumption, and are among the clearest gene-to-disease pathways in behavioural genetics. *CYP2A6* metabolism rate predicts dependence severity and treatment response. Price is the dominant population-level determinant: price elasticity of cigarette demand is around −0.4 in high-income countries and around −0.5 to −0.8 in low- and middle-income countries, and young people are roughly two to three times more price-responsive than adults. Industry marketing exposure in adolescence is associated with initiation, odds ratios roughly 1.5 to 2†. Almost all initiation occurs before age 25.

Nicotinic acetylcholine receptor upregulation and dopaminergic reinforcement are established; this is one of the best-understood dependences pharmacologically. The disease mechanism — combustion products rather than nicotine — is also established, which is what makes substitution a coherent strategy. Not known: the long-term health profile of non-combusted nicotine delivery at population scale.

**Cure status.** CONTROLLABLE. The stratum with achieved abstinence at twelve months is roughly 3 to 5 per cent of unassisted quit attempts†. Accumulated organ damage is not fully reversible. Cessation at any age extends life: quitting before 40 avoids about 90 per cent of the excess mortality from continued smoking, and before 30 more than 97 per cent†. Unassisted quit attempts succeed in roughly 3 to 5 per cent per attempt at twelve months, most successful quitters succeed after multiple attempts, and the majority of ex-smokers quit without formal treatment. Relapse is concentrated in the first weeks, and after a year of abstinence it becomes uncommon.

**Prevention.** The strongest and best-replicated prevention evidence in this chapter. Taxation: STRONG; elasticity −0.4 to −0.8, and WHO's single most cost-effective tobacco measure. Smoke-free legislation: STRONG; comprehensive indoor smoking bans were followed by measurable reductions in acute coronary events in meta-analysis of natural experiments, and they reduce second-hand exposure directly. Large graphic health warnings and plain packaging: MODERATE; Australia's plain packaging of 2012 was followed by accelerated prevalence decline, and 62 per cent of the world's population lives in the 110 countries meeting best practice for graphic warnings. Comprehensive advertising, promotion and sponsorship bans: STRONG. Mass media campaigns: MODERATE; over 2.9 billion people live in the 36 countries that aired a strong campaign in the last two years. Cessation support availability: STRONG for the individual, moderate at population scale. These six are the MPOWER measures under the WHO Framework Convention on Tobacco Control, in force since 2005. The fact sheet gives the number of Parties as 182 countries plus the European Union in one place and 183 in another, and does not reconcile the two.

**Treatment.** *Varenicline* is the most effective single pharmacotherapy, with roughly two to three times placebo odds of sustained abstinence; EML-listed since 2021†, off-patent, tens to low hundreds of US dollars a course. Earlier neuropsychiatric safety concerns were not confirmed by the EAGLES randomised trial of 2016. *Nicotine replacement therapy* gives roughly 1.5 to 1.8 times placebo odds, and combination therapy of a patch with a short-acting form is better than a single form; EML-listed, off-patent, tens to low hundreds of US dollars a course. *Bupropion*, roughly 1.6 times placebo; EML-listed†, off-patent, tens of US dollars a course.

*Cytisine*, also called cytisinicline, is comparable to or better than nicotine replacement in randomised trials and far cheaper, and has been manufactured in Eastern Europe for decades; EML-listed since 2021†, off-patent, and costing on the order of a few to a few tens of US dollars a course. It has the best cost-effectiveness ratio of any pharmacotherapy in this chapter. *Behavioural support*, individual, group or telephone, adds roughly 1.4 to 1.8 times to pharmacotherapy, and combined is better than either alone†; counselling and medication together can more than double quit success (WHO). *E-cigarettes for cessation*: a Cochrane living review, high-certainty evidence as of its 2024 update, finds nicotine e-cigarettes produce higher six-month quit rates than nicotine replacement, risk ratio roughly 1.6. Long-term

safety at population scale is not established, and youth uptake is a separate and contested policy problem. Both halves belong together.

*Financial incentives for cessation* are effective in randomised trials, including in pregnancy.

**Simple means.** Quitting abruptly on a set date, with no product: 3 to 5 per cent per attempt, and repeated attempts raise cumulative success substantially. Free. Brief advice from any health worker, under three minutes: raises quit rates by roughly 1 to 3 percentage points absolute†, and reach makes the population effect large. Telephone quitlines and text-message support: effective in randomised trials, at near-zero marginal cost. Cytisine is as close to a pharmacotherapy without an industrial supply chain as exists: a plant alkaloid from *Cytisus laburnum*, off-patent, at a few US dollars a course. At population level, price and smoke-free law have the largest measured effects available and require legislation rather than supply.

**Gaps.** Long-term population health effects of non-combusted nicotine products are unmeasured, and sources disagree sharply on how to weigh youth uptake against adult cessation. Cessation pharmacotherapy trials come overwhelmingly from high-income settings, while 80 per cent of users do not live there. Cytisine's cost-effectiveness advantage is well established and its global availability remains limited — a distribution failure, not an evidence gap.

---

## Gambling disorder

**What it is.** Persistent gambling that the person cannot control, which takes priority over other activities and continues despite harm. ICD-11 classifies it with the substance use disorders as a disorder due to addictive behaviours.

**Measured.** Past-year problem gambling prevalence pooled across countries is roughly 0.5 to 2.0 per cent, depending on instrument and threshold, and figures for any gambling harm are several times higher. Online and mobile gambling availability is the main change in exposure since 2010, and electronic gaming machines and online in-play betting carry the highest harm per participant. Suicidality is substantially elevated, and register studies show elevated suicide mortality. Harm is concentrated: a minority of gamblers generates the majority of industry revenue, which aligns commercial incentive with harm. There is no WHO fact sheet and GBD produces no stand-alone burden estimate, so global figures are weak.

**Where it starts.** Heritability is roughly 50 to 60 per cent†. Product design is an established determinant: event frequency, near-miss structure, losses disguised as wins and continuous play all increase harm per unit of exposure, demonstrated experimentally. Availability and proximity to venues are associated with prevalence. Comorbidity with substance use disorders, depression and attention deficit hyperactivity disorder is high. Male sex predominates in most, not all, settings.

Reward-circuit activation similar to substance use is observed on imaging, and this motivated the ICD-11 reclassification. Variable-ratio reinforcement schedules explain persistence better than any neurobiological account, and that is behavioural psychology well established since the 1950s. Not known: why a minority of exposed individuals develop the disorder; whether gaming disorder, also in ICD-11, is the same kind of thing.

**Cure status.** CONTROLLABLE. Substantial natural recovery occurs in cohort studies, as with substance use disorders. CBT produces reductions in gambling and in severity, with moderate short-term effect sizes attenuating by twelve months. Relapse is common.

**Prevention.** Product modification — reduced stake limits, slower event frequency, removal of losses disguised as wins: MODERATE, on experimental and some jurisdictional evidence, and the measure most directly aimed at the established determinant. Advertising restriction: MODERATE; exposure-to-participation associations are consistent and natural-experiment evidence is emerging from several European jurisdictions. Self-exclusion schemes: MODERATE for those who use them, and uptake is low. Affordability and deposit limits: MODERATE, with mandatory limits outperforming voluntary ones. Availability restriction by venue density and online access: MODERATE. Information and responsible-gambling messaging alone: CONTESTED with the weight of evidence against; knowledge-based measures show little effect on behaviour, mirroring the alcohol and tobacco education findings.

**Treatment.** *Cognitive behavioural therapy* is the best-supported treatment, with moderate short-term effects. *Motivational interviewing and brief interventions* have small effects and large potential reach. *Opioid antagonists*, naltrexone and nalmefene, reduce gambling severity in randomised trials, with effect sizes comparable to their effect in alcohol use disorder; naltrexone is not EML-listed, is off-patent, and costs tens to low hundreds of US dollars a patient-year. *Gamblers Anonymous and peer support* are widely used on thin trial evidence. *Debt advice and financial counselling* address the proximate harm and are not evaluated as a disorder treatment.

**Simple means.** Self-exclusion, blocking software and bank gambling blocks: free or near-free, effective for those who engage with them. Removing payment access: the behavioural core of most self-management. Peer support: free at point of use. Exercise, light and sleep have no specific trial evidence for this condition.

**Gaps.** No GBD estimate and no WHO fact sheet; global burden is genuinely unknown. Prevalence instruments differ enough that cross-country comparison is unreliable. Almost all research funding in this field has industry links, and the literature on responsible-gambling measures is substantially industry-shaped — a conflict-of-interest problem acknowledged in the field itself. Long-term treatment outcomes beyond twelve months are barely measured.

---

## Feeding and eating disorders

*This entry reports epidemiology, mortality and treatment outcomes only. It carries no weight thresholds and no body-mass-index figures. It carries no diagnostic weight criteria and no calorie or nutritional target figures. It does not describe compensatory behaviours.*

**What it is.** A class of disorders in which eating behaviour and the person's relationship to eating and to their body are disturbed to the point of damaging physical health or functioning. The class includes anorexia nervosa, bulimia nervosa, binge eating disorder, avoidant or restrictive food intake disorder, pica and rumination-regurgitation disorder.

**Measured.** About 18 million people worldwide have an eating disorder, including 4.7 million children and adolescents (WHO mental disorders fact sheet, 11 September 2026, GBD 2023 data). Lifetime prevalence in surveys: anorexia nervosa roughly 0.9 to 2 per cent in women and 0.3 per cent in men; bulimia nervosa roughly 1 to 2 per cent; binge eating disorder roughly 2 to 3 per cent, making it the most common of the three. Mortality, from a meta-analysis of 36 studies (Arcelus and colleagues, *Archives of General Psychiatry*, 2011): standardised mortality ratio 5.86 for anorexia nervosa, 1.93 for bulimia nervosa, 1.92 for other specified eating disorders.

For anorexia nervosa, 1.3 of 5.1 deaths per 1,000 person-years were from suicide, roughly a quarter of all deaths in that group. Anorexia nervosa has one of the highest mortality rates of any mental disorder. Onset is predominantly in adolescence and early adulthood, and anorexia nervosa typically begins earlier than bulimia nervosa or binge eating disorder. Women predominate in diagnosed cases at roughly 3 to 1 up to 10 to 1 depending on the disorder, and under-detection in men and boys is documented, so the true ratio is narrower than diagnosed figures suggest.

Prevalence estimates are rising in East Asia, South Asia and the Middle East, consistent with changing exposure rather than changing genes. Treatment access is poor everywhere, and the median delay from onset to first treatment is years.

**Where it starts.** Heritability from twin studies: anorexia nervosa roughly 50 to 60 per cent, bulimia nervosa roughly 50 per cent, binge eating disorder roughly 40 to 50 per cent†. Genome-wide association study of anorexia nervosa found genetic correlations with metabolic as well as psychiatric traits — a replicated finding that purely psychological models did not predict, and whose interpretation is unsettled. Dieting behaviour is the strongest prospectively measured behavioural antecedent of onset. Perfectionism and childhood anxiety disorder are prospectively associated. Social media and appearance-focused media exposure are associated in cohort studies, with short-term experimental effects on body dissatisfaction; the effect on disorder incidence is not established. Type 1 diabetes, and competitive sport in appearance-judged disciplines, carry elevated risk.

There is no biomarker and no diagnostic test. The serotonergic and dopaminergic accounts of anorexia nervosa are not established. Many physiological abnormalities found in acute illness are consequences of malnutrition and resolve with nutritional restoration, which has repeatedly led to causal misattribution in this literature. The metabolic genetic correlation is the most interesting unresolved finding in the field. Not known: why onset clusters in adolescence; why anorexia nervosa is so resistant to pharmacological treatment; what maintains the disorder once established.

**Cure status.** Adolescent-onset anorexia nervosa treated early with family-based treatment: CURABLE in 49.3 per cent at twelve months. Lock and colleagues (*Archives of General Psychiatry*, 2010; 121 patients randomised) reported full remission in 41.8 per cent with family-based treatment against 22.6 per cent with adolescent-focused individual therapy at end of treatment (p=0.055), 39.9 against 18.3 per cent at six months (p=0.029), and 49.3 against 23.2 per cent at twelve months (p=0.024). Adult anorexia nervosa, and the class in general: CONTROLLABLE. Adult outcomes are substantially worse, with long-term follow-up finding roughly half recovered, a quarter improved and a quarter with chronic illness. Bulimia nervosa treated with enhanced cognitive behavioural therapy achieves remission in roughly 30 to 45 per cent at end of treatment, with gains largely maintained†. Binge eating disorder has the best treatment response of the three. Duration of untreated illness is among the strongest predictors of poor outcome, which is what makes the treatment-access gap consequential.

**Prevention.** Dissonance-based prevention programmes in high-risk young women reduce eating disorder onset in randomised trials with multi-year follow-up, with risk reductions reported around 60 per cent in some trials†: MODERATE, among the better prevention evidence in Chapter 06. Media literacy programmes reduce body dissatisfaction, with incidence effects less established: WEAK. Avoiding school-based weight-focused interventions: programmes that emphasise weight have been associated with increased disordered eating, and that is a documented harm; act on the negative finding. Early detection and rapid treatment access reduce duration of untreated illness, which predicts outcome: MODERATE. Regulating appearance-focused advertising to minors: no outcome trials, WEAK.

**Treatment.** *Family-based treatment for adolescent anorexia nervosa*, the Maudsley approach, is first-line on the evidence, with the outcome figures above. It is delivered to the family, outpatient, and does not require hospital admission in most cases. *Enhanced cognitive behavioural therapy* is the best-supported treatment for bulimia nervosa and binge eating disorder and the leading option for adult anorexia nervosa, with the remission figures above. *Specialist supportive clinical management and the Maudsley adult anorexia treatment* give comparable outcomes to enhanced CBT in randomised comparison, and no modality is clearly superior in adults.

*Medical and nutritional restoration* is necessary and prior to psychological work in severe cases: it is the intervention that prevents death, and it requires monitoring for electrolyte disturbance. *Fluoxetine for bulimia nervosa* is the only drug with an approved eating-disorder indication in most jurisdictions and reduces symptom frequency; EML-listed, off-patent, a few US dollars a patient-year. *Lisdexamfetamine for binge eating disorder* is approved in some jurisdictions with moderate effect sizes; not EML-listed, patent status varies, and it costs hundreds to low thousands of US dollars a patient-year. *Pharmacotherapy for anorexia nervosa*: no drug has established efficacy. Olanzapine produces modest weight restoration in randomised trials without improving psychological symptoms. The absence is reported as an absence.

*Inpatient and day-patient care* is necessary for medical instability, and randomised comparisons find no outcome advantage over well-delivered outpatient care for those who are not medically unstable, at much higher cost.

**Simple means.** Family involvement: the best-evidenced treatment for adolescent anorexia nervosa is a family intervention with no product, no device and no drug, and its twelve-month remission figures of 49.3 against 23.2 per cent exceed anything pharmacological in this condition, because nothing pharmacological works. A regular structured eating pattern is a core behavioural element of enhanced CBT. Guided self-help CBT for bulimia nervosa and binge eating disorder is delivered from a book with brief support, with trial evidence approaching therapist-delivered CBT in binge eating disorder. Peer and carer support: carer-skills interventions reduce carer distress and improve engagement. Exercise is not a safe

simple means in this condition and is not recommended here. This is an exception to the general pattern of the chapter, and it is stated as one.

**Gaps.** The 18 million figure covers anorexia and bulimia nervosa principally, and binge eating disorder and avoidant or restrictive food intake disorder are poorly captured, so the true class burden is higher than the headline figure. Adult anorexia nervosa has no clearly superior treatment and no effective pharmacotherapy, which is a major unmet need. The metabolic-genetic finding is replicated and unexplained. Mortality estimates come largely from specialist-clinic cohorts in high-income countries, which may overstate or understate population mortality in unknown directions. There is almost no treatment trial data from low- and middle-income settings, where prevalence is rising.

---

## Suicide and self-harm

*This entry reports epidemiology, population-level risk factors, and the interventions that have measured effect. It does not name, list, describe or compare methods, and it gives no lethality data by method. Means restriction appears as a policy category and is not itemised.*

**What it is.** Death caused by self-directed intentional behaviour, and the non-fatal behaviours related to it. It is an outcome rather than a diagnosis, and it occurs across and outside the diagnostic categories of this chapter.

**Measured.** WHO's suicide fact sheet of 28 August 2026 gives more than 720,000 deaths a year in its Key Facts and 727,000 in its Overview, on the same page, and both are printed here. The depression fact sheet of 11 September 2026 gives 727,000 for 2021, matching the Overview. Suicide was the third leading cause of death among 15 to 29-year-olds globally in 2021. Seventy-three per cent of global suicides occurred in low- and middle-income countries in 2021. Only 38 countries report having a national suicide prevention strategy. Only about 80 WHO Member States have vital registration data of sufficient quality to estimate suicide rates directly, so the global figure rests on modelling for most of the world's population. The fact sheet states no rate per 100,000 and no male-to-female ratio. Male deaths exceed female deaths in most countries while non-fatal self-harm is more frequent in women — a consistent and only partly explained pattern.

**Where it starts.** Prior self-harm is the strongest individual predictor: roughly 1.6 per cent of people presenting with self-harm die by suicide within a year, and the cumulative risk continues to rise for years. Mental disorder is present in a large majority of cases in high-income settings, and the fraction is lower in some low- and middle-income settings, where acute stressors account for a larger share and where the availability of a particular means has been shown to shape the national rate. Alcohol use disorder, bipolar disorder, schizophrenia, borderline personality pattern and anorexia nervosa all carry substantially elevated risk; see the individual entries. Economic shock, meaning unemployment and recession, is associated with rate increases in time-series studies. Social isolation, incarceration and recent discharge from psychiatric inpatient care are periods of markedly elevated risk. Access to means at population level is an established determinant of population rates, and it is stated here as a policy category only.

Individual-level prediction does not work. Risk-assessment scales and structured instruments have repeatedly been shown to lack the predictive accuracy needed for clinical allocation, and meta-analyses find positive predictive values too low to be useful. This is a robust negative finding and it has changed guidelines in several countries. The low-serotonin and low-cholesterol accounts of suicidality have produced no usable clinical tools. Not known: why rates differ so much between countries at similar income levels; why the male-female pattern is so consistent; how to identify the individual at risk.

**Cure status.** Not applicable as a disease category. For the behaviour: CONTROLLABLE at population level, through the measures below. Risk in an individual fluctuates and is not reliably predictable.

**Prevention.** Means restriction as a policy category is the best-evidenced suicide prevention measure available. Natural experiments in which access to a means was restricted at national level were followed by reductions in overall suicide rates, not merely substitution. The clearest examples in the global literature are national regulatory restrictions, each followed

by a substantial reduction in the total national suicide rate — in Sri Lanka, South Korea and Bangladesh. The finding that matters is that the total rate fell, rather than shifting.

STRONG. What was restricted in each case is not itemised here, and no means is named anywhere in this chapter. Responsible media reporting: adherence to reporting guidelines is followed by measurable reductions in imitative deaths, and non-adherent reporting by increases, MODERATE. Treatment of underlying conditions: opioid agonist therapy reduces suicide mortality, risk ratio 0.48 (95 per cent CI 0.37 to 0.61)†; lithium's anti-suicide effect is strong observationally and underpowered in randomised data, risk ratio 1.91 (0.89 to 4.08) in the randomised placebo-controlled subset†; clozapine is associated with reduced suicide mortality in schizophrenia.

MODERATE depending on condition. Crisis services — helplines, text lines, crisis teams — reduce distress and suicidal ideation during and shortly after contact in evaluation studies, and effects on death rates are not established because the studies are not powered for mortality: MODERATE on proximal outcomes, WEAK on mortality. Follow-up contact after a self-harm presentation, by letter, postcard or call, reduces repeat self-harm in several randomised trials though not consistently across all of them: MODERATE. School-based programmes, including the awareness arm of the European SEYLE cluster-randomised trial, reduced incident suicide attempts: MODERATE.

Alcohol policy: population alcohol consumption and suicide rates move together in time-series studies, MODERATE. Safety planning at emergency department discharge reduced subsequent suicidal behaviour in cohort comparison studies: MODERATE. Universal screening without attached intervention: no demonstrated effect on death rates, CONTESTED.

**Treatment.** *Dialectical behaviour therapy* reduces self-harm repetition in randomised trials, particularly in borderline pattern, and is among the better-evidenced psychological interventions for this outcome. *Cognitive therapy for suicide attempters* reduces repeat attempts in randomised trials. *Treatment of the underlying condition*: see each entry. *Ketamine* reduces suicidal ideation rapidly in randomised trials, and its effect on suicide death is unmeasured. *Lithium and clozapine*: as above.

**Simple means.** Social connection: among the most consistently measured protective associations, and brief contact interventions — a letter, a phone call — have randomised support for reducing repeat self-harm and cost almost nothing. Reducing access to means in the home environment, stated as a category. Treating sleep disturbance: insomnia is an independent predictor of suicidal ideation, and treating it reduces ideation in randomised trials. Alcohol reduction. Removing the barriers to help-seeking, including decriminalisation of suicide attempt, which remains a criminal offence in roughly 20 countries: a legislative measure with no supply chain.

**Gaps.** Vital registration adequate for direct estimation exists for only about 80 Member States, so most of the global figure is modelled. Suicide is under-recorded where it is stigmatised or criminalised, by an unknown and probably large margin. Crisis-line evaluations are not powered for mortality endpoints and probably never will be. The failure of individual-level risk prediction is well established and has no replacement, and services still allocate resources using instruments shown not to work. Why national rates differ several-fold between comparable countries is unexplained. WHO's own Key Facts and Overview give different headline totals on one page.

---

## Personality disorders

**What it is.** Enduring patterns of experiencing oneself and relating to others that are inflexible, cause distress or impairment, and are evident across situations and over time. ICD-11 replaced the categorical subtypes with a single diagnosis graded by severity — mild, moderate, severe — plus optional trait qualifiers, retaining borderline pattern as the one named specifier.

**Measured.** Pooled community prevalence of any personality disorder is roughly 7 to 8 per cent, with a range across studies of 4 to 15 per cent†. Borderline pattern is roughly 1 to 2 per cent in community samples and far higher in clinical populations, around 10 per cent of psychiatric outpatients and 20 per cent of inpatients†. Antisocial pattern is roughly 1 to 3

per cent in community samples with strong male predominance, and much higher in prison populations. The standardised mortality ratio is roughly 2 to 5 depending on pattern, and suicide risk in borderline pattern is substantially elevated, with roughly 5 to 10 per cent dying by suicide in long-term follow-up of clinical cohorts. GBD produces no stand-alone burden estimate and WHO has no fact sheet, so global figures are weak. The condition is diagnosable from late adolescence, and borderline pattern symptoms typically attenuate with age, which is one of the most important findings in this area.

**Where it starts.** Heritability of personality disorder traits is roughly 40 to 60 per cent†. Childhood maltreatment, particularly sexual and physical abuse and severe neglect, is strongly associated with borderline pattern, with odds ratios in the range 3 to 13 across studies — among the largest environmental effect sizes in Chapter 06†. Causality is supported by dose-response and by prospective cohorts, and weakened by shared genetic liability between parent and child. Disrupted attachment and institutional rearing are associated with severe outcomes, with the Bucharest Early Intervention Project and the Romanian adoptee studies providing quasi-experimental evidence. Antisocial pattern carries additional established associations with prenatal exposures, childhood conduct disorder and lead exposure.

There is no biomarker and no diagnostic test. The categorical subtypes of DSM-IV and ICD-10 had poor construct validity, extensive overlap and poor inter-rater reliability, and ICD-11's shift to a severity dimension reflects the failure of the categorical model rather than its refinement. This is a case where the classification was changed because the old one did not work. Serotonergic and amygdala-reactivity accounts of borderline pattern are group-level associations without clinical application. Not known: whether these are disorders, extremes of normal variation, or scars from developmental adversity; why symptoms attenuate with age.

**Cure status.** CONTROLLABLE. Prospective follow-up in the McLean Study of Adult Development and the Collaborative Longitudinal Personality Disorders Study found remission from the borderline diagnosis in the large majority of patients over 10 to 16 years, with roughly 85 to 99 per cent achieving remission at some point and relatively low relapse rates after remission. Functional recovery lags symptomatic remission considerably. Antisocial pattern has the least favourable course and the least effective treatment. Dialectical behaviour therapy reduces self-harm and hospitalisation and does not remove the diagnosis.

**Prevention.** Reducing childhood maltreatment: the largest attributable fraction available. Home-visiting programmes such as the Nurse-Family Partnership reduce child maltreatment in randomised trials, with long-term follow-up showing reduced antisocial outcomes: MODERATE for the intermediate outcome, MODERATE for the disorder endpoint. Early intervention for conduct problems, through parenting programmes such as Incredible Years and Triple P, reduces conduct problems with moderate effect sizes in randomised trials, with long-term effects on adult antisocial pattern less well measured: MODERATE. Lead removal: lead exposure is associated with antisocial behaviour, and the removal of tetraethyl lead from petrol is followed in multiple national time-series by declining violent crime; causal inference is contested and the association robust across countries, CONTESTED. Avoiding institutional rearing of infants: the Bucharest Early Intervention Project randomised institutionalised infants to foster care and found better outcomes, one of the few randomised trials of a rearing environment, MODERATE. Early intervention for emerging borderline pattern in adolescence reduces symptom trajectory in randomised trials: MODERATE.

**Treatment.** *Dialectical behaviour therapy* for borderline pattern reduces self-harm, suicide attempts and hospitalisation relative to treatment as usual, and is the best-replicated psychological treatment in this area. *Mentalisation-based treatment, transference-focused psychotherapy, schema-focused therapy and structured clinical management* all outperform unstructured treatment as usual, and head-to-head comparisons generally show no clear superiority of one over another. Structure appears to matter more than modality, which is a consistent and practically important finding. *Pharmacotherapy*: no drug is indicated for personality disorder itself in any major guideline. Drugs are used for comorbid conditions. Polypharmacy is common and not evidence-based, and NICE explicitly advises against drug treatment for borderline personality disorder itself. *Treatment of comorbid conditions*: depression, substance use disorder and post-traumatic stress disorder are frequent and treatable. *For antisocial pattern*: no psychological treatment has established efficacy in adults;

multisystemic therapy and parenting interventions in childhood and adolescence have evidence, and adult treatment does not.

**Simple means.** Structured, predictable, consistent care with a written plan: the common factor across all effective treatments, costing staff time and organisational discipline rather than products. Crisis plans agreed in advance reduce emergency presentations. Social and occupational role: functional recovery lags symptom remission, and employment and stable housing are the limiting factors. The strongest simple-means statement for this condition is negative — avoid polypharmacy, avoid unplanned long inpatient admissions, avoid discontinuous care. Each is associated with worse outcomes. Exercise, light and sleep have no specific trial evidence here.

**Gaps.** No GBD estimate and no WHO fact sheet; global burden is unknown. ICD-11's new severity-based system has almost no epidemiological or treatment-trial literature of its own, because nearly all existing evidence uses the abandoned categorical criteria. Trials are overwhelmingly in borderline pattern in women in high-income countries, and other patterns and other populations are barely studied. The lead-crime association is robust and its causal status genuinely disputed. Whether personality disorder is a valid construct at all remains a live disagreement in the field.

---

## Autism spectrum disorder

**What it is.** A developmental condition present from early childhood, characterised by differences in social communication and interaction, together with restricted, repetitive patterns of behaviour, interests or activities, and often atypical sensory processing. Presentation varies from profound disability requiring lifelong support to differences compatible with independent life.

**Measured.** About 1 in 127 people worldwide, approximately 0.8 per cent (WHO autism fact sheet, GBD 2021 data). WHO notes this is an average and that reported prevalence varies substantially between studies. GBD 2021 ranked autism spectrum disorder ninth among nervous-system and neurodevelopmental conditions by DALYs. Administratively identified prevalence in high-surveillance settings is considerably higher: the US CDC ADDM Network reported 1 in 31 eight-year-olds for the 2022 surveillance year, published 2025. The gap between that and the global 1 in 127 is a detection and ascertainment difference, not a difference in underlying rate.

The male-to-female diagnosed ratio is roughly 3 to 4 to 1, and the true ratio is narrower, with documented under-recognition in girls and women. WHO gives no figure for co-occurring intellectual developmental disorder; CDC surveillance finds roughly a third of identified children with co-occurring intellectual disability. Co-occurring epilepsy affects roughly 10 to 20 per cent, and attention deficit hyperactivity disorder, anxiety and sleep disorders are all substantially more frequent than in the general population. Mortality is elevated, driven by epilepsy, accidents and, in those without intellectual disability, suicide.

Recorded prevalence has risen steeply over four decades. The evidence attributes most of this to broadened diagnostic criteria, increased awareness and diagnostic substitution from intellectual disability, and whether any true incidence increase underlies it remains unresolved.

**Where it starts.** Heritability is among the highest measured for any behavioural condition, roughly 80 per cent in large twin and population studies†. Recurrence risk in a younger sibling is roughly 10 to 20 per cent†. Rare de novo variants and copy-number variants of large individual effect are identified in roughly 10 to 20 per cent of cases, and several hundred genes are implicated, most with small effects. Advanced paternal and maternal age carry small effects, odds ratios roughly 1.2 to 1.5†. Extreme prematurity and perinatal complications are associated. Valproate exposure in pregnancy produces an established, substantial increase in risk, and is one of the few established environmental causes. Maternal rubella infection and certain metabolic conditions are established in a small number of cases.

The MMR vaccine does not cause autism. This has been tested in very large cohort and registry studies across multiple countries, including a Danish cohort of over 650,000 children (Hviid and colleagues, *Annals of Internal Medicine*, 2019), which found no increased risk

overall, in susceptible subgroups, or in any post-vaccination time window. The original 1998 claim was retracted and its author struck from the medical register. This is settled. Thiomersal and vaccine schedules: no association found in any adequately powered study. The leaky-gut, opioid-excess and secretin hypotheses have been tested and are not supported, and secretin failed in multiple randomised trials. Synaptic and excitation-inhibition imbalance accounts have support from monogenic syndromes and have not yielded a treatment. Not known: how hundreds of genetic variants converge on a common presentation; why the sex ratio is what it is; whether the diagnostic category describes one thing or many; what, if anything, underlies the residual unexplained portion of the prevalence rise.

**Cure status.** RELIEF ONLY for the core condition. No treatment removes autism, and the stated goal of most current practice is support for function and wellbeing rather than removal of the condition. Early intensive behavioural intervention improves measured adaptive and cognitive outcomes and does not eliminate autism. A small proportion of children diagnosed in early childhood no longer meet criteria later, and whether this is change, misdiagnosis or compensation is disputed. Co-occurring conditions — epilepsy, anxiety, sleep disorder, attention deficit hyperactivity disorder — are separately treatable, and that is where the most reliable gains are.

**Prevention.** Avoiding valproate in pregnancy: STRONG, an established, large, avoidable risk. Rubella vaccination: STRONG for the rubella-attributable fraction, which is now very small in vaccinated populations. Folate supplementation in early pregnancy: observationally associated with lower risk, no randomised evidence with this endpoint, WEAK. Preventing extreme prematurity: MODERATE for the attributable fraction. No other intervention has demonstrated prevention of autism, and given 80 per cent heritability, large-scale prevention is not a realistic prospect on present knowledge.

**Treatment.** *Early intensive behavioural intervention and naturalistic developmental behavioural interventions* improve adaptive behaviour and cognitive scores with moderate effect sizes, on variable trial quality with weak control conditions and blinding mostly impossible. The field's own systematic reviews rate certainty as low. *Parent-mediated interventions*: the Preschool Autism Communication Trial showed sustained improvement in symptom severity at six-year follow-up, one of the longest follow-ups in the field, and it is delivered through parents with modest professional input. *Speech-language and occupational support, and augmentative and alternative communication* are standard practice on an evidence base thinner than the practice volume.

*Treatment of co-occurring conditions* is the highest-yield pharmacological area: epilepsy, sleep disorder with randomised support for melatonin, attention deficit hyperactivity disorder with stimulants effective and with more adverse effects than in non-autistic children, and anxiety with adapted CBT. *Risperidone and aripiprazole for severe irritability and aggression* are effective for that specific target and not for autism itself; risperidone is EML-listed, off-patent, and costs tens of US dollars a patient-year. Harms: substantial weight gain, metabolic effects, sedation, prolactin elevation. *Melatonin for sleep onset problems* has randomised support in autistic children; not EML-listed, off-patent, tens of US dollars a year.

*Treatments tested and unsupported*: chelation, which is harmful; hyperbaric oxygen; secretin; gluten-free and casein-free diet, which had no effect in controlled trials; stem cell therapy. These are reported because families are actively marketed them.

**Simple means.** Parent-delivered interventions: the six-year follow-up result above came from an intervention delivered by parents after training, with no supply chain. Sleep timing and routine, with melatonin where needed: sleep problems affect a majority of autistic children, and improving them improves daytime function and family wellbeing. Predictable environment and sensory accommodation reduce distress; standard practice, poorly quantified in trials. Exercise: small randomised trials show improvements in stereotypy and in co-occurring symptoms. Social connection on the autistic person's own terms, including peer community, is associated with better mental health outcomes in observational studies of autistic adults. Augmentative communication: a picture board costs almost nothing and changes outcomes for non-speaking people.

**Gaps.** The 1-in-127 global and 1-in-31 US-surveillance figures differ by a factor of four; this is ascertainment, and no one can currently say what the true comparable rate is. Almost all intervention research is in children, and autistic adults, who are the majority of autistic

people, are barely studied. Trial outcome measures are contested: much of the literature measures reduction in autistic behaviour, which autistic-led research argues is the wrong endpoint, and sources genuinely disagree about what should be measured. Whether any real incidence increase underlies the recorded rise is unresolved. Prevalence data from low- and middle-income countries are very sparse.

---

## Attention deficit hyperactivity disorder

**What it is.** A developmental condition with persistent inattention, or hyperactivity and impulsivity, or both, beginning in childhood and impairing function across settings. It continues into adulthood in a majority of cases, usually with hyperactivity declining and inattention persisting.

**Measured.** WHO's mental disorders fact sheet gives no prevalence figure for attention deficit hyperactivity disorder (checked October 2026). Pooled childhood prevalence is roughly 5 to 8 per cent using research criteria, and adult prevalence roughly 2.5 to 3 per cent. Diagnosed prevalence varies several-fold between countries and even between neighbouring regions, far more than symptom-survey prevalence does — a service and threshold effect rather than a disease difference. The male-to-female diagnosed ratio is roughly 2 to 3 to 1 in childhood and closer to parity in adults, and under-recognition in girls is documented. Mortality is elevated, roughly twice all-cause in register studies, driven by accidents, and the relative risk is higher in those diagnosed as adults. Associated outcomes include elevated rates of road traffic collisions, substance use disorder, educational non-completion, unemployment and criminal justice contact. Diagnosis and prescribing have risen steeply over the past two decades, particularly in adults, while symptom prevalence in repeated population surveys has been broadly stable.

**Where it starts.** Heritability is roughly 70 to 80 per cent, among the highest in Chapter 06, against SNP-based heritability of roughly 20 per cent across many loci of small effect†. Extreme prematurity and very low birth weight carry roughly 2 to 3 times the risk†. Prenatal exposures to maternal smoking and alcohol are associated, and sibling-comparison and genetically informed designs substantially attenuate the maternal smoking association, suggesting much of it is confounded by shared familial liability. The attenuation is reported here, because this is a case where a widely cited risk factor weakened under better designs. Lead exposure is associated, with dose-response. Age relative to classmates matters: children who are youngest in their school year are substantially more likely to be diagnosed, up to roughly 1.3 to 1.8 times in several national studies — a measurement artefact in the diagnostic process, and a well-replicated one.

Dopaminergic and noradrenergic involvement is supported by drug efficacy, and drug efficacy is weak evidence of a cause. The dopamine-transporter-density account produced inconsistent imaging results and no clinical test. Structural imaging differences are small at group level and absent at individual level; there is no brain scan that diagnoses the condition, despite commercial claims. Executive function deficits are measurable, present in only a subset, and not specific. Not known: what the diagnostic boundary corresponds to; why prescribing varies so much between similar places; whether the condition is categorical or the tail of a continuous trait, where the evidence favours the continuum.

**Cure status.** CONTROLLABLE. Symptoms persist into adulthood in roughly 50 to 65 per cent of childhood cases, with full remission in a minority†. Medication effects are large and present only while the drug is active, and there is no evidence of disease modification. The MTA study's long-term follow-up found that initial group differences in symptom levels had converged by three years and beyond, which is the central and uncomfortable finding in this field. Discontinuation leads to symptom return.

**Prevention.** Lead removal: MODERATE for the lead-attributable fraction; see the intellectual developmental disorders entry for the magnitude of lead's neurodevelopmental burden. Preventing extreme prematurity: MODERATE. Avoiding alcohol in pregnancy: STRONG for fetal alcohol spectrum disorder, which includes attentional impairment, with a smaller condition-specific fraction. Maternal smoking cessation in pregnancy: CONTESTED for this condition specifically, given the sibling-comparison attenuation, and justified on every other ground. Not diagnosing the youngest children in a school year by comparison with their

classmates: STRONG as a measurement finding, because the correction prevents diagnoses. No intervention prevents the condition itself, given 70 to 80 per cent heritability.

**Treatment.** *Stimulants* have the largest effect sizes of any pharmacotherapy in Chapter 06. A network meta-analysis of 133 double-blind randomised trials covering 14,346 children and adolescents and 10,296 adults (Cortese and colleagues, *Lancet Psychiatry*, 2018) gives standardised mean differences against placebo on clinician-rated core symptoms at about twelve weeks: amphetamines, children −1.02 (95 per cent CI −1.19 to −0.85), adults −0.79 (−0.99 to −0.58); methylphenidate, children −0.78 (−0.93 to −0.62), adults −0.49 (−0.64 to −0.35); atomoxetine, children −0.56 (−0.66 to −0.45), adults −0.45 (−0.58 to −0.32); guanfacine, children −0.67 (−0.85 to −0.50), no adult trials identified; modafinil, children −0.62 (−0.84 to −0.41), adults +0.16 (−0.28 to 0.59), not superior to placebo.

GRADE certainty is moderate for amphetamines and methylphenidate in children and amphetamines in adults, and low for the rest. Methylphenidate is EML-listed, added in 2023 for this indication, off-patent, and costs tens to low hundreds of US dollars a patient-year, higher for extended-release. Dexamfetamine and lisdexamfetamine are not EML-listed, dexamfetamine is off-patent, and they cost from low hundreds to low thousands of US dollars a patient-year. Atomoxetine is not EML-listed, is off-patent, and costs tens to low hundreds of US dollars a patient-year.

Harms: appetite suppression and growth slowing in children, sleep onset delay, small blood pressure and heart rate increases, and diversion or misuse. Cardiovascular event risk in people without pre-existing disease is small in absolute terms. Two things sit oddly together here. Amphetamines have the larger effect size, and methylphenidate is the recommended first line in most guidelines, chiefly on tolerability and long-term safety data.

*Behavioural parent training and classroom behavioural intervention* improve parent-rated behaviour and parenting, and effects on blinded-rated core symptoms are small and inconsistent: effective for the associated problems, not for the core symptoms. *Combined medication and behavioural treatment* was superior for associated outcomes in the MTA trial and not clearly superior to medication alone for core symptoms, with the advantage fading by three years. *Cognitive training and working memory training* produce near-transfer gains on the trained task and do not transfer to symptoms or academic outcomes in blinded-rated trials: a clear negative result, heavily marketed regardless. *Omega-3 supplementation*: very small effects, SMD around 0.15 to 0.2, barely distinguishable from zero†. *Elimination diets*: effects appear in small trials with unblinded parent ratings and do not survive blinding. *CBT for adults* has moderate effects on functioning and comorbid symptoms as an adjunct to medication.

**Simple means.** Exercise improves executive function and symptoms with moderate effect sizes in randomised trials, on a small and mostly unblinded trial base, and it is not comparable to stimulant medication for this condition. The asymmetry is reported plainly: stimulant effect sizes of −0.78 to −1.02 are far larger than any non-drug intervention measured here, and this is one of the places where the chapter's general pattern does not hold. Sleep timing: delayed sleep phase is very common here, and treating sleep improves daytime symptoms in randomised trials. Environmental structure — written routines, external reminders, reduced distraction, broken-down tasks — is clinically standard, free and poorly quantified. Physical activity breaks in school show short-term improvement in classroom behaviour in small randomised trials.

**Gaps.** No WHO fact sheet and no stable GBD figure, so global burden is poorly characterised. The fading of treatment differences in long-term follow-up is the central unresolved problem and is rarely stated clearly in clinical materials. Trials are short: almost all efficacy data come from weeks to months, while treatment is given for years. Diagnostic variation between countries is several-fold and unexplained by anything except service factors. Adult diagnosis and prescribing are rising rapidly on a far thinner evidence base than the childhood literature.

---

## Intellectual developmental disorders

**What it is.** Significantly below-average intellectual functioning and adaptive behaviour, originating during the developmental period. ICD-11 grades it mild, moderate, severe or

profound, and recognises provisional and unspecified categories where standardised testing is not possible.

**Measured.** Pooled global prevalence is roughly 1 to 1.5 per cent, higher in low- and middle-income countries where preventable causes are more frequent. GBD 2021 includes intellectual disability within its nervous-system analysis, and found that controlling lead exposure alone could reduce the intellectual disability burden by 63 per cent — the largest single preventable fraction attributed to any condition in that analysis. Lead exposure overall was associated with more than 3.5 million deaths and more than 71.5 million DALYs globally in 2023, mainly cardiovascular (WHO lead poisoning fact sheet, 10 June 2026, IHME/GBD 2023 data).

Blood lead at 3.5 micrograms per decilitre and above is associated with decreased intelligence, behavioural difficulty and learning problems, and WHO's clinical action threshold is 5 micrograms per decilitre. Children absorb up to four to five times as much lead from an ingested dose as adults. As of January 2024 only 48 per cent of countries had legally binding controls on lead paint. Iodine deficiency remains the leading preventable cause of intellectual impairment worldwide where salt iodisation is incomplete. Mortality is substantially elevated, with life expectancy reduced by roughly twenty years in the severe and profound categories and a large documented excess of deaths from avoidable causes. Down syndrome occurs in roughly 1 in 700 to 1,000 live births globally, with wide variation by maternal age structure and prenatal screening practice.

**Where it starts.** Unusually for this chapter, much of the aetiology is actually known. *Genetic*: Down syndrome, fragile X syndrome, and several hundred single-gene and copy-number causes, collectively accounting for a substantial and rising fraction of cases as genomic testing improves; fragile X is the commonest inherited cause. *Iodine deficiency in pregnancy*: established, dose-responsive and preventable; severe deficiency causes cretinism and moderate deficiency causes measurable loss of intelligence across the whole exposed population. *Lead exposure*: established, with no identified threshold below which there is no effect, and an attributable fraction of 63 per cent on GBD 2021.

*Alcohol in pregnancy*: fetal alcohol spectrum disorder, established and dose-responsive with no established safe level. *Perinatal asphyxia and neonatal encephalopathy*: GBD 2021 ranked neonatal encephalopathy second among all nervous-system conditions by DALYs. *Congenital hypothyroidism*: established, and detectable by newborn screening, which prevents the disability entirely if treated promptly. *Phenylketonuria and other inborn errors*: established, preventable by newborn screening plus dietary management. *Congenital infections* — rubella, cytomegalovirus, syphilis, Zika — together with neonatal jaundice and kernicterus, meningitis, severe malnutrition and folate-preventable neural tube defects all contribute. Heritability estimates for intelligence in the normal range are high, 50 to 80 per cent in adults†, and they do not transfer to the pathological tail, where single large-effect causes dominate.

For a large fraction of cases the cause is now identified at the molecular or exposure level — a different evidential situation from the rest of Chapter 06. For the remaining idiopathic cases, nothing is known. Not known: why the same genetic condition produces widely different functional outcomes; the mechanism of lead neurotoxicity in detail; whether there is any threshold for lead.

**Cure status.** Established intellectual disability: RELIEF ONLY. Specific treatable causes caught before damage occurs: CURABLE. Congenital hypothyroidism treated early gives normal development and untreated gives permanent severe disability, so newborn screening plus levothyroxine is one of the highest-yield interventions in all of medicine. Phenylketonuria has the same structure: screening plus dietary management prevents the disability. Iodine deficiency is prevented by supplementation in pregnancy and is not reversed afterwards. Removing lead exposure stops further loss and does not recover lost function. The pattern across this condition is that prevention is curative and treatment is not. That is the central fact.

**Prevention.** This is the strongest prevention section in the chapter. Universal salt iodisation: STRONG, and the single most cost-effective intellectual-disability prevention measure known. Global household coverage of iodised salt rose from roughly 20 per cent in 1990 to around 88 to 90 per cent by the 2020s, and the number of iodine-deficient countries fell from over

100 to around 20†. Moderate iodine deficiency in pregnancy is associated with deficits of several intelligence points in the offspring, and correction removes this. Lead removal from petrol, paint, pipes, cookware, cosmetics and spices: STRONG.

GBD 2021 attributes 63 per cent of the intellectual disability burden to lead. Tetraethyl lead was eliminated from on-road petrol globally by 2021, after a phase-out that produced measurable population blood-lead declines of roughly 90 per cent in countries that completed it early. Paint controls remain legally binding in only 48 per cent of countries (WHO, January 2024), the largest remaining gap. Folic acid fortification of staple foods for neural tube defects: STRONG. In the United States combined neural tube defect prevalence fell from 10.8 per 10,000 in 1995 to 1996 to 6.9 per 10,000 by the end of 2006, a 36 per cent decline, with affected pregnancies falling from about 4,000 to about 3,000 a year (CDC *MMWR*, 2010).

Randomised trial evidence from the MRC Vitamin Study of 1991 established a roughly 70 per cent reduction in recurrence with periconceptional folic acid, and over 80 countries now mandate fortification. Newborn screening for congenital hypothyroidism, phenylketonuria and other treatable metabolic conditions: STRONG, because it prevents the disability outright. Rubella vaccination: STRONG; congenital rubella syndrome is near-eliminated where coverage is high. Alcohol avoidance in pregnancy: STRONG. Obstetric and neonatal care — skilled birth attendance, resuscitation, management of jaundice, treatment of neonatal infection: STRONG for the neonatal encephalopathy fraction, which GBD ranks second among all nervous-system conditions.

Prevention and prompt treatment of childhood meningitis: STRONG; conjugate vaccines reduced confirmed serogroup A disease by 99 per cent in vaccinated populations in the African meningitis belt (WHO meningitis fact sheet, 29 September 2026). Consanguinity counselling where relevant, and prenatal and preconception genetic counselling: MODERATE.

**Treatment.** *Early intervention and educational support* improve adaptive function with modest effect sizes, on an evidence base weaker than the practice volume. *Treatment of the specific cause where one exists*: levothyroxine for congenital hypothyroidism, dietary management for phenylketonuria, enzyme replacement for some lysosomal disorders. Levothyroxine is EML-listed as a selected medicine for hypothyroidism, confirmed against the 24th List, off-patent, and costs on the order of a few to a few tens of US dollars a patient-year — and it prevents a lifetime of severe disability. *Treatment of co-occurring conditions*: epilepsy, which is very frequent in the severe and profound categories, sensory impairment and mental disorders. Addressing these produces the most reliable functional gains. *Communication support and augmentative or alternative communication* is standard practice. *Supported employment and supported living* improve participation outcomes. *Antipsychotics for challenging behaviour* are widely prescribed and not supported by trial evidence for that indication in this population; the largest randomised trial found no benefit over placebo. Over-prescribing in this group is a documented quality-of-care problem in several national audits.

**Simple means.** Iodised salt: a few cents per person per year, preventing loss of intelligence across whole populations. The single best cost-to-effect ratio in this chapter. Folic-acid-fortified flour: similarly cheap, with the 36 per cent reduction in neural tube defects measured above. Removing lead from the home environment — paint, water pipes, cookware, imported spices and cosmetics: no clinical supply chain, large measured effect. Exclusive breastfeeding and adequate nutrition in the first thousand days: associated with better cognitive outcomes. Newborn examination and a heel-prick blood spot: a card, a lancet and a laboratory. Communication boards: paper and pictures.

**Gaps.** Prevalence data are poorest exactly where preventable causes are most common. The 63 per cent lead-attributable fraction is a modelled estimate with wide uncertainty, resting on an assumed no-threshold dose-response that is plausible and not directly measurable at low exposures. Adults with intellectual disability have markedly worse health outcomes for avoidable reasons, and the measurement of this exists in only a few countries. Antipsychotic prescribing for challenging behaviour continues at scale against the evidence: an implementation failure, not an evidence gap.

## Dementia and neurocognitive disorders

*ICD-11 codes dementia in Chapter 06, under neurocognitive disorders, with the underlying aetiology cross-coded to Chapter 08. So Alzheimer disease appears as a nervous-system disease in Chapter 08 and the dementia syndrome it causes appears here. This entry covers the syndrome, its care, the full prevention evidence and the anti-amyloid antibody data.*

**What it is.** Acquired, persistent decline in two or more cognitive domains, severe enough to interfere with independence. It is a syndrome with many causes, and it is progressive in most of them.

**Measured.** 57 million people were living with dementia worldwide in 2021, and over 60 per cent live in low- and middle-income countries (WHO dementia fact sheet, 3 July 2026, 2021 data). Nearly 10 million new cases a year. Alzheimer disease accounts for 60 to 70 per cent of cases. Dementia is the seventh leading cause of death globally, and WHO's Global Health Estimates for 2023 place Alzheimer's disease and other dementias fifth among all causes of death at 2.1 million. Alzheimer's disease and other dementias rank twenty-second among all causes of years lived with disability at 12.2 million YLDs (95 per cent UI 8.52 to 15.6) in 2023.

The economic cost was US$1.3 trillion in 2019, about half of it attributable to informal carers, who provide about five hours of care a day; 70 per cent of care hours are provided by women. Young-onset dementia, before age 65, accounts for up to 9 per cent of cases. GBD 2021 ranked Alzheimer disease and other dementias fourth among nervous-system conditions by DALYs. Prevalence roughly doubles with every five years of age after 65. Absolute numbers are rising with population ageing, and age-specific incidence has been falling in several high-income countries — roughly 13 per cent per decade in pooled Western cohort analyses — consistent with improving vascular risk and rising education. That is a genuinely encouraging finding and it coexists with rising absolute numbers. The proportion in low- and middle-income countries is rising fastest.

**Where it starts.** The Lancet Commission on dementia prevention of 2024 identified 14 modifiable risk factors with a combined population attributable fraction of 45 per cent: low education, hearing loss, hypertension, smoking, obesity, depression, physical inactivity, diabetes, excessive alcohol consumption, traumatic brain injury, air pollution, social isolation, high midlife LDL cholesterol with a PAF of 7 per cent, and untreated vision loss in late life with a PAF of 2 per cent. The last two were added in 2024. GBD 2021 estimates that normalising high fasting plasma glucose alone could reduce the dementia burden by about 15 per cent. Age is the dominant non-modifiable factor. *APOE* ε4 carries roughly three times the risk for one copy and roughly 8 to 12 times for two, the largest common genetic effect in late-onset dementia. Autosomal dominant mutations in *APP*, *PSEN1* and *PSEN2* have near-complete penetrance and account for less than 1 per cent of cases. Heritability of late-onset Alzheimer disease is roughly 60 to 80 per cent in twin studies†, which coexists with the 45 per cent modifiable PAF because the two are not additive.

The amyloid cascade hypothesis has driven the field for three decades. Anti-amyloid antibodies now demonstrate that removing amyloid produces a small slowing of decline, which supports some causal role, while the effect size is far smaller than the hypothesis predicted. Dozens of amyloid-targeting agents failed before two succeeded marginally. The position that holds: amyloid is causally involved, and it is not the whole story and not the main lever. Tau pathology correlates better with clinical severity than amyloid does. The vascular contribution is substantial and under-recognised, and mixed pathology is the rule at autopsy rather than the exception. On the literature's integrity: a widely cited 2006 *Nature* paper on amyloid-beta*56 was retracted in 2024 after image-manipulation findings, and several other papers in the field have been retracted. That did not invalidate the amyloid hypothesis, which rests on genetics and much other work, and it is part of the record. Not known: what initiates the pathology decades before symptoms; why some people with heavy pathology at autopsy had no dementia, since cognitive reserve is a label rather than a mechanism; whether treating amyloid earlier would do more.

**Cure status.** RELIEF ONLY, with the anti-amyloid antibodies producing measurable slowing that does not alter the ultimate course on present evidence. Reversible causes exist and must be excluded — hypothyroidism, B12 deficiency, normal pressure hydrocephalus, subdural haematoma, depression, medication effects — and those are CURABLE, which is why they

are looked for. They are a small fraction of presentations. Cholinesterase inhibitors produce small symptomatic benefit without altering progression. Anti-amyloid antibodies slow measured decline by roughly a quarter to a third over eighteen months, without stopping it.

**Prevention.** The strongest prevention evidence in Chapter 06 after intellectual developmental disorders.

*Blood pressure control*: MODERATE. SPRINT MIND (Williamson and colleagues, *JAMA*, 2019; 9,361 participants, systolic target below 120 against below 140 mm Hg) did **not** meet its dementia endpoint. Probable dementia hazard ratio 0.83 (95 per cent CI 0.67 to 1.04) — **not statistically significant** — with 149 against 176 cases, 7.2 against 8.6 per 1,000 person-years. Mild cognitive impairment hazard ratio 0.81 (0.69 to 0.95) was significant, 14.6 against 18.3 per 1,000 person-years. The combined endpoint of mild cognitive impairment or probable dementia, hazard ratio 0.85 (0.74 to 0.97), was significant, 20.2 against 24.1 per 1,000 person-years.

The trial stopped early for cardiovascular benefit and was consequently underpowered for dementia. Only the mild cognitive impairment outcome and the composite reached significance; the dementia endpoint did not. This is frequently misreported. Meta-analyses of antihypertensive trials support a modest protective effect. Hypertension context: about 1.4 billion adults aged 30 to 79 had hypertension in 2024, 33 per cent of that age group; about 630 million were diagnosed and treated; about 320 million were controlled, 23 per cent; about 600 million were unaware (WHO hypertension fact sheet, 25 September 2025, 2024 data).

The same page assigns 44 per cent to both the unaware group of 600 million and the treated group of 630 million, and 630 of 1,400 is 45 per cent; the discrepancy is the page's own.

*Hearing aid use*: CONTESTED. ACHIEVE (Lin and colleagues, *Lancet*, 2023; 977 participants, three years) found **no significant difference in the full cohort**: three-year cognitive change difference 0.002 standard deviation units (95 per cent CI −0.077 to 0.081; p=0.96). **The primary outcome was null.** In the pre-specified high-risk ARIC subgroup of 238 participants, hearing intervention was associated with a 48 per cent reduction in three-year cognitive change, difference 0.191 SD units (0.022 to 0.360; p=0.027). The 48 per cent figure that circulates widely is that subgroup result, not the primary outcome. Hearing loss remains in the Lancet Commission's 14 factors on observational grounds.

*Education*: MODERATE. Low education is in the 14 factors, and Mendelian randomisation studies support a causal protective effect of educational attainment. Education also raises cognitive reserve, delaying symptom onset for the same pathology burden. *Smoking cessation*: MODERATE. *Physical activity*: MODERATE; the observational association is consistent, and randomised exercise trials with dementia incidence endpoints have mostly been null or underpowered, with sources disagreeing on how much of the observational association is reverse causation from the long prodrome. *Diabetes and glycaemic control*: MODERATE; GBD attributes about 15 per cent of the dementia burden to high fasting plasma glucose†.

*Midlife LDL cholesterol control*: MODERATE, PAF 7 per cent†. *Treating vision loss* by cataract surgery and spectacles: MODERATE, PAF 2 per cent, with observational evidence that cataract surgery is associated with lower dementia incidence. *Alcohol reduction*: MODERATE. *Head injury prevention* through helmet law, road safety and sport protocols: MODERATE. Helmets reduce the risk of death by more than six times and brain injury risk by up to 74 per cent; seat-belts reduce occupant death risk by up to 50 per cent; a 1 per cent increase in mean traffic speed produces a 4 per cent increase in fatal crash risk; road deaths are about 1.16 million a year (WHO road traffic injuries fact sheet, 20 July 2026). The brain-injury-to-dementia link is the weaker leg of that chain.

*Air pollution reduction*: MODERATE. *Addressing social isolation*: MODERATE, with intervention trials using dementia endpoints absent. *Multidomain intervention*: CONTESTED; the FINGER trial in Finland showed benefit on a composite cognitive score and subsequent multidomain trials were null or marginal. *Cognitive training*: CONTESTED; ACTIVE showed durable gains on trained abilities with limited transfer, and commercial brain-training claims are not supported.

**Treatment.** *Cholinesterase inhibitors* — donepezil, rivastigmine, galantamine — give small symptomatic benefit, roughly two to three points on ADAS-cog over six months, with no effect on progression. Donepezil is not EML-listed, is off-patent, and costs on the order of tens of

US dollars a patient-year; rivastigmine likewise, at tens to low hundreds. *Memantine* gives small benefit in moderate-to-severe disease; not EML-listed, off-patent, tens of US dollars a patient-year.

*Anti-amyloid monoclonal antibodies*, the measured effect, the price and the harms:

**Lecanemab** (Clarity AD; van Dyck and colleagues, *NEJM*, 2023; 1,795 participants, 18 months) produced a CDR-SB difference of **−0.45 points** on an 18-point scale, a **27 per cent slowing** of decline against placebo (p=0.00005). The minimum clinically important difference on CDR-SB in mild Alzheimer disease is generally put at 0.5 to 1.0 points, so the measured effect is at or below the usual threshold for clinical detectability in an individual patient. Harms: ARIA-E, brain oedema, **12.5 per cent against 1.7 per cent** on placebo; ARIA-H, microhaemorrhage, **17.0 per cent against 8.7 per cent**, with isolated ARIA-H 8.8 against 7.6 per cent. Deaths occurred in the open-label extension in patients on anticoagulants. The price is approximately **US$26,500 a year** at US list price†, plus the cost of amyloid PET or cerebrospinal fluid confirmation, *APOE* genotyping, infusion every two weeks, and serial MRI monitoring for ARIA. Not EML-listed; on patent.

**Donanemab** (TRAILBLAZER-ALZ 2; Sims and colleagues, *JAMA*, 2023; 1,736 enrolled, 1,182 in the low-and-medium-tau primary analysis population, 18 months) produced **22 per cent slowing on the iADRS in all participants and 35 per cent in the primary analysis population**. Within the low-and-medium-tau population, slowing was 60 per cent on iADRS and 46 per cent on CDR-SB in mild cognitive impairment (n=214); 30 and 38 per cent in mild Alzheimer dementia (n=534); 48 and 45 per cent under age 75 (n=542); 25 and 29 per cent at 75 or older (n=551). Harms: **ARIA-E 24 per cent**; **ARIA-H 31.4 per cent against 13.6 per cent** on placebo; serious ARIA 1.6 per cent†. Trial deaths attributed to ARIA were reported in the primary publication. The price is approximately **US$32,000 a year** at US list†, with the same ancillary costs. Not EML-listed; on patent.

Both drugs produce a real, statistically robust, small slowing. Neither halts nor reverses decline. Both carry a rate of imaging abnormality between roughly one in four and one in three, with a smaller rate of symptomatic and occasionally fatal events. Neither is on the WHO Essential Medicines List; the Expert Committee considered them and did not add them. And the infrastructure they require — amyloid confirmation, biweekly or monthly infusion, serial MRI — does not exist in the countries where over 60 per cent of people with dementia live. Set beside them the alternative with its own cost: blood pressure control with off-patent EML-listed drugs.

Hydrochlorothiazide, amlodipine, enalapril and losartan are all EML-listed and all off-patent. The NHS Drug Tariff for England and Wales, September 2026, gives amlodipine 5 mg at 64 pence for a pack of 28 tablets, 2.3 pence a tablet, and amlodipine 10 mg at 72 pence for 28, 2.6 pence a tablet; at one tablet a day that is £8 to £9 a patient-year, roughly ten to twelve US dollars. The unit on the Drug Tariff column was not confirmed from the retrieved document and pence is the conventional unit and consistent with the magnitudes. That regimen produced the SPRINT MIND composite hazard ratio of 0.85.

The antibodies cost three to four orders of magnitude more, and the exact multiple is not printed here because the cholinesterase-inhibitor and antihypertensive prices the earlier comparison rested on were unsourced estimates. The price source the book had counted on, the MSH International Medical Products Price Guide, has a last edition of 2017 and its site was retired after 30 June 2024.

*Aducanumab* was withdrawn from the market in 2024, after an approval that the regulator’s own advisory committee had voted against.

*Non-pharmacological interventions for the syndrome*: cognitive stimulation therapy improves cognition and quality of life in randomised trials, and reminiscence work, music and structured activity reduce agitation. *Carer support and training* reduces carer depression and delays institutionalisation in randomised trials, and given that informal carers provide about half the US$1.3 trillion cost and five hours of care daily, this is where cost-effectiveness is largest. *Antipsychotics for behavioural symptoms* give small benefit for aggression, offset by a roughly 1.5 to 1.7 times increase in mortality† and increased stroke risk, with black-box warnings; use is appropriate only for severe risk, short-term, reviewed. *Managing vascular risk after diagnosis* continues to matter for mixed pathology. *Avoiding anticholinergic and*

*sedative medication burden* is associated with better cognition, and deprescribing is a free intervention.

**Simple means.** Blood pressure control with off-patent EML drugs, at the prices above, which produced the SPRINT MIND composite hazard ratio of 0.85. Physical activity: moderate observational effect, free. Hearing aids: the ACHIEVE primary outcome was null, so this is stated as unproven for cognition despite being clearly worthwhile for hearing, and a hearing aid still costs far less than an antibody. Spectacles and cataract surgery: cataract surgery is among the most cost-effective surgical procedures in medicine on its own merits, and the dementia benefit is observational. Education: the strongest simple means in this entry, supported by Mendelian randomisation, and a policy rather than a clinical act. Social connection and continued activity: in the 14 factors, with thin intervention evidence. Salt reduction, for the vascular contribution: global mean intake is about 4,278 mg a day of sodium, roughly 11 g a day of salt, more than double the WHO recommended limit of under 2,000 mg of sodium, under 5 g of salt; about 1.7 million deaths a year are associated with excess sodium (WHO sodium reduction fact sheet, 11 May 2026; intake 2021, deaths 2023). Carer support: a trained relative, not a product.

**Gaps.** SPRINT MIND's dementia endpoint did not reach significance and the trial was underpowered; sources frequently report it as if it had. ACHIEVE's primary outcome was null, and the circulating 48 per cent is a subgroup. Both are common misreportings and both are printed correctly above. The Lancet Commission's 45 per cent combined PAF assumes independence between factors and complete elimination; it is an upper bound on a counterfactual, not an achievable target. Anti-amyloid antibody trials were in selected, mostly white, high-income populations with confirmed amyloid and without anticoagulation or high microhaemorrhage burden, so real-world safety and effect may differ. There are no long-term randomised data beyond eighteen months for the antibodies, and whether the small slowing accumulates, plateaus or reverses is unknown. The falling age-specific incidence in high-income countries is well measured and not fully explained. Diagnosis rates are low everywhere, and the 57 million figure is modelled from sparse prevalence surveys.

# 07 — Sleep-wake disorders

*ICD-11 gave sleep-wake disorders their own chapter for the first time, having previously distributed them between the mental disorders and nervous system chapters of ICD-10. The chapter covers insomnia disorders, sleep-related breathing disorders, central disorders of hypersomnolence, circadian rhythm sleep-wake disorders, sleep-related movement disorders and parasomnias. Not one of these conditions has a stand-alone GBD burden estimate, as the chapter introduction states.*

---

## Insomnia disorder

**What it is.** Persistent difficulty falling asleep, staying asleep, or waking too early, despite adequate opportunity to sleep, with daytime consequences. Chronic insomnia disorder requires the pattern to persist for at least three months.

**Measured.** Insomnia symptoms occur in roughly 30 to 35 per cent of adults; insomnia *disorder* meeting full criteria in roughly 6 to 10 per cent†. The distinction matters and is often collapsed in reporting. Women roughly 1.4 to 1.5 times men†. Prevalence rises with age, and in older adults symptom prevalence exceeds 40 per cent in some surveys†, though much of that is comorbid rather than primary. There is no WHO fact sheet, and GBD produces no stand-alone burden estimate, so global DALY figures are unavailable — a notable gap given the prevalence. Insomnia is an independent prospective risk factor for incident depression, roughly twice the risk, and for hypertension and suicidal ideation. Hypnotic prescribing has shifted away from benzodiazepines toward Z-drugs and newer agents, and total sedative-hypnotic use remains high in most high-income countries.

**Where it starts.** Heritability is roughly 30 to 40 per cent†. Female sex, older age, shift work and comorbid mental or physical disorder are all established. Hyperarousal is the best-supported model: people with the disorder show elevated physiological and cognitive arousal measures, and that is a description of state rather than a cause. Conditioning — the association between bed and wakefulness — is the target of stimulus control and sleep restriction therapy, and the therapies' efficacy supports the model, which is as close to a demonstrated mechanism as this chapter gets. Objective sleep measures correlate only weakly with the subjective complaint; that is one of the best-replicated findings in sleep medicine and it complicates every prevalence estimate. There is no biomarker, and diagnosis is by history. Orexin antagonist efficacy demonstrates that the wake-promoting orexin system is a usable target, and does not establish an orexin abnormality as the cause. Not known: why the subjective complaint and objective measures diverge; whether insomnia disorder is one condition.

**Cure status.** Treated with cognitive behavioural therapy for insomnia: CURABLE in roughly 40 to 50 per cent (remission)†. Treated with drugs: CONTROLLABLE. This is one of the clearest cases in the book where a non-drug treatment produces durable remission and a drug does not. Cognitive behavioural therapy for insomnia gives response in roughly 60 to 70 per cent of those treated and remission in roughly 40 to 50 per cent, and gains are maintained or continue to improve at six to twelve months after treatment ends. Hypnotics are effective while taken, with rebound insomnia on discontinuation and no durable benefit after stopping. Head-to-head and sequential trials find the behavioural treatment equal or superior to hypnotics acutely and clearly superior at follow-up.

**Prevention.** Treating insomnia prevents other conditions, which is the headline here: digital cognitive behavioural therapy for insomnia reduced incident depression in randomised trials, and the SHUTi and related trials showed reductions in depressive symptom onset, MODER-

ATE. Sleep hygiene education alone: WEAK. As a standalone intervention it has repeatedly failed, and it is effective only as one component of the full behavioural treatment. It is widely dispensed and performs poorly. Shift schedule design — forward-rotating, adequate recovery, limiting consecutive nights: MODERATE. Limiting evening light and screen use: WEAK; melatonin suppression by evening light is well demonstrated physiologically and the effect on incident insomnia disorder is not established. Avoiding hypnotic initiation for transient insomnia prevents dependence: MODERATE.

**Treatment.** *Cognitive behavioural therapy for insomnia* is first-line in every major guideline, including the American College of Physicians, the European Sleep Research Society and NICE. Effect sizes are moderate-to-large on sleep onset latency and wake after sleep onset and moderate on sleep efficiency and subjective quality, and durability after treatment ends is its distinguishing feature. Its components are sleep restriction, stimulus control, cognitive restructuring, relaxation and sleep hygiene. *Digital delivery* achieves effect sizes approaching face-to-face delivery in randomised trials, including large pragmatic trials, at near-zero marginal cost per additional user: the most scalable effective intervention in this chapter.

*Brief behavioural treatment for insomnia*, a two-to-four session version deliverable by a nurse or primary care worker, is effective in randomised trials, which is what matters where therapists do not exist. *Dual orexin receptor antagonists* — suvorexant, lemborexant, daridorexant — give modest effects, roughly 10 to 20 minutes improvement in sleep onset and 20 to 40 minutes in total sleep time against placebo, with a better safety profile than Z-drugs on current evidence and less tolerance signal. They are not EML-listed, on patent, and cost thousands of US dollars a patient-year at list price. *Z-drugs* — zolpidem, zopiclone, eszopiclone — are effective short-term, with concerns about falls and fractures in older adults, complex sleep behaviours that regulators have warned about, next-day impairment, tolerance and dependence; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year.

*Benzodiazepines* are effective short-term, with dependence, tolerance, falls and cognitive effects in older adults; diazepam is EML-listed for other indications, off-patent, and costs a few tens of US dollars a patient-year at most, and guidelines advise against long-term use. *Low-dose doxepin* is effective for sleep maintenance with fewer of the Z-drug problems; off-patent, not EML-listed, tens to low hundreds of US dollars a patient-year. *Melatonin* has a small effect on sleep onset latency, roughly 7 to 12 minutes in meta-analysis, larger in circadian disorders than in primary insomnia, and is most useful in children, in older adults with low endogenous melatonin, and in circadian misalignment; not EML-listed, off-patent, tens of US dollars a year, with documented variability in supplement content.

*Antihistamines and sedating antidepressants used off-label for sleep* are widespread and poorly evidenced, with anticholinergic burden concerns; trazodone and mirtazapine are used far more than their sleep evidence supports. *Exercise* improves sleep quality with small-to-moderate effect sizes in randomised trials, smaller than the behavioural treatment.

**Simple means.** Sleep restriction and stimulus control: the two most effective components of the first-line treatment are purely behavioural instructions — restrict time in bed to actual sleep time and then extend it gradually; get out of bed when not sleeping; use the bed only for sleep. They are deliverable from a single printed page, and they are the active ingredients of the first-line treatment for a condition affecting hundreds of millions. This is the strongest simple-means finding in the chapter. Fixed wake time, seven days a week: the single most important instruction, anchoring the circadian system. Morning light at a fixed hour: advances and stabilises circadian phase, with the physiological effect well quantified. Exercise, at small-to-moderate effect sizes. Reducing evening light: physiologically demonstrated melatonin suppression. Caffeine and alcohol timing: alcohol reduces sleep onset latency and degrades sleep architecture in the second half of the night, demonstrated polysomnographically.

**Gaps.** No GBD burden estimate and no WHO fact sheet, for a condition with 6 to 10 per cent disorder prevalence. The subjective-objective discordance is unexplained and undermines both prevalence estimation and outcome measurement. The behavioural treatment is first-line everywhere and available almost nowhere, and the gap between guideline and provision is the largest in this chapter. Long-term hypnotic safety data beyond a year are almost entirely observational. Orexin antagonist trials are short and sponsor-run.

## Obstructive sleep apnoea

**What it is.** Repeated collapse of the upper airway during sleep, causing breathing pauses, oxygen desaturation and arousals. It fragments sleep and produces daytime sleepiness. Many people with the physiological finding have no symptoms.

**Measured.** 936 million adults **aged 30 to 69** worldwide have mild-to-severe obstructive sleep apnoea, at an apnoea-hypopnoea index of 5 or more (95 per cent CI 903 to 970 million). 425 million adults **aged 30 to 69** have moderate-to-severe disease, at an index of 15 or more (95 per cent CI 399 to 450 million). The source is a literature-based analysis across 193 countries using the AASM 2012 criteria (Benjafield and colleagues, *Lancet Respiratory Medicine*, 2019;7(8):687–698). Both figures are for adults aged 30 to 69 only, not for all adults, and the age band travels with them every time they appear.

**The study's funding statement is the single word ResMed**, and ResMed manufactures CPAP devices. On these criteria and within that age band, this is by prevalence one of the largest conditions in the book. The large majority remain undiagnosed, with estimates of the undiagnosed proportion exceeding 80 per cent in most settings†. The male-to-female ratio is roughly 2 to 1 at equivalent severity, and the gap narrows after menopause†. Prevalence rises with age and with body weight, and obesity is the dominant modifiable determinant. The condition is associated with hypertension, atrial fibrillation, type 2 diabetes, stroke and road traffic collision risk in observational studies, and untreated moderate-to-severe apnoea with roughly two to three times collision risk. There is no WHO fact sheet and no stand-alone GBD burden estimate.

**Where it starts.** Obesity is the strongest modifiable risk factor. A 10 per cent weight gain is associated with roughly a 32 per cent increase in the apnoea-hypopnoea index and roughly six times the odds of developing moderate-to-severe apnoea; a 10 per cent weight loss is associated with roughly a 26 per cent reduction in the index (Peppard and colleagues, *JAMA*, 2000). A well-quantified dose-response in both directions. Craniofacial structure — retrognathia, maxillary narrowing, tonsillar hypertrophy, which is the dominant cause in children — is established. Male sex, age and menopause are established. Alcohol and sedatives worsen events acutely. Nasal obstruction, smoking and fluid-shift conditions such as heart failure and renal failure are contributory. Heritability is roughly 35 to 40 per cent, largely mediated through craniofacial and body-composition traits.

The mechanism here is mechanical and well understood: anatomical narrowing plus reduced upper-airway dilator muscle tone during sleep. That is an unusually clear mechanistic picture compared with most of this chapter. Four physiological traits — anatomy, muscle responsiveness, arousal threshold and loop gain — have been characterised and vary between patients, which explains differential treatment response and is the basis of current phenotyping work. Not known: why the cardiovascular associations have not translated into trial benefit from treatment, which is the central unresolved problem in this field.

**Cure status.** Treated with CPAP or an oral appliance: CONTROLLABLE, effective only while used. Substantial weight loss in weight-related cases, adenotonsillectomy in most children, and maxillomandibular advancement surgery in selected adults: CURABLE. CPAP abolishes events while worn and they return immediately on stopping. Adenotonsillectomy in children with adenotonsillar hypertrophy resolves the apnoea in the large majority — a genuine cure. Bariatric surgery produces remission in a substantial proportion of severely obese patients. Adherence is the limiting factor: roughly 30 to 50 per cent of CPAP users do not reach commonly used adherence thresholds.

**Prevention.** Weight management at population level: MODERATE on the dose-response above, with no randomised prevention trials using incident apnoea endpoints. Treating childhood adenotonsillar hypertrophy: MODERATE, and it addresses a cause rather than a symptom. Avoiding alcohol and sedatives before sleep: WEAK, on demonstrated acute physiological effect. Smoking cessation: WEAK. Note the asymmetry with other conditions in this chapter: here the main preventive lever, body weight, is itself a condition the health system struggles to influence at population level.

**Treatment.** *CPAP* is the reference treatment. It abolishes apnoea events, reduces daytime sleepiness with moderate-to-large effect sizes, improves quality of life, and reduces blood

pressure by roughly 2 to 3 mm Hg†. The cardiovascular outcome evidence is negative and is reported as such. SAVE (McEvoy and colleagues, *NEJM*, 2016; 2,717 participants aged 45 to 75 with moderate-to-severe apnoea and established cardiovascular disease, mean follow-up 3.7 years) found a primary composite cardiovascular hazard ratio of **1.10 (95 per cent CI 0.91 to 1.32; p=0.34)**, with 229 events on CPAP against 207 on usual care: **no cardiovascular benefit**.

CPAP did significantly reduce sleepiness and apnoea symptoms and improved quality-of-life measures. Low adherence in the trial, at a mean under four hours a night, is the standard explanation and remains a hypothesis rather than an established finding. Subsequent trials, RICCADSA and ISAACC, were similarly null on cardiovascular endpoints. So CPAP reliably treats the symptoms and the physiology, and has not been shown to reduce cardiovascular events in randomised trials, despite strong observational associations. On cost, the sources in this book disagree.

This chapter's compilation gave the device as a one-off cost in the low hundreds of US dollars, with annual mask and consumable costs of roughly one to three hundred. Another dossier gives the machine at hundreds to thousands of euro lasting five to ten years, with masks and filters at hundreds of euro a year. Those are the same items in a different currency, with a different top end, and with a service life where the first states a one-off. Both stand, unresolved.

*Mandibular advancement devices* are less effective than CPAP on the apnoea-hypopnoea index and comparable on sleepiness and blood pressure, because adherence is higher. Another dossier in this book quantifies this as a reduction in the index of roughly 50 per cent, less than CPAP, with better adherence, so that health outcomes are often equivalent, which is a less hedged conclusion than the one above, and both stand. On cost, that dossier gives hundreds to thousands of euro for a custom device and tens to hundreds of euro for a thermoplastic one, splitting a device type that this chapter's compilation treated as one; the compilation's own figure was an unsourced estimate and is not printed.

*Weight loss* is the only intervention that addresses the cause in most adult cases; see simple means. *Positional therapy* for position-dependent apnoea is effective in a defined subgroup and cheap. *Surgery*: adenotonsillectomy is first-line in children; maxillomandibular advancement has high efficacy in selected adults, roughly 85 per cent surgical success in series†; uvulopalatopharyngoplasty is modest and declining in use; hypoglossal nerve stimulation is effective in selected patients at a device cost in the tens of thousands of US dollars. *GLP-1 receptor agonists*: tirzepatide reduced the apnoea-hypopnoea index substantially in randomised trials in obese patients (SURMOUNT-OSA, 2024), by roughly 25 to 30 events an hour, and gained a regulatory indication. On patent, not EML-listed, and costing thousands of US dollars a patient-year at list price. *Modafinil and solriamfetol* treat residual sleepiness on treatment, and the symptom only. *Supplemental oxygen alone* corrects desaturation without addressing fragmentation and is not a treatment for the disorder.

**Simple means.** Weight loss: roughly 26 per cent reduction in the apnoea-hypopnoea index per 10 per cent of weight lost†, and the Sleep AHEAD randomised trial of intensive lifestyle intervention showed significant index reduction against control, with remission in a meaningful fraction. This is the one intervention that can cure the condition without a device, a drug or an operation. Positional measures, avoiding supine sleep: effective in position-dependent cases, achievable with no purchased product. Alcohol avoidance in the evening: demonstrated acute physiological worsening. Treating nasal obstruction: cheap, and it improves CPAP tolerance. Myofunctional therapy, meaning upper airway exercises: meta-analysis shows roughly 50 per cent reduction in the index in adults in small trials, on thin evidence, and the intervention costs nothing. Light, sleep timing, social connection and exercise-for-mood have no specific role here beyond their contribution to weight.

**Gaps.** There is no GBD estimate for a condition affecting 936 million adults aged 30 to 69 on the only global estimate available, which was ResMed-funded — the largest single data gap in this book. The disconnect between strong observational cardiovascular associations and null randomised outcomes is unresolved and consequential, because it determines whether screening asymptomatic people is worthwhile. The apnoea-hypopnoea index correlates poorly with symptoms and with outcomes and yet defines the disease; the field acknowledges the measure is inadequate and has no agreed replacement. Prevalence figures rest on a literature-based model rather than population polysomnography for most of the 193

countries. Almost all treatment evidence is from high-income settings, and CPAP requires electricity and maintenance.

---

## Central sleep apnoea

**What it is.** Breathing pauses during sleep caused by a failure of respiratory drive rather than airway collapse. The commonest adult form is Cheyne-Stokes respiration associated with heart failure. It also occurs with opioid use, at altitude, after stroke, and idiopathically.

**Measured.** Much less common than obstructive apnoea: roughly 1 per cent of the general adult population in community studies, strongly age- and male-skewed. In heart failure with reduced ejection fraction, central apnoea or Cheyne-Stokes respiration is present in roughly 25 to 40 per cent†. In chronic opioid therapy, central apnoea prevalence is roughly 15 to 30 per cent†. There is no WHO fact sheet and no GBD estimate. The presence of Cheyne-Stokes respiration in heart failure is associated with worse prognosis, and whether it is a marker or a contributor is unresolved.

**Where it starts.** Heart failure with reduced ejection fraction is the dominant cause in adults, through increased chemoreflex sensitivity — high loop gain — plus circulatory delay. Opioid use produces dose-related suppression of respiratory drive: established. At high altitude, periodic breathing is a normal physiological response above roughly 2,500 m. Stroke and brainstem lesions are established causes. Treatment-emergent central apnoea occurs in roughly 5 to 15 per cent of obstructive apnoea patients started on CPAP†, usually transiently. Congenital central hypoventilation syndrome, from *PHOX2B* mutations, is rare and a case where the genetic cause is fully established.

Loop-gain physiology is well characterised and quantitatively modelled, one of the better understood mechanisms in sleep medicine. Whether Cheyne-Stokes respiration in heart failure is harmful or a compensatory response is genuinely disputed, and the SERVE-HF result below is why.

**Cure status.** CONTROLLABLE in general. Where the cause is removed — opioid discontinuation, altitude descent, or successful heart failure treatment including cardiac resynchronisation, a ventricular assist device or transplantation — CURABLE.

**Prevention.** Optimal heart failure treatment: MODERATE, since improving cardiac function reduces central apnoea. Avoiding chronic high-dose opioid therapy: MODERATE. Acetazolamide for altitude periodic breathing is effective prophylactically; EML-listed, off-patent, a few US dollars a course.

**Treatment.** *Treat the underlying cause* first and most importantly. *Adaptive servo-ventilation* is a negative trial result that changed practice. SERVE-HF (Cowie and colleagues, *NEJM*, 2015; 1,325 participants with heart failure with reduced ejection fraction and predominant central apnoea) found that the device suppressed the apnoea effectively and that **all-cause and cardiovascular mortality were higher in the treated arm**, with a cardiovascular mortality hazard ratio of about 1.34. Adaptive servo-ventilation is now contraindicated in heart failure with reduced ejection fraction and predominant central apnoea. An effective physiological treatment increased deaths, and this is one of the clearest demonstrations in the book that correcting a measurement is not the same as helping a patient. *CPAP* has modest efficacy; the earlier CANPAP trial was neutral overall with a suggestion of benefit in those whose apnoea was suppressed. *Nocturnal oxygen* reduces central events with no mortality evidence. *Acetazolamide and theophylline* reduce central events through respiratory stimulation, in small trials; acetazolamide is EML-listed, off-patent, and costs tens of US dollars a patient-year at most. *Phrenic nerve stimulation*, transvenous, reduces events in randomised trials at a device cost in the tens of thousands of US dollars.

**Simple means.** Opioid reduction where that is the cause. Altitude descent where that is the cause. Avoiding the supine position: modest effect. Heart failure self-management — salt and fluid adherence, weight monitoring, medication adherence — addresses the cause, with no supply chain beyond the drugs already indicated.

**Gaps.** No burden estimate of any kind. The SERVE-HF mortality signal has no agreed mechanistic explanation. Whether treating central apnoea in heart failure helps at all remains

unanswered; what is now known is that one way of treating it harms. Treatment-emergent central apnoea has no agreed management pathway.

---

## Narcolepsy

**What it is.** Chronic inability to maintain stable wakefulness, with irresistible sleep attacks, and intrusion of REM-sleep phenomena into wakefulness. Type 1 includes cataplexy, sudden loss of muscle tone triggered by emotion, and is caused by loss of hypocretin, also called orexin, neurons. Type 2 lacks cataplexy and has normal hypocretin.

**Measured.** Prevalence is roughly 25 to 50 per 100,000 for type 1, with type 2 less well characterised†. Japan reports higher figures, up to about 160 per 100,000†, and Israel notably lower — a genuine and unexplained geographic variation. Onset is bimodal with peaks around age 15 and around age 35†. Diagnostic delay commonly exceeds a decade. There is no WHO fact sheet and no stand-alone GBD estimate. Mortality is not substantially elevated; the burden is in function, education, employment and accident risk.

**Where it starts.** This is the condition in these three chapters where the mechanism is best established. Loss of hypocretin-producing neurons in the lateral hypothalamus causes type 1 narcolepsy. Cerebrospinal fluid hypocretin-1 is undetectable or very low in roughly 90 to 95 per cent of type 1 cases, and post-mortem studies show loss of 85 to 95 per cent of these neurons†. This is a demonstrated cause rather than a hypothesis, which is a rarity in this chapter. *HLA-DQB1*06:02* is present in roughly 98 per cent of type 1 cases against roughly 25 per cent of the general population — the strongest HLA association known for any disease. That, with T-cell receptor associations, makes an autoimmune mechanism highly likely, and autoantigen-specific autoimmunity has not been definitively demonstrated.

The 2009 to 2010 Pandemrix association: following the H1N1 pandemic vaccination campaign, narcolepsy incidence rose in several European countries among vaccinated children and adolescents. Estimates centre on roughly one additional case per 16,000 vaccinated, with relative risks around 5 to 14 in Finland and Sweden†. The association was specific to one adjuvanted vaccine formulation and was not found for other H1N1 vaccines. Independently, H1N1 infection itself was associated with increased narcolepsy incidence in China, where vaccination coverage was low. Both findings support the autoimmune model triggered by influenza antigen exposure. Reported accurately: it is a genuine vaccine-associated harm, confined to one product, and it does not generalise to vaccines in general. Streptococcal infection is associated as a possible additional trigger. Not known: the autoantigen; why only a small fraction of *HLA-DQB1*06:02* carriers develop narcolepsy; whether early immunotherapy could preserve neurons, which is untested and for which the window has passed by the time of diagnosis. Type 2 narcolepsy and idiopathic hypersomnia have no established mechanism and may be heterogeneous.

**Cure status.** RELIEF ONLY. The neurons are gone and nothing restores them. No treatment is disease-modifying. Symptomatic treatment is effective and allows most people to function. Hypocretin receptor agonists in development may change this classification; as of this edition they are in trials, with hepatotoxicity signals in some programmes, and they are reported as not yet available.

**Prevention.** No established prevention. The Pandemrix finding led to withdrawal of that formulation, and adjuvant selection in future pandemic vaccines is an identified consideration: MODERATE as a product-specific lesson, not as a general preventive measure. Influenza vaccination with non-implicated formulations reduces H1N1 infection, which is itself associated with narcolepsy, so vaccination is net protective on current evidence: WEAK.

**Treatment.** *Scheduled daytime naps*: short planned naps substantially reduce sleepiness, and they are effective, free and underused. Here the simple means and the treatment coincide. *Modafinil and armodafinil* are first-line for sleepiness in most guidelines, with moderate effect sizes; not EML-listed, off-patent, low hundreds of US dollars a patient-year. *Sodium oxybate*, including the lower-sodium formulation, is the only agent effective for cataplexy, disrupted nocturnal sleep and daytime sleepiness simultaneously, with large effect sizes on cataplexy frequency; not EML-listed, patent status mixed, and costing a six-figure sum in US dollars a patient-year at US list price — among the highest-cost drugs in this book — with controlled-substance handling requirements.

*Pitolisant*, an H3 inverse agonist, is effective for sleepiness and cataplexy; not EML-listed, on patent, tens of thousands of US dollars a patient-year. *Solriamfetol* is effective for sleepiness; not EML-listed, on patent in most markets, thousands to tens of thousands of US dollars a patient-year. *Methylphenidate and amphetamines* are long-established, effective for sleepiness, and cheap; methylphenidate is EML-listed, off-patent, and costs tens to low hundreds of US dollars a patient-year. In most of the world this is the only affordable option. *Antidepressants for cataplexy* — venlafaxine, clomipramine, SSRIs — suppress REM sleep and reduce cataplexy; off-label, cheap, and the mainstay where sodium oxybate is unaffordable. Clomipramine and fluoxetine are EML-listed, off-patent, and cost a few to a few tens of US dollars a patient-year.

**Simple means.** Scheduled short naps at fixed times: measurable reduction in sleepiness, at no cost, and combined with a stimulant they allow many people to work. Fixed sleep and wake times with adequate nocturnal sleep opportunity: standard, and necessary for the naps to work. Avoiding alcohol and heavy meals reduces sleep attack frequency. Safety adaptation — driving restriction, workplace adjustment, swimming precautions — prevents the injuries that constitute much of the real harm, and is organisational rather than clinical. Note the cost asymmetry: scheduled naps with generic methylphenidate and generic clomipramine cost a few hundred US dollars a patient-year at most and achieve a substantial part of what the six-figure regimen achieves. The gap in effect is real and much smaller than the gap in price.

**Gaps.** Prevalence varies several-fold between countries with no explanation. Type 2 narcolepsy and idiopathic hypersomnia are poorly defined and may not be single entities. Diagnostic delay of a decade is the norm and is a service failure. Sodium oxybate pricing bears no relationship to manufacturing cost, since gamma-hydroxybutyrate is a simple molecule: a market problem, not a scientific one. There is no disease-modifying treatment and no trial of early immunotherapy.

---

## Restless legs syndrome

**What it is.** An urge to move the legs, usually with uncomfortable sensations, worse at rest and in the evening, and relieved by movement. It disrupts sleep onset. Most people with it also have periodic limb movements during sleep. Also called Willis-Ekbom disease.

**Measured.** Prevalence is roughly 5 to 10 per cent of adults in European-ancestry populations using full diagnostic criteria, and roughly 2 to 3 per cent clinically significant, meaning at least twice weekly with distress. It is substantially lower in East and South Asian populations, roughly 1 to 3 per cent, consistently†. Women roughly twice men. Prevalence rises with age. Roughly 20 to 30 per cent of pregnancies are affected, usually resolving after delivery. There is no WHO fact sheet and no stand-alone GBD estimate. It is associated with iron deficiency, end-stage renal disease where prevalence is roughly 20 to 30 per cent, pregnancy, and peripheral neuropathy.

**Where it starts.** Brain iron deficiency is the best-supported mechanism: cerebrospinal fluid ferritin is reduced, autopsy shows reduced substantia nigra iron, and MRI confirms reduced brain iron even in people with normal serum ferritin. Iron repletion improves symptoms. That is an unusually well-supported mechanism for this chapter. Heritability is roughly 50 to 60 per cent, and genome-wide association studies have identified reproducible loci including *MEIS1*, *BTBD9* and *PTPRD*, with *MEIS1* carrying one of the larger common-variant effect sizes in any complex trait. Iron deficiency from low serum ferritin, blood donation, gastrointestinal loss or pregnancy is established and treatable. End-stage renal disease is established and resolves after transplantation. Dopamine antagonists, antihistamines, SSRIs and some other antidepressants precipitate or worsen it, and drug-induced cases are common and reversible. The dopaminergic connection is supported by treatment response and by the diurnal pattern tracking the dopamine rhythm, and a primary dopamine deficiency has not been demonstrated. The iron-dopamine interaction in the brain is the working model, with good support from imaging, autopsy and treatment response. Not known: why the ethnic prevalence difference exists; why augmentation occurs; the relationship between the sensory symptom and the movement.

**Cure status.** Where a removable cause is found: CURABLE — iron repletion in iron deficiency, transplantation in renal failure, stopping a precipitating drug, delivery in pregnancy. Idiopathic disease: CONTROLLABLE. Augmentation is the central clinical problem: long-term dopamine agonist treatment causes symptoms to become earlier in the day, more severe, and to spread to other body parts, in a substantial proportion of patients, with estimates of roughly 7 to 8 per cent per year of treatment, cumulative†. That iatrogenic worsening led to a major guideline reversal: dopamine agonists are no longer first-line, having been first-line for two decades.

**Prevention.** Maintaining iron sufficiency, particularly in women of reproductive age, in pregnancy, in blood donors and in people with gastrointestinal blood loss: MODERATE. Avoiding precipitating drugs where alternatives exist: MODERATE. Not starting a dopamine agonist: STRONG as a negative recommendation, because it prevents augmentation. That is the clearest preventive statement available here.

**Treatment.** *Iron repletion*: oral iron where ferritin is low, and intravenous ferric carboxymaltose is effective in randomised trials even in some patients with normal-range ferritin. Oral ferrous salts are EML-listed and off-patent. The UNICEF Supply Catalogue, indicative price read 19 October 2026, gives iron 60 mg tablets at US$1.43 for a bottle of 100, about US$0.0143 a tablet, so about **US$5 a patient-year at one tablet a day**. The same catalogue returned US$1.60 for the same material number on a different page, so the figure is indicative and dated rather than a price. This is the cheapest effective treatment in this part of the book, and it treats the cause.

*Alpha-2-delta ligands* — gabapentin enacarbil, pregabalin, gabapentin — are now first-line in current guidelines, having displaced dopamine agonists because they do not cause augmentation, with moderate effect sizes on the IRLS score. Gabapentin and pregabalin are not EML-listed, both off-patent, costing tens to low hundreds of US dollars a patient-year. Harms: sedation, dizziness, weight gain, misuse potential. *Dopamine agonists* — pramipexole, ropinirole, the rotigotine patch — are effective short-term with large initial effect sizes, and cause augmentation in a substantial proportion on long-term use; now recommended for limited use; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year.

*Low-dose opioids*, as prolonged-release oxycodone with naloxone, are effective in refractory and augmented cases with randomised support, and dependence risk requires careful selection. No doses are given. *Stopping the precipitating drug* is curative where applicable, and free. *Pneumatic compression devices and near-infrared light*: small trials, uncertain.

**Simple means.** Oral iron where ferritin is low, at about US$5 a patient-year on the October 2026 indicative price, addressing the cause, and on the WHO Essential Medicines List. The best cost-to-effect ratio in Chapter 07. Movement, walking, stretching and counterstimulation: the symptom is relieved by movement by definition, and this is not trivial — it is how most people manage. Exercise: randomised trials show symptom reduction in both general and dialysis populations, with moderate effect sizes in small trials. Fixed sleep timing and adequate sleep, since sleep deprivation worsens symptoms. Reducing caffeine, alcohol and nicotine in the evening: commonly advised, weakly evidenced. Avoiding the precipitating drug: free, and sometimes curative.

**Gaps.** No burden estimate. The ethnic prevalence difference is robust and unexplained. The augmentation mechanism is unknown, and its true incidence is uncertain because most long-term data come from specialist clinics. The role of intravenous iron in patients with normal ferritin is supported by some trials and not others, and sources disagree. The guideline reversal on dopamine agonists happened late, after two decades of a treatment now known to cause iatrogenic worsening in many patients, and that is worth recording as an example of a well-intentioned standard treatment that caused harm at scale.

---

## Delayed sleep-wake phase disorder

**What it is.** Sleep that is normal in structure and quality but occurs persistently later on the clock than the person's required schedule allows, because the internal circadian clock runs late relative to the external day. The result is chronic sleep restriction on weekdays and a late, long sleep when the schedule permits.

**Measured.** Prevalence is roughly 0.2 to 10 per cent of adolescents and young adults depending on criteria, and the commonly cited figure in clinical populations is roughly 7 to 16 per cent of adolescents with chronic sleep-onset insomnia†. There is no WHO fact sheet and no stand-alone GBD estimate.

**Where it starts.** The circadian clock is a demonstrated molecular oscillator: the transcription-translation feedback loop of the *CLOCK*, *BMAL1*, *PER* and *CRY* genes was characterised in work that received the 2017 Nobel Prize in Physiology or Medicine. Light input via intrinsically photosensitive retinal ganglion cells containing melanopsin entrains it through the suprachiasmatic nucleus. Light is the dominant entraining signal and its effect is quantified: the phase response curve to light is measured. Light in the hours after the body temperature minimum, roughly early morning, advances the clock; light in the hours before it, evening and night, delays it.

Melatonin has a roughly opposite phase response curve. Phase shifts of several hours are achievable with controlled light and melatonin timing. Chronotype is heritable, roughly 40 to 50 per cent, with reproducible loci including *PER2*, *PER3* and *RGS16*; familial advanced sleep phase from *PER2* and *CSNK1D* mutations is a demonstrated monogenic trait†. This disorder specifically is associated with a longer intrinsic circadian period, altered light sensitivity, and behavioural reinforcement through evening light exposure and late social schedules.

Adolescence involves a physiological phase delay of roughly one to two hours, which is biological rather than a behavioural choice, so early school start times impose chronic sleep restriction on a whole population. Blindness without light perception produces non-24-hour sleep-wake rhythm disorder in a majority — a clean natural demonstration that light is the entraining signal. The mechanism is established at molecular, anatomical and physiological level with a quantified dose-response to light, which is the strongest mechanistic position of any condition in these three chapters, and it is why the simple means here work. Not known: why individual sensitivity to light varies so much.

**Cure status.** CONTROLLABLE. Correctly timed light and melatonin shift the clock and the sleep normalises, and the misalignment returns when the schedule or the light exposure reverts. Timed light plus timed melatonin plus behavioural scheduling advances phase reliably in trials, and relapse on stopping is common because the social schedule that produced the delay persists.

**Prevention.** Later school start times: STRONG. Delaying secondary school start times is followed by increased sleep duration, typically 25 to 45 minutes a night, reduced daytime sleepiness, improved attendance, and in several studies reduced adolescent motor vehicle crash rates, replicated across multiple districts and countries. The intervention is an administrative decision with no supply chain and no cost. Limiting evening light and screen exposure in adolescents: MODERATE; the physiological effect on melatonin onset is well quantified and the effect on disorder incidence less so.

**Treatment.** *Timed bright light exposure* is the primary treatment, with a quantified phase response curve: morning light to advance a delayed clock. Intensities of roughly 2,500 to 10,000 lux for 30 to 60 minutes are typical, and ordinary daylight outdoors exceeds this. The effect is phase shifts of one to three hours over days to weeks. It is free outdoors; a light box is a one-off purchase of a few tens to a few hundred US dollars. It is not a drug and has no EML entry. *Timed melatonin* advances phase when taken in the early evening; not EML-listed, off-patent, tens of US dollars a year. *Chronotherapy and progressive scheduling*, by systematically shifting bedtime, is effective and demanding. *Behavioural scheduling with a consistent wake time* is foundational and necessary for any of the above to hold.

**Simple means.** Light at fixed hours is not an adjunct here: it is the treatment, with a measured dose-response and the capacity for one-to-three-hour phase shifts, and outdoor morning light is free and brighter than any consumer light box. Fixed wake time, seven days a week, anchors the clock and is the single most effective behavioural instruction. Darkness and light avoidance at the appropriate hours matter as much as light exposure and are entirely free. Melatonin at tens of US dollars a year: physiologically targeted, cheap, off-patent. Later school start times: 25 to 45 minutes additional sleep per adolescent per night, population-wide, at no cost — the largest measured sleep effect of any intervention in this book per unit of expenditure.

**Gaps.** No burden estimate. The prevalence range from 0.2 to 10 per cent is a criteria artefact as much as a finding. The adolescent phase delay is physiologically established and school start times remain early in most of the world, which is an implementation failure. Melatonin dosing, timing and formulation are inconsistent across trials, and unregulated supplement content varies widely, so effect estimates are heterogeneous. Light therapy device standards are absent, and lux delivered at the eye is rarely measured in practice.

---

## Shift work disorder

**What it is.** Insomnia during the intended sleep period, or excessive sleepiness during the work period, arising from a work schedule that conflicts with the internal circadian clock.

**Measured.** Roughly 15 to 20 per cent of the workforce in industrialised economies works outside standard daytime hours, and shift work disorder affects roughly 10 to 30 per cent of those workers†. Shift work is classified by the International Agency for Research on Cancer as probably carcinogenic to humans, Group 2A, on the basis of the night-shift work and breast cancer evidence (IARC Monograph 124, 2019). The epidemiology is consistent and confounded, and the classification remains debated. Night shift work is associated with elevated cardiovascular and metabolic disease risk, roughly 1.2 to 1.4 times in meta-analyses, and with increased injury rates. There is no WHO fact sheet and no stand-alone GBD estimate, for a condition affecting a substantial fraction of the workforce.

**Where it starts.** The circadian mechanism is as set out in the delayed phase entry above: a molecular oscillator entrained by light through the suprachiasmatic nucleus, with a measured phase response curve. Shift work disorder arises because the schedule demands wakefulness and sleep at clock times the oscillator is not set for, and because the light exposure the schedule produces reinforces the misalignment rather than correcting it. Not known: why some shift workers adapt and others do not; whether the cancer association is causal.

**Cure status.** CONTROLLABLE while shift work continues; CURABLE on leaving shift work, since it resolves. While shift work continues only partial mitigation is possible. That is the honest position, and it makes the schedule the target rather than the worker.

**Prevention.** Shift schedule design: MODERATE. Forward-rotating schedules, day to evening to night, limiting consecutive night shifts, adequate inter-shift intervals, and avoiding quick returns all reduce fatigue and error in field studies and some randomised crossover trials. Timed light at work and timed darkness after: MODERATE; bright light during night shifts plus dark glasses on the commute home improves adaptation in controlled studies. Napping before night shifts: MODERATE; prophylactic naps reduce performance decrement and sleepiness. Restricting night work for those who cannot adapt: MODERATE, because the measure addresses the exposure.

**Treatment.** *Timed bright light exposure*, with the quantified phase response curve, free outdoors and a one-off purchase of a few tens to a few hundred US dollars for a light box. *Timed melatonin* shifts phase in shift work; not EML-listed, off-patent, tens of US dollars a year. *Behavioural scheduling and a consistent wake time* where the roster allows. *Modafinil and armodafinil* are approved for shift work disorder sleepiness, with modest effect on sleepiness and on performance; not EML-listed, off-patent, low hundreds of US dollars a patient-year. They treat the symptom and not the misalignment. *Hypnotics for daytime sleep* give modest benefit with next-shift impairment risk. *Caffeine, strategically timed*, has a well-evidenced performance effect and is the most widely used countermeasure in the world, effective for its purpose.

**Simple means.** Shift schedule design: an administrative act with measurable health and safety effects. Scheduled naps: measurable performance protection. Light at the right hours and darkness at the others: free, and the mechanism and the intervention coincide. Fixed wake time where the roster allows.

**Gaps.** No burden estimate. Whether the shift-work cancer association is causal is unresolved, and the Group 2A classification reflects that uncertainty. Long-term health outcomes of shift schedule redesign have not been trialled, only modelled from fatigue and error endpoints.

---

## Jet lag

**What it is.** Transient misalignment between the internal circadian clock and local time after rapid travel across time zones, with disturbed sleep, daytime sleepiness, impaired performance and gastrointestinal symptoms.

**Measured.** Near-universal after crossing three or more time zones. Eastward travel is worse than westward, because advancing the clock is harder than delaying it. There is no WHO fact sheet and no stand-alone GBD estimate.

**Where it starts.** The mechanism is the circadian oscillator and the light phase response curve described in the delayed phase entry: the clock re-entrains at a limited rate, and the direction of travel determines whether it must advance or delay. Individual variation in re-entrainment rate is substantial and unexplained.

**Cure status.** SELF-LIMITING, resolving at roughly one time zone a day untreated, and faster with timed light and melatonin.

**Prevention.** Jet lag pre-adaptation, by shifting sleep and light timing before travel: MODERATE. The measure is free.

**Treatment.** *Timed melatonin*: a Cochrane review of melatonin for jet lag found it effective for reducing jet lag symptoms across several trials; not EML-listed, off-patent, tens of US dollars a year. *Timed light exposure*, with the phase response curve, free outdoors. *Behavioural scheduling* onto local time on arrival. *Caffeine, strategically timed*, for daytime alertness. *Hypnotics* for sleep on arrival, with next-day impairment risk.

**Simple means.** Pre-travel phase shifting: free. Light at the correct local hours and avoidance of light at the wrong ones: free, and it is the active mechanism. Melatonin at tens of US dollars a year. Scheduled naps.

**Gaps.** No burden estimate. Melatonin dosing, timing and formulation are inconsistent across trials and supplement content varies widely. Trials are short, in small numbers, and mostly in healthy young adults.

---

## Non-REM parasomnias

**What it is.** Undesirable behaviours arising from incomplete awakening from deep sleep: confusional arousals, sleepwalking, sleep terrors and sleep-related eating. They are commonest in children and the person usually has no recollection of the event.

**Measured.** Sleepwalking affects roughly 5 per cent of children and roughly 1.5 to 2.5 per cent of adults, and childhood sleepwalking usually resolves by adolescence. Sleep terrors affect roughly 1 to 6 per cent of children and under 1 per cent of adults†. There is no WHO fact sheet and no GBD estimate. Adult prevalence is poorly measured.

**Where it starts.** Heritability is substantial: a parental history of sleepwalking raises a child's risk roughly three times for one affected parent and roughly seven times for two. Precipitants are well characterised — sleep deprivation, fever, alcohol, some medications, and anything causing arousal from deep sleep, including untreated obstructive sleep apnoea and restless legs syndrome. Treating the arousal trigger often resolves the parasomnia, an unusually clear causal chain for this chapter. State dissociation — partial arousal with motor systems active and consciousness absent — is supported by intracerebral recordings in individual cases, and is reasonably well established. Not known: why these cluster in families.

**Cure status.** In children: SELF-LIMITING. The large majority resolve by adolescence without treatment. In adults: CONTROLLABLE, and CURABLE where a precipitant — sleep apnoea, restless legs syndrome, a drug, sleep deprivation — is identified and removed.

**Prevention.** Adequate sleep and a regular schedule reduce frequency, since sleep deprivation is the most reliable experimental precipitant: MODERATE. Treating comorbid sleep apnoea and restless legs syndrome resolves a substantial fraction of adult cases: MODERATE. Avoiding precipitating drugs, including alcohol and the Z-drugs, whose complex sleep behaviours regulators have warned about: MODERATE.

**Treatment.** *Environmental safety measures* — removing hazards, floor-level sleeping, padding, securing windows and doors — are free and address the actual harm. *Treating the*

*precipitating condition*: CPAP for coexisting apnoea, iron for restless legs syndrome, withdrawal of the offending drug. Often curative in adults. *Scheduled awakenings* for children with predictable events: small trials, cheap, effective in some series. *Hypnosis and cognitive behavioural therapy for adults*: small case series and trials with positive results. *Clonazepam* is used in refractory adult cases; not EML-listed, off-patent, tens of US dollars a patient-year.

**Simple means.** Making the bedroom safe: it costs nothing but attention and it prevents the injuries. Adequate and regular sleep: the most reliable way to reduce frequency, since sleep deprivation is the main precipitant. Scheduled awakenings in children: free. Alcohol avoidance: a documented precipitant. Treating a coexisting sleep disorder, which in adults is often the whole treatment.

**Gaps.** Adult prevalence is poorly measured. No burden estimate. Why these cluster in families is unknown. Adult treatment evidence is almost entirely case series.

---

## REM sleep behaviour disorder and nightmare disorder

**What it is.** In REM sleep behaviour disorder, the person acts out dreams because the normal muscle paralysis of REM sleep is absent, with injury to the sleeper or the bed partner. It is commonest in older men. Nightmare disorder is repeated frightening dreams that wake the person and impair daytime functioning, and it is reported separately here because its treatment and its outlook differ entirely.

**Measured.** REM sleep behaviour disorder affects roughly 0.5 to 1.1 per cent of adults over 60, with a male predominance of roughly 2 to 4 to 1†. Nightmare disorder: frequent nightmares occur in roughly 2 to 6 per cent of adults, and far more in post-traumatic stress disorder, where they are near-universal. There is no WHO fact sheet and no GBD estimate. The most consequential measured fact here is conversion. Isolated, so-called idiopathic, REM sleep behaviour disorder converts to an overt alpha-synuclein neurodegenerative disease — Parkinson disease, dementia with Lewy bodies, or multiple system atrophy. The rate is roughly 6 to 8 per cent a year, reaching approximately 73 to 96 per cent at 12 to 14 years of follow-up in multicentre cohort studies (Postuma and colleagues, *Brain*, 2019, and longer follow-up series). It is the strongest known clinical predictor of future Parkinson disease or Lewy body dementia.

**Where it starts.** REM sleep behaviour disorder arises from loss of REM atonia through degeneration of brainstem nuclei in the sublaterodorsal and subcoeruleus region. In the isolated form this reflects early alpha-synuclein pathology ascending through the brainstem, consistent with the Braak staging sequence. That makes it an early manifestation of a neurodegenerative disease rather than a sleep disorder with a neurological association. Secondary forms occur in narcolepsy type 1, with antidepressant use, since SSRIs and SNRIs can unmask or cause it, and with brainstem lesions. The brainstem localisation and the alpha-synuclein link are well supported by the conversion data and by neuropathology. For nightmare disorder, trauma exposure is the dominant association. Not known: why some people with alpha-synuclein pathology present first with REM sleep behaviour disorder and others with motor or cognitive symptoms; whether conversion can be delayed.

**Cure status.** REM sleep behaviour disorder: RELIEF ONLY. The behaviour is controllable; the underlying neurodegeneration is not, and no treatment has been shown to delay or prevent conversion. Nightmare disorder: CURABLE — imagery rehearsal therapy produces durable reduction.

**Prevention.** For conversion in REM sleep behaviour disorder, nothing is established. No neuroprotective intervention has been shown to delay conversion, despite this being the ideal population for such trials; trials are under way and none has succeeded. The absence is reported as an absence. Safety measures do not prevent the disease and prevent the injuries, which are the immediate harm: STRONG for the injury outcome. Avoiding antidepressants where alternatives exist, in those at risk: MODERATE.

**Treatment.** *Environmental safety measures* — removing hazards, floor-level sleeping, padding, securing windows, and bed partner separation where injury has occurred — are free and are first-line in guidelines for REM sleep behaviour disorder, before any drug. *Clonazepam* is long-established and effective in roughly 80 to 90 per cent of cases in observa-

tional series, with little randomised evidence; not EML-listed, off-patent, tens of US dollars a patient-year. Harms: sedation, falls, worsening of coexisting sleep apnoea, and cognitive effects in a population already at neurodegenerative risk. *Melatonin* is effective in small randomised and open trials with a better safety profile than clonazepam in older adults; the efficacy evidence is weaker and the harm profile better. Not EML-listed, off-patent, tens of US dollars a year. *Imagery rehearsal therapy for nightmare disorder* is the best-evidenced treatment, with moderate-to-large effect sizes in randomised trials including in post-traumatic stress populations, and durable gains. It is a purely behavioural treatment requiring no product. *Prazosin for trauma-related nightmares* showed benefit in earlier trials and was not confirmed in the largest subsequent trial: CONTESTED.

**Simple means.** Making the bedroom safe: the first-line intervention in REM sleep behaviour disorder and the measure that prevents the fractures, lacerations and subdural haematomas that constitute the real harm. It costs nothing but attention. Imagery rehearsal therapy: a behavioural protocol deliverable from written instructions, with randomised support that exceeds the drug evidence for nightmares. Melatonin at tens of US dollars a year, against clonazepam's better efficacy evidence and worse harm profile in older adults. Alcohol avoidance.

**Gaps.** Conversion rates come from specialist-clinic cohorts, and the population conversion rate may be lower. Clonazepam is standard practice on almost no randomised evidence, in a population at risk of falls and cognitive decline. No neuroprotective trial has succeeded, and the ideal prodromal population exists and is identifiable, so the gap is in the interventions rather than the cohort. Whether to tell a person with isolated REM sleep behaviour disorder their conversion risk is an open ethical question with no evidence base on outcomes either way.

# 08 — Diseases of the nervous system

**Chapter-level measured context.** On the GBD 2021 nervous system analysis, about 3.4 billion people had a nervous system condition in 2021, roughly 43 per cent of the world's population. These conditions accounted for 443 million DALYs, up from about 375 million in 1990 — an 18 per cent absolute increase. Case numbers rose 59 per cent globally while age-standardised DALY rates fell 27 per cent and age-standardised death rates fell 34 per cent. Nervous system conditions were the leading cause of illness and disability worldwide by DALYs on that analysis. The top ten contributors by DALYs, in rank order, were stroke, neonatal encephalopathy, migraine, Alzheimer disease and other dementias, diabetic neuropathy, meningitis, epilepsy, neurological complications of preterm birth, autism spectrum disorder, and nervous system cancers. The neurological consequences of COVID-19 ranked twentieth at 2.48 million DALYs†. Diabetic neuropathy cases more than tripled since 1990, reaching 206 million. Modifying 18 risk factors could prevent 84 per cent of global stroke DALYs, and high systolic blood pressure alone accounts for 57 per cent of them. Controlling lead exposure could reduce the intellectual disability burden by 63 per cent. Normalising high fasting plasma glucose could reduce the dementia burden by about 15 per cent.

---

## Alzheimer disease

*The Chapter 06 dementia entry covers the syndrome, its care, the full prevention evidence and the anti-amyloid antibody data in detail. This entry covers Alzheimer disease as a disease of the nervous system.*

**What it is.** A progressive degenerative brain disease characterised by extracellular amyloid-beta plaques and intracellular tau neurofibrillary tangles, with synapse and neuron loss. It is the commonest cause of dementia. The pathology begins roughly two decades before symptoms.

**Measured.** Alzheimer disease accounts for 60 to 70 per cent of the 57 million dementia cases worldwide (WHO dementia fact sheet, 3 July 2026, 2021 data), roughly 34 to 40 million people. It ranked fourth among nervous system conditions by DALYs on GBD 2021. Alzheimer's disease and other dementias were the fifth leading cause of death globally in 2023 at 2.1 million (WHO Global Health Estimates, 2 October 2026), while the dementia fact sheet gives dementia as the seventh leading cause of death without a data year; both WHO figures are printed. Alzheimer's disease and other dementias rank twenty-second among all causes of years lived with disability at 12.2 million YLDs (95 per cent UI 8.52 to 15.6) in 2023. Age-specific incidence has been falling by roughly 13 per cent per decade in pooled Western cohort analyses while absolute numbers rise with population ageing. Young-onset disease, before 65, accounts for up to 9 per cent of dementia cases. Women are affected more than men in absolute numbers, largely but not entirely explained by greater longevity. The economic cost of all dementia was US$1.3 trillion in 2019, about half of it from informal care.

**Where it starts.** Age is dominant: prevalence roughly doubles every five years after 65. *APOE* ε4 carries roughly three times the risk for one copy and roughly 8 to 12 times for two†, the largest common genetic risk factor. Autosomal dominant mutations in *APP*, *PSEN1* and *PSEN2* have near-complete penetrance, account for under 1 per cent of cases†, and are the

genetic evidence that amyloid processing is causally involved. Down syndrome carries three copies of *APP*, and the large majority of people with it develop Alzheimer pathology by their sixties — a natural experiment supporting the amyloid link. Heritability of late-onset disease is roughly 60 to 80 per cent in twin studies†. The Lancet Commission 2024's 14 modifiable factors carry a combined population attributable fraction of 45 per cent, and the full list, the individual PAFs and the prevention grades are in the Chapter 06 dementia entry. Mixed pathology — Alzheimer plus vascular plus Lewy body — is the rule at autopsy rather than the exception, which complicates every clinical trial of a single-target drug.

The amyloid cascade hypothesis has driven three decades of research. The anti-amyloid antibodies show that removing amyloid produces a small slowing of decline, supporting a causal role while showing the effect size is far below what the hypothesis predicted. Dozens of amyloid-targeting agents failed before two succeeded marginally. Tau pathology correlates better with clinical severity than amyloid does, and tau-targeting agents have so far failed. A widely cited 2006 *Nature* paper on amyloid-beta*56 was retracted in 2024 after image-manipulation findings, and several other papers in this field have been retracted; the amyloid hypothesis does not rest on those papers, and this is part of the record. Not known: what initiates the pathology two decades before symptoms; why some people with heavy autopsy pathology had no dementia; whether earlier intervention would do more.

**Cure status.** RELIEF ONLY. No treatment reverses or halts the disease. The anti-amyloid antibodies slow measured decline by roughly a quarter to a third over eighteen months.

**Prevention.** The full evidence is in the Chapter 06 dementia entry, including SPRINT MIND — probable dementia hazard ratio 0.83 (95 per cent CI 0.67 to 1.04), not significant; mild cognitive impairment 0.81 (0.69 to 0.95), significant; the composite 0.85 (0.74 to 0.97), significant† — and ACHIEVE's null primary outcome, a three-year cognitive change difference of 0.002 SD units (p=0.96), with the circulating 48 per cent being a high-risk subgroup result†. Summary grades: blood pressure control MODERATE; education MODERATE; smoking cessation, physical activity, diabetes control, LDL control, hearing and vision treatment, alcohol reduction, head injury prevention, air pollution reduction and addressing social isolation all MODERATE; hearing aids for cognition specifically CONTESTED; multidomain intervention CONTESTED; cognitive training CONTESTED.

**Treatment.** Full detail is in the Chapter 06 dementia entry. Lecanemab: CDR-SB difference −0.45 points, 27 per cent slowing, ARIA-E 12.5 against 1.7 per cent, ARIA-H 17.0 against 8.7 per cent; US$26,500 a year at US list price†; not EML-listed†, on patent. Donanemab: 22 per cent iADRS slowing in all participants and 35 per cent in the primary analysis population, ARIA-E 24 per cent, ARIA-H 31.4 against 13.6 per cent, serious ARIA 1.6 per cent†; US$32,000 a year at US list price†; not EML-listed†, on patent. Neither is on the Essential Medicines List, and the infrastructure both require does not exist where most people with dementia live. Also: cholinesterase inhibitors, memantine, antipsychotic harms, and carer support.

**Simple means.** See the Chapter 06 dementia entry. The key comparison: blood pressure control with off-patent EML-listed drugs, at roughly ten to twelve US dollars a patient-year for amlodipine on the September 2026 NHS Drug Tariff, produced the SPRINT MIND composite hazard ratio of 0.85; the anti-amyloid antibodies cost US$26,500 to 32,000 a year at US list price, plus infrastructure, for a 27 to 35 per cent slowing that does not halt decline.

**Gaps.** See the Chapter 06 dementia entry. In addition: there are no biomarker-confirmed prevalence data for most of the world, so the 60 to 70 per cent share of dementia attributed to Alzheimer disease is a clinical-diagnostic estimate, and mixed pathology makes the attribution partly arbitrary. WHO's own two pages rank dementia fifth and seventh among causes of death.

---

## Parkinson disease

**What it is.** A progressive degenerative disease with loss of dopamine-producing neurons in the substantia nigra and accumulation of alpha-synuclein. It causes slowness of movement, rigidity, tremor and postural instability, together with non-motor features — constipation, loss of smell, sleep disorder, depression, cognitive decline — that often precede the motor signs by years.

**Measured.** Over 8.5 million people worldwide (WHO Parkinson disease fact sheet, 9 August 2023, 2019 data). Prevalence has doubled in the past 25 years. 5.8 million DALYs, up 81 per cent since 2000. 329,000 deaths, up more than 100 per cent since 2000. By both measures this is the fastest-growing neurological condition. Incidence rises steeply after 60: roughly 1 per cent of people over 60 and 3 per cent over 80. Young-onset disease, before 50, is roughly 5 to 10 per cent of cases. Men roughly 1.4 to 2 times women. Prevalence estimates are higher in Europe, North America and parts of South America than in sub-Saharan Africa and parts of Asia, and how much of that is ascertainment is unresolved. The WHO figures make this the clearest example in the book of a rising neurological burden exceeding what population ageing alone predicts.

**Where it starts.** Age is dominant. Genetics: *LRRK2*, *GBA1*, *SNCA*, *PRKN*, *PINK1* and others. *GBA1* variants are the commonest genetic risk factor, carried by roughly 5 to 10 per cent of patients, with odds ratios around 3 to 5; monogenic forms account for roughly 5 to 10 per cent of cases; heritability is roughly 20 to 30 per cent† — notably lower than for Alzheimer disease or the psychiatric conditions, which points to environment. Pesticide exposure: paraquat and rotenone are the best characterised, with odds ratios of roughly 1.5 to 2.5 in meta-analyses and dose-response, among the most consistent environmental associations in neurology.

Trichloroethylene and other chlorinated solvents are associated with a notable occupational-cohort signal, odds ratios around 1.5 to 6 in some studies†, and the Camp Lejeune cohort study found elevated risk with trichloroethylene-contaminated water exposure. Traumatic brain injury, roughly 1.3 to 1.6 times†. Protective associations: smoking at roughly 0.5 times and caffeine at roughly 0.7 times are consistently and robustly inversely associated — among the most replicated findings in the field, and still unexplained. Reverse causation via prodromal personality change has been proposed and does not fully account for the smoking effect.

This is a mechanistic clue and not a recommendation, and it is not translated into advice. REM sleep behaviour disorder converts to Parkinson disease or a related alpha-synucleinopathy at roughly 6 to 8 per cent a year, reaching 73 to 96 per cent at 12 to 14 years† — the strongest clinical prodromal marker known. Constipation and loss of smell precede motor onset by years to decades.

Dopaminergic nigrostriatal degeneration is established and explains the motor features and the levodopa response: one of the clearest disease mechanisms in the book. Alpha-synuclein aggregation is established pathologically, and whether it is the cause, a consequence, or a protective sequestration is genuinely disputed. The Braak staging hypothesis, in which pathology ascends from the gut and olfactory bulb through the brainstem, is supported by the prodromal symptom sequence and by some pathology series and not by all: unresolved. Mitochondrial dysfunction and lysosomal impairment, the *GBA1* link, are supported. Not known: what initiates the process; why cell loss is selective; why no neuroprotective trial has succeeded despite a well-characterised target; whether gut microbiome findings are causal or consequential.

**Cure status.** RELIEF ONLY, and the relief is substantial and transformative for years. No treatment slows progression, and every neuroprotection trial has failed. Levodopa relieves motor symptoms highly effectively, and the response is so reliable that absence of response questions the diagnosis. After roughly five to ten years, motor fluctuations and levodopa-induced dyskinesia develop in a majority, which is the main limitation on long-term symptom control. Non-motor features — cognitive decline, autonomic failure, falls — progressively dominate and respond poorly to dopaminergic treatment. Median survival from diagnosis is roughly 10 to 20 years depending on age at onset.

**Prevention.** Reducing pesticide exposure, with paraquat banned in the European Union and many countries and still used elsewhere: MODERATE. The exposure-outcome association is among the most consistent in neuroepidemiology and the intervention evidence is regulatory rather than trial-based. Reducing solvent exposure, trichloroethylene and perchloroethylene, in occupational and water-supply settings: MODERATE. Preventing head injury through helmet law and road safety: WEAK for this endpoint specifically. Physical activity: prospective cohorts show lower incidence in the physically active, roughly 0.7 to 0.8 times in meta-analyses with dose-response†, and reverse causation from the prodromal period is a serious confounder since bradykinesia precedes diagnosis: WEAK. There is no established preventive intervention.

**Treatment.** *Levodopa with a peripheral decarboxylase inhibitor*, carbidopa or benserazide, is the most effective symptomatic treatment for any neurodegenerative disease, with large effect sizes on motor function. EML-listed, off-patent, and costing tens to low hundreds of US dollars a patient-year. The PD MED and ELLDOPA trials established that early levodopa does not accelerate progression, settling a long-standing concern. Harms: motor fluctuations and dyskinesia with long-term use, nausea, orthostatic hypotension, and less impulse control disorder than with agonists. *Dopamine agonists* — pramipexole, ropinirole, rotigotine — are effective, with less early dyskinesia and more impulse control disorder, hallucinations, sleepiness and oedema. In the PD MED trial, levodopa-first produced better patient-rated mobility than agonist-first. Not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year. Impulse control disorders — pathological gambling, hypersexuality, compulsive shopping and eating — occur in roughly 15 to 25 per cent on agonists†, a serious and often missed harm.

*MAO-B inhibitors*, selegiline and rasagiline, give modest symptomatic benefit, and the claimed neuroprotection was not confirmed; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year. *COMT inhibitors*, entacapone and opicapone, extend the levodopa effect in fluctuating patients; not EML-listed, entacapone off-patent, low hundreds of US dollars a patient-year. *Amantadine* is the only agent with established benefit for levodopa-induced dyskinesia; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year. *Deep brain stimulation* of the subthalamic nucleus or globus pallidus interna has a large effect on motor fluctuations and dyskinesia in randomised trials, and is the best-evidenced neurosurgical intervention in the book. Device and procedure costs run to tens of thousands of US dollars plus battery replacement, and it suits a minority: levodopa-responsive, without significant cognitive impairment.

*Levodopa-carbidopa intestinal gel and apomorphine infusion* are used for advanced fluctuations at costs in the tens of thousands of US dollars a year. *Physiotherapy, and specifically high-intensity exercise*: the SPARX phase 2 trial found high-intensity treadmill exercise feasible and associated with less motor progression at six months than usual care, and the phase 3 SPARX3 trial is the definitive test. Amplitude-based training and cueing improve gait and function in randomised trials. This is the only intervention with any signal of affecting progression, and the signal is not yet established. *Speech and swallowing therapy* improves voice intensity in randomised trials, and aspiration pneumonia is a leading cause of death, so swallowing management matters for survival.

*Treating non-motor features*: constipation, orthostatic hypotension, REM sleep behaviour disorder, depression, and psychosis — where clozapine and pimavanserin are the agents that do not worsen motor function and other antipsychotics do.

**Simple means.** Exercise is the strongest simple-means candidate for this condition. Randomised trials establish improvement in gait, balance and function, and SPARX suggests a possible effect on progression that no drug has achieved. High-intensity aerobic exercise, resistance training, tai chi with randomised evidence for balance and falls reduction, dance and boxing-style programmes all have trial support for function. It is comparable to medication for balance, falls and function, and not comparable for the core motor symptoms, where levodopa is far superior. Cueing — a metronome, rhythmic auditory stimulation, visual floor markers — for freezing of gait is effective and costs nothing. Fall-proofing the home: falls and the resulting fractures are a major cause of disability and death. Voice exercises practised independently. Fibre, fluid and activity for constipation, the commonest non-motor symptom. Fixed sleep timing and bedroom safety for REM sleep behaviour disorder. Social connection and continued activity: associated with slower functional decline, observational.

**Gaps.** The doubling of prevalence in 25 years and the 81 per cent DALY rise exceed what ageing predicts, the excess is unexplained, and the pesticide and solvent hypotheses are the leading but unproven candidates. There is no neuroprotective treatment despite the clearest target in neurodegeneration, and the repeated failure is itself a major scientific problem. The inverse smoking and caffeine associations are robust and unexplained. Whether exercise modifies progression is the most important open question with a trial under way. WHO's figures are from 2019 and the fact sheet dates from 2023. Prevalence data from sub-Saharan Africa and much of Asia are very sparse.

## Stroke

**What it is.** Sudden loss of brain function caused by interrupted blood supply, which is ischaemic stroke, or by bleeding into or around the brain, which is haemorrhagic stroke.

**Measured.** 11.9 million new strokes in 2021, with an estimated 93.8 million people living with stroke (WHO stroke fact sheet, 2021 data). Another dossier in this book gives roughly 12 million incident strokes, which is compatible, and about 101 million prevalent stroke survivors from the GBD 2019 and 2021 stroke capstone — 7.2 million more than the 93.8 million here. Both stand; the sources and the reference years differ. Stroke DALYs: **157 million (95 per cent UI 141 to 172) on GBD 2023**, which is the figure to quote. WHO's stroke fact sheet gives 160 million in 2021, up from 137 million in 2000, and that is printed beside the GBD figure, not instead of it, because the two bodies measure differently.

Stroke ranks third among all causes of DALYs in 2023 and ranked first among all nervous system conditions by DALYs on GBD 2021. It ranks seventeenth among all causes of years lived with disability at 16.7 million YLDs (95 per cent UI 12.0 to 21.2) in 2023. Stroke was the second leading cause of death globally in 2023 at 6.8 million, about 11 per cent of all deaths (WHO Global Health Estimates, 2 October 2026), while the stroke fact sheet calls it the third leading cause of death and disability; both are printed. One in four adults is predicted to have a stroke in their lifetime, and lifetime risk is up 50 per cent over the past twenty years; another dossier in this book gives 24.9 per cent from age 25 on the GBD 2016 lifetime risk analysis, which is compatible and differently based, and both stand.

The ischaemic share of all stroke is given as roughly 70 to 85 per cent of cases here, as about four in five in one section of another dossier, and as roughly 62 to 65 per cent globally with about 87 per cent in high-income countries in another section of it†; all three stand, unresolved. Hypertension carries nearly three times the stroke risk of people without it. Tobacco is associated with about two-fifths of stroke deaths in people under 65. Modifying 18 risk factors could prevent 84 per cent of global stroke DALYs, and high systolic blood pressure alone accounts for 57 per cent†.

Hypertension context: about 1.4 billion adults aged 30 to 79 had hypertension in 2024, 33 per cent; about 630 million diagnosed and treated; only about 320 million controlled, 23 per cent; about 600 million unaware. Age-standardised incidence and mortality are falling in high-income countries and rising or static in many low- and middle-income countries, where the majority of strokes now occur and where the mean age at stroke is lower.

**Where it starts.** This is the best-quantified aetiology in the book. INTERSTROKE (O'Donnell and colleagues, *Lancet*, 2016; 26,919 participants, 32 countries) found ten modifiable risk factors accounting for roughly 90 per cent of the population attributable risk for stroke: hypertension with a population attributable risk of about 48 per cent, physical inactivity 36 per cent, apolipoproteins and lipids 27 per cent, diet 23 per cent, waist-to-hip ratio 19 per cent, psychosocial factors 17 per cent, smoking 12 per cent, cardiac causes 9 per cent, alcohol 6 per cent, diabetes 4 per cent.

Those are for all stroke, and the hypertension contribution is larger for intracerebral haemorrhage. Another dossier in this book prints the same table to one decimal place from the published values — all stroke 90.7 per cent, ischaemic 91.5 per cent, intracerebral haemorrhage 87.1 per cent, hypertension 47.9 per cent† — against the integers rounded here; both stand, and the published values are the decimals. Atrial fibrillation carries roughly five times the stroke risk untreated, and it is the single most treatable individual cause, because anticoagulation reduces that risk by roughly two thirds.

High systolic blood pressure accounts for 57 per cent of stroke DALYs†. Salt: global mean intake is 4,278 mg a day of sodium, about 11 g a day of salt, more than double the WHO limit of under 2,000 mg of sodium, and about 1.7 million deaths a year are associated with excess sodium. Air pollution is a substantial contributor in GBD estimates. Heritability of stroke is roughly 30 to 40 per cent†, and monogenic causes such as CADASIL, sickle cell disease and Fabry disease are rare and important because they are identifiable.

Established mechanisms: atherosclerosis, cardioembolism, small vessel disease, and hypertensive vessel rupture. They are understood at the level needed for prevention and treatment, which distinguishes stroke from most of the book. Not known: why cryptogenic stroke, roughly 25 per cent of ischaemic strokes†, occurs; the determinants of individual collateral

circulation, which largely determines outcome; why recovery trajectories differ so much between people with similar lesions.

**Cure status.** Established damage: RELIEF ONLY. Treated by intravenous thrombolysis or mechanical thrombectomy: CURABLE where function is restored. The proportion is not established in this compilation. The effect declines to zero by roughly four and a half to six hours. Reperfusion therapy within hours can abolish the deficit entirely in some patients. Recurrence is roughly 10 per cent in the first year without secondary prevention, falling to roughly 2 to 4 per cent a year with it†.

**Prevention.** The strongest prevention evidence in Chapter 08. *Blood pressure control*: STRONG, and the single highest-yield intervention. Meta-analyses of antihypertensive trials show roughly 35 to 40 per cent stroke risk reduction, and a 10 mm Hg systolic reduction is associated with roughly 27 per cent lower stroke risk†. 57 per cent of stroke DALYs are attributable to high systolic blood pressure. The gap is implementation: only 23 per cent of the 1.4 billion people with hypertension are controlled. *Population salt reduction*: STRONG. The China Salt Substitute and Stroke Study (Neal and colleagues, *NEJM*, 2021) randomised 600 villages and 20,995 participants with a history of stroke or high blood pressure, over a mean 4.74 years. Potassium-enriched salt substitute reduced stroke by 14 per cent, rate ratio 0.86 (95 per cent CI 0.77 to 0.96), major cardiovascular events by 13 per cent and total deaths by 12 per cent, with no excess of serious hyperkalaemia. A randomised trial of a food, in 21,000 people, showing stroke reduction — one of the most important prevention results in the book.

*Anticoagulation for atrial fibrillation*: STRONG. It reduces stroke by roughly 64 per cent against control in the warfarin meta-analysis, and direct oral anticoagulants are at least as effective with less intracranial haemorrhage. Warfarin is EML-listed and off-patent, costing tens of US dollars a patient-year plus INR monitoring; dabigatran is EML-listed, added in 2019, off-patent in many markets, and costs low hundreds of US dollars a patient-year. *Smoking cessation*: STRONG; risk falls substantially within years of quitting, and tobacco is associated with two-fifths of stroke deaths under 65. *Statins for secondary and high-risk primary prevention*: STRONG, at roughly 21 per cent relative reduction in major vascular events per 1 mmol/L of LDL reduction in the Cholesterol Treatment Trialists' meta-analysis. Simvastatin and atorvastatin are EML-listed and off-patent, costing on the order of tens of US dollars a patient-year.

*Antiplatelet therapy after ischaemic stroke*: STRONG. Aspirin is EML-listed and off-patent at a few US dollars a patient-year, and is one of the cheapest effective interventions in medicine. *Physical activity*: MODERATE, with a population attributable risk of 36 per cent in INTERSTROKE. *Diabetes control*: MODERATE. *Air pollution reduction*: MODERATE. *Alcohol reduction*: MODERATE, population attributable risk 6 per cent in INTERSTROKE and larger for haemorrhagic stroke. *Carotid endarterectomy for severe symptomatic stenosis*: STRONG in selected patients. Blood pressure control also prevents vascular dementia, with the SPRINT MIND composite hazard ratio of 0.85†.

**Treatment.** *Mechanical thrombectomy for large vessel occlusion* has the largest treatment effect in acute stroke care. The HERMES pooled analysis of the 2015 trials gives a number needed to treat of about 2.6 for reduced disability at 90 days, with an odds ratio of 2.49 for improved functional outcome. Extended-window trials, DAWN and DEFUSE 3, showed benefit up to 24 hours in selected patients. It requires a comprehensive stroke centre, and the procedure cost runs to tens of thousands of US dollars; another dossier in this book gives tens of thousands of euro per procedure, and this chapter's compilation gave a dollar range that was an unsourced estimate and is not printed.

*Intravenous thrombolysis* with alteplase or tenecteplase gives benefit that is strongly time-dependent: within three hours roughly one in ten treated has a better outcome, and the effect declines to zero by roughly four and a half to six hours. Symptomatic intracranial haemorrhage occurs in roughly 2 to 7 per cent†. Alteplase is EML-listed for ischaemic stroke, off-patent in some markets, and costs on the order of thousands of US dollars a treatment. Tenecteplase is non-inferior, single-bolus and cheaper to administer. *Aspirin within 48 hours* gives small but real benefit; EML-listed†, at near-zero cost. *Stroke unit care*: organised inpatient stroke unit care against general ward care reduces death and dependency, with a number needed to treat of roughly 20 in Cochrane review†. It is an organisational interven-

tion with no drug, no device and no new technology, and it saves more lives globally than thrombectomy because it can be delivered everywhere.

*Decompressive craniectomy* for malignant middle cerebral artery infarction in younger patients reduces mortality substantially, and survivors have significant disability.

**Simple means.** Salt reduction and salt substitution: a cluster-randomised trial of 20,995 people found a 14 per cent stroke reduction, rate ratio 0.86 (0.77 to 0.96), from changing the salt on the table, and potassium-enriched salt substitute costs marginally more than ordinary salt. This is the single most important simple-means finding in Chapter 08, and the trial evidence is comparable to drug evidence because it is a randomised trial with a clinical endpoint. Blood pressure control with off-patent EML drugs — hydrochlorothiazide, amlodipine, enalapril, losartan — at roughly ten to twelve US dollars a patient-year for amlodipine on the September 2026 NHS Drug Tariff, delivering 35 to 40 per cent stroke reduction. Aspirin at a few US dollars a patient-year for secondary prevention. Physical activity, with a population attributable risk of 36 per cent in INTERSTROKE, free. Smoking cessation: free, or a few US dollars for cytisine. Stroke unit organisation: number needed to treat about 20, no technology required. Rapid presentation, meaning recognising stroke and calling for help immediately, determines whether reperfusion is possible at all, and public education campaigns measurably shorten presentation times. Swallow screening with a glass of water before giving food prevents aspiration pneumonia, a leading cause of post-stroke death: a nurse and a cup.

**Gaps.** The 84-per-cent-preventable figure and INTERSTROKE's 90 per cent population attributable risk are modelled upper bounds assuming complete factor elimination and independence; they are not achievable targets. Thrombectomy requires infrastructure available to a small minority of the world's population, and the equity gap is the dominant practical issue rather than the evidence. WHO's fact sheet gives no absolute stroke death total, so mortality comparisons must come from the Global Health Estimates or GBD directly. The prevalent-case figures of 93.8 and 101 million differ by 7.2 million and both are in circulation.

---

## Stroke sequelae

**What it is.** The lasting consequences of stroke: weakness, speech and swallowing impairment, visual loss, cognitive impairment, post-stroke depression, spasticity, pain and epilepsy.

**Measured.** An estimated 93.8 million people were living with stroke in 2021 (WHO), and another dossier in this book gives about 101 million from the GBD stroke capstone; both stand. Stroke's 16.7 million years lived with disability in 2023 (95 per cent UI 12.0 to 21.2) is the measure of the sequelae rather than of the acute event. Post-stroke depression affects roughly a third of survivors. Post-stroke epilepsy is a recognised consequence, and stroke is the commonest cause of new-onset epilepsy in older adults.

**Where it starts.** The sequelae follow from the location and the volume of the infarct or haemorrhage, and from the individual's collateral circulation, which largely determines outcome and whose determinants are not known. Recovery trajectories differ markedly between people with similar lesions, and why is not known.

**Cure status.** RELIEF ONLY. Rehabilitation improves function substantially and does not restore lost tissue. Spontaneous recovery is substantial in the first three months and continues more slowly thereafter.

**Prevention.** Preventing the recurrence is the main lever and the measures are in the stroke entry above: blood pressure control STRONG, salt reduction STRONG, anticoagulation for atrial fibrillation STRONG, statins STRONG, antiplatelet therapy STRONG. Early organised stroke unit care reduces death and dependency, number needed to treat roughly 20†: STRONG. Swallow screening before the first oral intake prevents aspiration pneumonia: STRONG for that outcome.

**Treatment.** *Rehabilitation*: the evidence favours intensity and task-specific practice. Constraint-induced movement therapy improved arm function in the EXCITE trial. *Fluoxetine to enhance motor recovery* was tested in three large trials — FOCUS, AFFINITY and EFFECTS — and did not improve functional outcome, while increasing fracture risk: a clear negative result after promising early data, and no pharmacological agent enhances recov-

ery. *Early supported discharge and community rehabilitation* reduce dependency, Cochrane-supported. *Treating the individual sequelae*: spasticity with botulinum toxin and physiotherapy; post-stroke depression, prevalent in roughly a third, with antidepressants that are effective; dysphagia, where swallow screening prevents aspiration pneumonia; central post-stroke pain with amitriptyline, which is EML-listed, off-patent and costs a few US dollars a patient-year, or with gabapentinoids; post-stroke epilepsy, for which see the epilepsy entry; shoulder pain; and fatigue.

**Simple means.** Task-specific practice and repetition: the active ingredient of rehabilitation, and family members can deliver supervised repetition. Swallow screening with a glass of water before giving food: a nurse and a cup, preventing a leading cause of post-stroke death. Amitriptyline at a few US dollars a patient-year for central post-stroke pain. Positioning and early mobilisation. Falls prevention in the home.

**Gaps.** Rehabilitation trials are small, heterogeneous and poorly blinded, and the dose-response for therapy intensity is not established. No pharmacological agent enhances recovery, and the fluoxetine trials closed off the leading candidate. Long-term outcome data from low- and middle-income settings, where most strokes now occur, are sparse.

---

## Epilepsy

**What it is.** A tendency to recurrent unprovoked seizures, caused by abnormal excessive synchronous neuronal activity. It is not one disease but a group of conditions with many causes. Seizures vary from brief lapses of awareness to prolonged convulsions.

**Measured.** About 50 million people worldwide have epilepsy (WHO epilepsy fact sheet, 7 February 2024); the page gives no data year for that figure. Active epilepsy prevalence is 4 to 10 per 1,000 at any time. About 5 million new diagnoses a year: 49 per 100,000 a year in high-income countries and up to 139 per 100,000 in low- and middle-income countries. Nearly 80 per cent of people with epilepsy live in low- and middle-income countries. Epilepsy ranked seventh among nervous system conditions by DALYs on GBD 2021. The risk of premature death is up to three times higher than the general population, with causes including sudden unexpected death in epilepsy, status epilepticus, drowning, falls and burns.

**Up to 70 per cent of people with epilepsy could become seizure-free with appropriate antiseizure medication**. **About three quarters of people with epilepsy in low-income countries may not receive the treatment they need**. Generic antiseizure medicine availability in low- and middle-income-country public sectors is less than 50 per cent. About 25 per cent of cases are potentially preventable, and the cause is unknown in about 50 per cent. The age pattern is bimodal, with peaks in early childhood and after 60, and the older-adult incidence peak is now the largest in high-income countries, driven by stroke.

Incidence is roughly three times higher in low- and middle-income countries, driven by preventable causes — perinatal injury, head trauma, central nervous system infection and neurocysticercosis.

The delivery gap, stated plainly: up to 70 per cent of people with epilepsy could become seizure-free on medication; about three quarters of people with epilepsy in low-income countries receive no treatment; and phenobarbital, the cheapest effective antiseizure drug in existence, is EML-listed as a selected medicine for epilepsy and status epilepticus, confirmed against the 24th List, and off-patent. The UNICEF Supply Catalogue, read 19 October 2026, gives phenobarbital 30 mg tablets at US$1.71 for a pack of 100, about US$0.0171 a tablet, so **about US$6.24 a patient-year at one tablet a day**. The gap is distribution, not discovery, and it is the single largest avoidable-suffering figure in Chapter 08.

**Where it starts.** Causes are known in a large proportion of cases, which distinguishes epilepsy from much of this chapter. *Structural*: stroke, which is the commonest cause of new-onset epilepsy in older adults; traumatic brain injury; tumour; cortical malformation; hippocampal sclerosis; perinatal hypoxic-ischaemic injury. *Infectious*: neurocysticercosis is the single largest preventable cause worldwide, accounting for roughly 30 per cent of epilepsy in endemic regions and an estimated 2 to 3 million cases globally†; also bacterial meningitis, cerebral malaria, tuberculous meningitis, HIV, and in some regions onchocerciasis-associated epilepsy. *Genetic*: several hundred genes identified, with monogenic epilepsies

— *SCN1A* in Dravet syndrome, *KCNQ2*, tuberous sclerosis — individually rare and collectively significant; heritability of the common epilepsies is roughly 25 to 30 per cent†. *Metabolic and immune*: autoimmune encephalitis, with NMDA receptor or LGI1 antibodies, is a recognised and treatable cause identified only in the past two decades. Most children with febrile seizures do not develop epilepsy, and prolonged febrile seizures carry higher risk.

Ion channel and neurotransmitter mechanisms are established for several monogenic epilepsies, and the mechanism of several drugs is known at the molecular level. Epileptogenesis — how a normal brain becomes epileptic after an injury — is not understood well enough to interrupt. No antiepileptogenic drug exists, and every trial of post-injury prophylaxis has failed to prevent later epilepsy. Not known: why seizures start when they do; what causes sudden unexpected death in epilepsy; why 30 per cent of patients are drug-resistant regardless of which drug; why the same lesion causes epilepsy in one person and not another.

**Cure status.** On medication: CONTROLLABLE in up to 70 per cent, who become seizure-free. Many remain so. WHO's own threshold for considering discontinuation is two seizure-free years. Drug-resistant epilepsy, roughly 30 per cent†, defined as failure of two appropriately chosen and adequately trialled drugs: that proportion has not improved despite more than twenty new antiseizure medications since 1990, which is a striking and important negative fact about four decades of drug development. Drug-resistant temporal lobe epilepsy treated surgically: CURABLE in 58 per cent at one year, free of seizures impairing awareness. Wiebe and colleagues (*NEJM*, 2001; 80 patients randomised, 40 to surgery and 40 to one year of medical therapy) found **58 per cent of the surgical group free of seizures impairing awareness at one year against 8 per cent of the medical group (p<0.001)**. Surgical complications occurred in 4 patients, 10 per cent: one small thalamic infarct with sensory change, one wound infection, and verbal memory decline interfering with work in two; asymptomatic superior quadrantic visual field defects occurred in 22 of 40, 55 per cent. One unexplained death occurred in the medical group and none in the surgical group. Where the cause is removable — treating neurocysticercosis or autoimmune encephalitis, removing a tumour — CURABLE.

**Prevention.** Unusually strong, because the causes are known. Pork tapeworm control and sanitation to prevent neurocysticercosis: STRONG, and it is the largest single preventable cause globally. Measures include meat inspection, pig husbandry, sanitation, mass drug administration and health education, and WHO targets it under its neglected tropical diseases roadmap. Perinatal care — skilled birth attendance, neonatal resuscitation, prevention and treatment of neonatal infection and jaundice: STRONG. Neonatal encephalopathy ranks second among all nervous system conditions by DALYs, and perinatal injury is a leading epilepsy cause.

Head injury prevention through helmet law, road safety and fall prevention: STRONG for the trauma-attributable fraction. Helmets reduce the risk of death by more than six times and brain injury risk by up to 74 per cent; seat-belts reduce occupant death risk by up to 50 per cent; a 1 per cent rise in mean speed produces a 4 per cent rise in fatal crash risk; road deaths are about 1.16 million a year. Vaccination against meningitis and prompt treatment of central nervous system infection: STRONG. Conjugate vaccine reduced confirmed serogroup A meningococcal disease by 99 per cent in vaccinated populations in the African meningitis belt.

Malaria control: STRONG for the cerebral malaria fraction. Stroke prevention: STRONG, since stroke is the leading cause of new epilepsy in older adults and 57 per cent of stroke DALYs are attributable to high systolic blood pressure. Post-traumatic and post-stroke antiseizure prophylaxis to prevent epilepsy: CONTESTED, with the evidence against. The drugs prevent early provoked seizures and do not prevent later epilepsy, and the negative result is reported. Avoiding valproate in pregnancy prevents fetal valproate syndrome rather than epilepsy, and it is the most important prescribing-safety measure in this condition.

**Treatment.** Some people withdraw medication without relapse, and the proportion is not given. *Antiseizure medications*, with up to 70 per cent seizure freedom. First-line choice depends on seizure type, and the SANAD trials established carbamazepine and lamotrigine for focal epilepsy and valproate for generalised epilepsy as reference comparators on effectiveness, with valproate's teratogenicity now restricting its use in women of childbearing potential. Carbamazepine is EML-listed and off-patent, costing tens of US dollars a patient-

year. Valproic acid is EML-listed and off-patent, tens of US dollars a patient-year, and is a major teratogen.

**Phenobarbital** is EML-listed as a selected medicine, confirmed against the 24th List, off-patent, and costs about **US$6.24 a patient-year** on the UNICEF indicative price of US$1.71 per 100 tablets of 30 mg, read 19 October 2026, at one tablet a day. It is the cheapest effective antiseizure drug in existence and still first-line in many low-income settings, with sedation and cognitive effects as the trade-off. Phenytoin is EML-listed and off-patent at tens of US dollars a patient-year at most. Lamotrigine is EML-listed and off-patent, tens to low hundreds of US dollars a patient-year, and is preferred in pregnancy.

Levetiracetam is EML-listed and off-patent, tens to low hundreds of US dollars a patient-year, also preferred in pregnancy, with behavioural adverse effects in a minority. Ethosuximide for childhood absence epilepsy is EML-listed and off-patent, tens to low hundreds of US dollars a patient-year. Diazepam, lorazepam and midazolam for acute seizures and status epilepticus are EML-listed and off-patent at a few US dollars a dose, and buccal or intranasal midazolam can be given by a family member without injection, which matters where no clinician is present. No dose is given for any substance of misuse in this chapter.

*Epilepsy surgery*, with the Wiebe figures above: 58 against 8 per cent seizure freedom at one year†. Also lesionectomy, hemispherotomy in children, and laser interstitial thermal therapy. The cost runs to tens of thousands of US dollars, and it is available to a very small fraction of those who would benefit. *Ketogenic diet for drug-resistant epilepsy*: a Cochrane review (Martin-McGill and colleagues, 2020; 13 randomised trials, 932 participants, of whom 711 children and 221 adults, follow-up 2 to 16 months), as summarised in *American Family Physician* in 2021.

In children, seizure freedom was 66 per 1,000 on the diet against 21 per 1,000 on usual diet, an absolute risk reduction of 4.5 per cent, number needed to treat 22 (95 per cent CI 7 to 250), on very low quality evidence. In children, a 50 per cent or greater seizure reduction occurred in 453 per 1,000 against 78 per 1,000, an absolute risk reduction of 37.5 per cent, **number needed to treat 3 (95 per cent CI 1 to 5)**, on low quality evidence — a large effect. In adults, no participant became seizure-free across 141 participants in two studies, and a 50 per cent or greater reduction occurred in 144 against 29 per 1,000, not statistically significant.

Adult treatment withdrawal was 461 per 1,000 on the diet against 86 per 1,000 on usual diet, so tolerability is the limiting factor in adults. In children, gastrointestinal adverse effects were no more likely than on usual diet, across 425 participants in five studies. So: substantial benefit for a 50 per cent or greater seizure reduction in children, number needed to treat 3; marginal for seizure freedom, number needed to treat 22; and ineffective and poorly tolerated in adults. It requires dietetic supervision, which is the practical constraint, not the food.

*Vagus nerve stimulation and responsive neurostimulation*: roughly 50 per cent of patients achieve a 50 per cent or greater seizure reduction, and seizure freedom is rare; device costs run to tens of thousands of US dollars. *Cannabidiol* is effective in Dravet and Lennox-Gastaut syndromes and in tuberous sclerosis in randomised trials, with roughly 20 to 40 per cent median seizure reduction above placebo; not EML-listed†, on patent in pharmaceutical grade, and costing tens of thousands of US dollars a patient-year at list price. *Treating the cause*: albendazole with corticosteroids for neurocysticercosis — albendazole is EML-listed as a selected medicine, confirmed against the 24th List — immunotherapy for autoimmune encephalitis, tumour resection.

*Status epilepticus*: a benzodiazepine first, then a second-line agent, and the ESETT trial found levetiracetam, fosphenytoin and valproate equivalent as second-line, which matters because it means the cheapest available agent is an acceptable choice.

**Simple means.** Phenobarbital at US$6.24 a patient-year at the UNICEF Supply Catalogue indicative price, October 2026, in a condition where up to 70 per cent can become seizure-free and roughly three quarters of patients in low-income countries get nothing. The gap here is distribution, not discovery. Sleep regularity: sleep deprivation is a well-established seizure precipitant, and regular adequate sleep reduces seizure frequency. Free. Adherence support: missed doses are a leading cause of breakthrough seizures and status epilepticus, and a pill box and a routine address it. Avoiding alcohol, which lowers the seizure threshold on withdrawal. Safety adaptation: supervised bathing rather than baths, since drowning

is a leading cause of epilepsy death; kitchen and fire safety; swimming supervision. These prevent a substantial share of the three-fold excess mortality and cost nothing. Buccal or intranasal midazolam given by a family member for prolonged seizures prevents status epilepticus without a clinician or a needle. Ketogenic diet in children: number needed to treat 3 for a 50 per cent or greater seizure reduction, using food; it needs dietetic supervision and no manufactured product. Pig husbandry and sanitation prevent the largest single cause of epilepsy worldwide, with no clinical supply chain at all.

**Gaps.** The 50 million figure and the regional incidence difference rest on sparse door-to-door surveys, and WHO's page carries no data year for the 50 million. The drug-resistant proportion has not fallen despite more than twenty new drugs, which is unexplained and rarely stated plainly. There is no antiepileptogenic treatment, and every prophylaxis trial has failed. The mechanism of sudden unexpected death in epilepsy is unknown and it is a leading cause of epilepsy death in young adults. Ketogenic diet evidence is rated low to very low quality by Cochrane, with short follow-up. Surgical candidacy is assessed in a tiny minority of eligible patients even in high-income countries.

---

## Multiple sclerosis

**What it is.** An immune-mediated disease in which the myelin sheaths of central nervous system axons are attacked, producing scattered areas of inflammation and scarring. It typically begins with attacks that partly recover, the relapsing-remitting form, and in many people later becomes steadily progressive. Symptoms depend on lesion location: vision loss, weakness, numbness, imbalance, bladder dysfunction, fatigue and cognitive impairment.

**Measured.** Over 1.8 million people have multiple sclerosis worldwide (WHO multiple sclerosis fact sheet, 7 August 2023; the page states no data year for the estimate). The MS International Federation's *Atlas of MS*, third edition, 2020, gives 2.8 million, a figure that is widely used and differs from WHO's by more than 50 per cent. Both are printed and the disagreement is named. Prevalence shows a strong latitude gradient: roughly 100 to 300 per 100,000 in northern Europe, North America, Australia and New Zealand, against under 20 per 100,000 near the equator. Women are affected roughly two to three times as often as men, and the ratio has been rising over decades in multiple registries — a change that must be environmental, since the genome has not changed. Onset is most commonly between 20 and 40 years. Life expectancy is reduced by roughly 7 to 10 years, a gap that has narrowed with treatment†. Recorded prevalence is rising, driven by better ascertainment, longer survival, and probably a true incidence increase in women.

**Where it starts.** This is one of the clearest aetiological stories in Chapter 08, built in the last decade. Epstein-Barr virus infection is very likely a necessary cause. Bjornevik and colleagues (*Science*, 2022) used serial serum samples from over 10 million US military personnel: seroconversion preceded multiple sclerosis onset, and **Epstein-Barr virus infection was associated with a 32-fold increase in risk, hazard ratio 32.4 (95 per cent CI 4.3 to 245.3)**, with no comparable effect for cytomegalovirus or other viruses, and with seroconversion preceding the first rise in neurofilament light chain.

Among 801 cases, only one was Epstein-Barr-negative at onset†. That is the largest effect size for an environmental exposure anywhere in the book. The virus is necessary and far from sufficient: over 90 per cent of adults are seropositive† and almost none develop multiple sclerosis. *HLA-DRB1*15:01* carries roughly three times the risk and is the strongest genetic factor, with over 200 further loci of small effect and heritability roughly 30 to 50 per cent†. Low vitamin D and low sun exposure: the latitude gradient, migration studies in which risk tracks the country of childhood residence rather than of birth or adulthood, and Mendelian randomisation supporting a causal role for genetically low vitamin D give MODERATE causal evidence — the association is strong and the randomised supplementation trials are negative.

Adolescent obesity carries roughly twice the risk, supported by Mendelian randomisation. Smoking carries roughly 1.5 times the risk and faster progression, and the association with progression is better established than for most exposures. Symptomatic Epstein-Barr infection in adolescence, infectious mononucleosis, carries roughly twice the risk beyond seropositivity alone. Organic solvent exposure interacts with smoking and HLA genotype.

Autoimmune demyelination is established. B cells are centrally involved, demonstrated by the efficacy of anti-CD20 therapy, which was a surprise since T cells had been the assumed driver. The Epstein-Barr link is epidemiologically very strong and its mechanism is not settled, with molecular mimicry between Epstein-Barr nuclear antigen 1 and GlialCAM demonstrated in vitro, and bystander activation and persistence of infected B cells as alternatives. Progression is mechanistically distinct from relapse: anti-inflammatory drugs that abolish relapses do not stop progression. That is the central unsolved problem and it indicates a second process — chronic smouldering inflammation, mitochondrial failure, or age-related repair failure — that is not understood. Not known: what converts Epstein-Barr infection into multiple sclerosis in one in a thousand infected people; what drives progression; why the sex ratio is rising.

**Cure status.** For relapses: CONTROLLABLE. For progression: RELIEF ONLY. High-efficacy disease-modifying therapies reduce relapse rate by roughly 50 to 70 per cent and new MRI lesions by over 80 per cent†. No treatment stops progression, though some slow it modestly. Autologous haematopoietic stem cell transplantation produces prolonged disease inactivity — no evidence of disease activity for years — in highly selected patients with active relapsing disease, in randomised and observational data, and it is the closest to a cure available; treatment-related mortality is roughly 0.2 to 2 per cent depending on protocol and era†. About 10 to 15 per cent have benign disease with minimal disability after decades, and this is not predictable at onset.

**Prevention.** Epstein-Barr vaccination: no licensed vaccine exists. If the virus is necessary, vaccination is in principle the most powerful prevention possible for this disease, and candidate vaccines are in early trials. It is the most important prospect and it is currently unavailable. Vitamin D supplementation: CONTESTED. The observational and Mendelian randomisation evidence supports a causal role, and randomised supplementation trials, including VITAL and the multiple sclerosis-specific SOLAR and CHOLINE trials, have not shown reduction in incidence or robust reduction in activity. Both halves are reported. Preventing adolescent obesity: MODERATE, supported by Mendelian randomisation. Smoking cessation and prevention: MODERATE for incidence, MODERATE for slowing progression in diagnosed patients. Sun exposure in childhood and adolescence: MODERATE on the latitude and migration evidence, confounded with vitamin D.

**Treatment.** *Anti-CD20 monoclonal antibodies* — ocrelizumab, ofatumumab, rituximab — are among the most effective agents, with roughly 50 to 70 per cent relapse reduction against interferon in head-to-head trials, and ocrelizumab showed a modest effect in primary progressive disease, the first agent to do so. Rituximab is widely used off-label with comparable observational effectiveness and is off-patent, available as biosimilars at a small fraction of the originator antibody prices; ocrelizumab costs tens of thousands of US dollars a year at US list price. Rituximab **is** EML-listed as a selected medicine, under section 5.1.2 Medicines for multiple sclerosis, complementary list, confirmed against the 24th List; ocrelizumab is not EML-listed†. Another dossier in this book gives a rituximab price range of tens to thousands of US dollars a patient-year in a sentence whose construction excludes rituximab from that range, so it gives no rituximab price, and a third asserts EML status with no price; this chapter's compilation gave a dollar range for biosimilars that was an unsourced estimate and is not printed. Three dossiers, three treatments of one drug.

*Natalizumab* gives roughly 68 per cent relapse reduction in the AFFIRM trial, with a risk of progressive multifocal leukoencephalopathy stratified by JC virus serology; not EML-listed, biosimilars emerging, and costing tens of thousands of US dollars a year. *Alemtuzumab and cladribine* have high efficacy and are given as short courses; cladribine is off-patent as a generic injectable used off-label and the oral tablet form is on patent, and neither agent is EML-listed, with the oral form costing tens of thousands of US dollars a year-equivalent and the generic injectable a small fraction of that. *Oral agents* — fingolimod, dimethyl fumarate, teriflunomide, siponimod — have moderate efficacy, roughly 30 to 50 per cent relapse reduction; several are now off-patent, and generics cost thousands of US dollars a patient-year against originator pricing in the tens of thousands; none is EML-listed.

*Interferon beta and glatiramer acetate*, the original agents, give roughly 30 per cent relapse reduction, are largely superseded, are still used, and are the safest in pregnancy planning; not EML-listed, off-patent, thousands to tens of thousands of US dollars a year. *Corticosteroids for acute relapse* shorten relapse duration with no effect on long-term disability;

methylprednisolone and prednisolone are EML-listed, off-patent, and cost on the order of tens of US dollars a course. *Autologous haematopoietic stem cell transplantation*: the MIST randomised trial showed superiority to disease-modifying therapy for disability progression in active relapsing disease, at a one-off cost in the tens to low hundreds of thousands of US dollars, which may be less than a decade of a high-cost antibody.

*Symptomatic treatment*: fampridine for walking speed; baclofen and tizanidine for spasticity, both EML-listed, off-patent, at tens of US dollars a patient-year; anticholinergics or botulinum toxin for bladder; amitriptyline or gabapentinoids for neuropathic pain; modafinil or amantadine for fatigue. *Exercise and rehabilitation*: randomised trials show improvement in walking, balance, fatigue and quality of life with moderate effect sizes, and exercise does not worsen the disease, contrary to decades of earlier advice — a reversed recommendation worth recording.

**Simple means.** Exercise: randomised trials establish improvement in fatigue, which is one of the most disabling symptoms and one with no good drug, and in walking and balance. For fatigue specifically, exercise has better evidence than any medication, since the modafinil and amantadine trials have been largely negative. This is a case where a simple means outperforms the drugs for a specific symptom. Smoking cessation: slows progression; free, or a few US dollars with cytisine. Weight management in adolescence: Mendelian-randomisation-supported prevention. Heat management — cooling, avoiding overheating: Uhthoff's phenomenon is well characterised, and a cool shower or a fan restores function temporarily. Free. Sun exposure: the latitude and migration evidence supports it and the supplement trials do not, so sun rather than capsules, with the honest caveat that this is unresolved. Bladder management routines and pelvic floor training reduce infections, which are a leading cause of hospitalisation and death in advanced disease. Vitamin D is cheap and harmless at ordinary doses, with negative trial evidence for multiple sclerosis outcomes, and is not oversold here.

**Gaps.** WHO says 1.8 million and the MS Atlas says 2.8 million; the sources disagree by more than 50 per cent and both are widely cited. The Epstein-Barr finding is epidemiologically powerful and has produced no intervention, and no licensed vaccine exists. Progression is untreatable and mechanistically unexplained. The rising female-to-male ratio is well documented and unexplained. Vitamin D is a textbook case of observational and randomised evidence disagreeing. Disease-modifying therapy pricing bears no relation to cost of goods, and rituximab demonstrates that an effective treatment can cost a small fraction of the alternatives; access in low- and middle-income countries is minimal. There are no trials in the populations with lowest prevalence, so natural history outside high-prevalence regions is poorly described.

---

## Motor neurone disease and amyotrophic lateral sclerosis

**What it is.** Progressive degeneration of the motor neurons in the brain and spinal cord, causing weakness and wasting that spreads, with loss of speech, swallowing and ultimately breathing. Sensation and usually eye movement are spared. Cognitive and behavioural change of frontotemporal type occurs in a substantial minority.

**Measured.** WHO has no dedicated fact sheet for motor neurone disease (checked October 2026). Incidence is roughly 1.5 to 2.5 per 100,000 a year in European-ancestry populations and prevalence roughly 4 to 8 per 100,000; prevalence is low relative to incidence because survival is short. Global prevalent cases in GBD estimates are roughly 200,000 to 350,000. Median survival from symptom onset is roughly 2 to 4 years, and roughly 10 per cent survive 10 years. Bulbar-onset disease has shorter survival than limb-onset. Men roughly 1.2 to 1.5 times women. Peak onset is 55 to 75 years. Lifetime risk is roughly 1 in 300 to 1 in 400. Incidence is rising modestly with population ageing, and age-standardised rates are broadly stable.

**Where it starts.** Roughly 10 per cent of cases are familial, and genetic causes are found in roughly 10 to 15 per cent of apparently sporadic cases†. The *C9orf72* hexanucleotide repeat expansion is the commonest cause in European populations, accounting for roughly 40 per cent of familial and 5 to 10 per cent of sporadic cases, and linking the disease to frontotemporal dementia. *SOD1*, *TARDBP* and *FUS* are the other major genes, and heri-

tability is roughly 40 to 60 per cent†. Age and male sex are established. Smoking is the most consistently replicated environmental risk factor, roughly 1.4 to 1.6 times†. Military service is consistently associated across multiple national cohorts, roughly 1.5 to 2 times, with the cause unidentified†. Physical activity and elite athleticism are associated in several studies, including a well-documented excess in professional footballers, and whether that reflects exercise, head injury, or shared genetic predisposition toward athleticism is genuinely unresolved — and the hypotheses point in opposite directions for advice. Head injury, heavy metals, pesticides and electrical work are reported inconsistently. The Guam and Kii peninsula ALS-parkinsonism-dementia complex, linked to cycad consumption and BMAA, is historically important and declined with dietary change, which supports an environmental cause in that specific setting.

TDP-43 protein mislocalisation and aggregation is present in roughly 97 per cent of cases† and is the defining pathology; established as a hallmark, with a causal role that is probable and not proven. RNA processing failure, protein clearance failure, glutamate excitotoxicity, mitochondrial failure and glial contribution are all supported by evidence, and no single mechanism explains the disease. The riluzole mechanism, glutamate modulation, was the basis for a generation of excitotoxicity-targeted trials that all failed apart from riluzole's own small effect. Not known: what initiates degeneration; why it spreads contiguously; why motor neurons specifically; why the same mutation causes disease at age 40 in one carrier and 70 in another.

**Cure status.** RELIEF ONLY. This is the clearest RELIEF ONLY designation in Chapter 08. No treatment halts or reverses the disease. Riluzole extends survival by roughly two to three months. Non-invasive ventilation extends survival by roughly seven months in those with preserved bulbar function and improves quality of life — the largest survival effect of any intervention. Multidisciplinary clinic attendance is associated with roughly seven months longer survival in observational studies. Reported reversals are vanishingly rare and generally reflect misdiagnosis of mimics, which is why mimics — multifocal motor neuropathy, myasthenia gravis, cervical myelopathy, inclusion body myositis — must be excluded.

**Prevention.** No established prevention. Smoking cessation is the only replicated modifiable risk factor: WEAK for this endpoint specifically, and justified on every other ground. Genetic counselling for families with known mutations is not prevention of the disease and enables informed reproductive choice; pre-symptomatic testing is available for *C9orf72* and *SOD1*. Dietary and supplement claims: none supported.

**Treatment.** *Non-invasive ventilation* has the largest measured survival and quality-of-life benefit: roughly **seven months additional median survival** in randomised trial data (Bourke and colleagues, *Lancet Neurology*, 2006) in patients with preserved bulbar function. The device is a one-off cost in the low thousands of US dollars plus consumables, and it is not a drug. *Multidisciplinary specialist clinic care* is associated with roughly seven months longer survival in observational comparisons, through better nutrition, earlier ventilation and secretion management rather than a new treatment. Organisational.

*Riluzole* extends median survival by roughly two to three months, about a 9 per cent improvement in one-year survival on Cochrane review†; not EML-listed, off-patent, and costing on the order of hundreds to low thousands of US dollars a patient-year as a generic. *Edaravone* was approved in some jurisdictions on a small trial in a narrowly defined subgroup, where the effect was a 33 per cent slowing of functional decline over six months on the ALSFRS-R, and the European regulator refused the application for insufficient evidence. Sources and regulators disagree. Not EML-listed, on patent in most markets, and costing a six-figure sum in US dollars a patient-year for the intravenous form.

*Tofersen*, an antisense oligonucleotide for *SOD1*-associated disease, reduces neurofilament light chain substantially; the primary clinical endpoint in the VALOR trial was not met, with suggestive effects in secondary and open-label extension analyses, and it was approved in the United States under accelerated approval on the biomarker. An important precedent and not an established clinical benefit. Not EML-listed, on patent, costing a low six-figure sum in US dollars a year, and applicable to roughly 2 per cent of patients. *The counterexample*: sodium phenylbutyrate with taurursodiol, marketed as Relyvrio, was approved in the United States on a phase 2 trial, failed its phase 3 trial, and was withdrawn from the market in 2024. Recorded.

*Gastrostomy feeding* maintains nutrition and is associated with survival benefit in observational data, with no randomised trial. *Symptomatic treatment*: saliva management with anticholinergics, botulinum toxin or radiotherapy to the salivary glands; spasticity with baclofen, which is EML-listed, off-patent and costs tens of US dollars a patient-year; cramps; pain; emotional lability with dextromethorphan-quinidine; communication aids, where eye-gaze systems transform participation at costs of thousands to low tens of thousands of US dollars; and palliative care. *Exercise*: moderate exercise does not accelerate decline and improves function modestly in small randomised trials, and the earlier advice to avoid exertion was not evidence-based.

**Simple means.** Communication: a letter board or alphabet chart costs almost nothing and preserves the ability to communicate for people who lose speech. Low-technology communication should be available before high-technology devices and often outlasts their battery life. Positioning, secretion management and cough assistance, taught to family carers, prevent aspiration and distress. Nutrition maintenance: weight loss predicts shorter survival, and attention to calorie-dense food is free; no numeric targets are given. Breathing position and manual assisted cough: taught, free. Advance care planning ensures the person's choices about ventilation and feeding are known while they can state them: a conversation, documented. Exercise within tolerance does not harm and improves function modestly. The honest statement: simple means here address comfort, communication and dignity rather than survival, and the survival interventions are ventilation and multidisciplinary care, both of which need equipment and staff. No simple means approaches the effect of medication here, because medication's effect is also very small.

**Gaps.** No WHO fact sheet, and GBD figures for motor neurone disease are among the least precise in Chapter 08. Three regulatory decisions in this field — edaravone, Relyvrio, tofersen — show regulators and evidence diverging in different directions, and one approved drug was withdrawn after phase 3 failure. The athleticism association is unresolved and its two leading explanations imply opposite advice. The military service association is consistent and unexplained. Almost all trials are in European-ancestry populations. Biomarker-based accelerated approval is a precedent whose validity here is unestablished.

---

## Migraine

**What it is.** A recurrent headache disorder with attacks of moderate to severe, often one-sided, pulsating headache, worsened by activity and accompanied by nausea and sensitivity to light and sound. About a third of people have aura: transient visual or other neurological symptoms before or during the attack.

**Measured.** Migraine ranks third in both age-standardised DALYs for neurological disease burden and global DALYs overall, after stroke and neonatal encephalopathy (WHO headache disorders fact sheet, 24 October 2025, citing Global Health Estimates 2021 and GBD 2021). Headache disorders collectively affect approximately 40 per cent of the global population, about 3.1 billion people in 2021, and rank sixth among all causes of years lived with disability at 45.5 million YLDs (95 per cent UI 31.4 to 62.0) in 2023. Migraine prevalence is roughly 14 to 15 per cent globally, about 1.1 billion people; WHO's fact sheet gives no migraine-specific prevalence figure. Attacks usually last 4 to 72 hours, and the headache can last hours to two or three days. Migraine most often begins around puberty and generally affects people aged 35 to 45 — the peak working and caregiving years. Women roughly two to three times men after puberty, and before puberty the rates are similar. Medication-overuse headache may affect up to 5 per cent of some populations, more women than men. Chronic migraine, meaning 15 or more headache days a month, affects roughly 1 to 2 per cent of the population†. Age-standardised rates are broadly stable, and migraine's DALY rank has risen as other conditions have fallen.

**Where it starts.** Heritability is roughly 40 to 60 per cent, with over 100 loci identified, mostly in genes related to vascular and ion channel function. Familial hemiplegic migraine is monogenic, from *CACNA1A*, *ATP1A2* or *SCN1A*, and demonstrates that ion channel dysfunction can cause migraine. Female sex and hormonal fluctuation: a menstrual association is present in a majority of affected women, and attacks typically improve after menopause and during the later trimesters of pregnancy. Medication overuse: acute treatment taken

too frequently converts episodic to chronic migraine, an iatrogenic and reversible cause affecting up to 5 per cent of some populations. Obesity, snoring and sleep apnoea, depression and anxiety are associated with chronic migraine progression. On attack triggers, the evidence is weaker than patient report suggests. Controlled provocation studies confirm nitric oxide donors, CGRP infusion and PACAP as reliable triggers. For dietary triggers, blinded challenge studies have generally failed to confirm chocolate, cheese and red wine, and premonitory-phase food craving may explain the apparent association. The asymmetry between belief and blinded evidence is reported. Sleep disruption, missed meals, stress letdown and menstruation have better support.

Migraine is not a vascular disease in the way it was taught for most of the twentieth century. The vasodilation theory was abandoned; migraine is a disorder of brain excitability and of the trigeminovascular pain system. Cortical spreading depression is established as the mechanism of aura, demonstrated directly in animals and inferred from human imaging. CGRP, calcitonin gene-related peptide, is established as a key mediator: it is released during attacks, infusing it triggers migraine in susceptible people, and blocking it prevents and treats attacks. That is the clearest mechanism-to-drug success story in the book — the mechanism was identified, drugs were designed against it, and they worked. Not known: what initiates an attack; the role of the hypothalamus in the premonitory phase; why attacks recur in cycles; why some people develop chronic migraine.

**Cure status.** CONTROLLABLE. Individual attacks are SELF-LIMITING, resolving in 4 to 72 hours. Medication-overuse headache is CURABLE by withdrawal of the overused acute medication, and the majority revert to episodic migraine — a genuinely curable iatrogenic condition. Many people's migraine remits with age, particularly after menopause in women. Preventive treatment reduces attack frequency by roughly 50 per cent in responders, does not remove the disorder, and symptoms return on stopping in most.

**Prevention.** Avoiding medication overuse: STRONG. Limiting acute treatment frequency prevents chronification, and withdrawal reverses it. The clearest preventable cause. Regular sleep and meal timing: MODERATE, on cohort and small trial data. Aerobic exercise: MODERATE; randomised trials show exercise reduces attack frequency, with effect sizes comparable to some preventive drugs. Weight loss in obesity: MODERATE; obesity is associated with chronification and bariatric surgery cohorts show reduced headache days. Treating coexisting sleep apnoea and insomnia: MODERATE. Stress management and relaxation training: MODERATE, with randomised support. Dietary trigger elimination: CONTESTED; blinded challenge studies are largely negative, and elimination diets commonly cause more restriction than benefit.

**Treatment.** *Acute.* **Triptans** are the reference acute treatment, with two-hour pain freedom in roughly 20 to 40 per cent against roughly 10 per cent on placebo, and a number needed to treat of roughly 3 to 6 for two-hour headache relief†. Sumatriptan is EML-listed and off-patent, costing on the order of tens of US dollars a year at generic prices for typical use. Contraindicated in established cardiovascular disease. **NSAIDs and aspirin** are effective, with high-dose aspirin and ibuprofen comparable to some triptans in trials. Aspirin and ibuprofen are EML-listed and off-patent; the UNICEF Supply Catalogue gives ibuprofen 400 mg at US$2.23 for a pack, with US$1.43 returned for the same material number on a different page, read 19 October 2026, so the figure is indicative and dated. These are among the cheapest effective treatments in the book. **Paracetamol with an antiemetic** is effective in mild to moderate attacks; both EML-listed, off-patent, a few US dollars a year, with metoclopramide or domperidone treating the nausea and improving absorption. **Gepants** — ubrogepant, rimegepant — and **lasmiditan** are effective acutely and usable where there is a cardiovascular contraindication; not EML-listed, on patent, and costing from hundreds to thousands of US dollars a year depending on use frequency. **Avoiding opioids and butalbital**, which are associated with chronification and poor outcomes, and which guidelines advise against.

*Preventive.* **Propranolol and metoprolol** give roughly 50 per cent reduction in attack frequency in roughly 40 to 50 per cent of patients; propranolol is EML-listed†, off-patent, and costs a few US dollars a patient-year. **Amitriptyline** is an effective preventive; EML-listed, off-patent, a few US dollars a patient-year. **Topiramate and valproate** are effective, and topiramate reduces monthly migraine days by roughly 1.5 to 2 against placebo; valproate is EML-listed† for epilepsy and is a teratogen; topiramate is not EML-listed, is off-patent, costs

tens to low hundreds of US dollars a patient-year, and is also teratogenic with cognitive adverse effects.

**Candesartan and flunarizine** are effective, cheap and off-patent. **CGRP monoclonal antibodies** — erenumab, fremanezumab, galcanezumab, eptinezumab — reduce monthly migraine days by roughly 1.5 to 2.5 more than placebo; roughly 50 per cent of patients achieve a 50 per cent reduction against roughly 30 per cent on placebo; and they are well tolerated†. Not EML-listed, on patent, and costing thousands to tens of thousands of US dollars a patient-year at list price. The honest comparison: the absolute effect size is similar to propranolol or topiramate, at three to four orders of magnitude the cost.

The exact multiple is not printed here, because both price inputs in the earlier compilation were unsourced estimates. The advantage is tolerability and usability where the cheap drugs are contraindicated or not tolerated, which is a real advantage for many patients and not a larger effect. **Atogepant and rimegepant as preventives** are oral CGRP antagonists with similar effect sizes; on patent, thousands to tens of thousands of US dollars a year. **OnabotulinumtoxinA for chronic migraine** gives roughly two fewer headache days a month than placebo; not EML-listed, on patent in most markets, thousands of US dollars a patient-year.

**Non-invasive neuromodulation** — external trigeminal, vagus nerve, remote electrical — gives modest effects at a device cost in the hundreds of US dollars. **Riboflavin, magnesium and coenzyme Q10** have small effects in small trials, and are cheap and low-harm; riboflavin reduced attack frequency in a small randomised trial, and replication is limited. **CBT, biofeedback and relaxation** have effect sizes comparable to preventive drugs in meta-analysis with durable benefit, and combination with drug treatment is better than either alone.

**Simple means.** Aerobic exercise: randomised trials show attack frequency reduction, with at least one trial finding exercise comparable to topiramate and to relaxation training. This is a condition where exercise has trial evidence comparable to a standard preventive medication. Fixed sleep and wake times: schedule regularity reduces attack frequency, and sleep disruption is among the better-supported triggers. Regular meals: missed meals are a supported trigger. Limiting acute medication frequency: prevents the iatrogenic chronic form affecting up to 5 per cent of some populations, and withdrawal cures it. Free. Aspirin or ibuprofen for acute attacks, at indicative pack prices of US$1.43 to 2.23 for ibuprofen 400 mg in October 2026, and propranolol or amitriptyline for prevention at a few US dollars a patient-year, against the CGRP antibodies at thousands to tens of thousands for a similar absolute effect. Relaxation training and biofeedback: meta-analytic effect sizes comparable to drugs, deliverable from recordings or printed instructions. A dark quiet room and sleep during an attack terminates many attacks at no cost. Hydration and caffeine: caffeine has a genuine acute analgesic-adjuvant effect and a genuine withdrawal-headache risk, and both are real.

**Gaps.** WHO's fact sheet gives migraine's DALY rank and no prevalence figure, so the 1.1 billion figure comes from GBD publications rather than the fact sheet. The gap between reported dietary triggers and blinded challenge results is large and under-communicated to patients. Preventive drug trials are short, typically three to six months, for a lifelong condition. There are no head-to-head trials of CGRP antibodies against cheap generics at adequate doses, so the cost-effectiveness comparison rests on indirect comparison. Migraine's enormous DALY burden attracts a small fraction of the research funding of conditions with lower burden, a well-documented disparity.

---

## Tension-type headache

**What it is.** Bilateral, pressing or tightening headache of mild to moderate intensity, without the nausea, throbbing quality or activity-worsening of migraine. It is the most common headache disorder and in most people episodic and brief.

**Measured.** Headache disorders collectively affect about 40 per cent of the global population, about 3.1 billion people in 2021, and rank sixth among all causes of years lived with disability at 45.5 million YLDs in 2023. WHO gives no overall tension-type headache prevalence figure, and reports that episodic tension-type headache, occurring on fewer than 15 days a month, is reported by more than 70 per cent of some populations. Chronic tension-type headache, 15

or more days a month, affects roughly 1 to 3 per cent of adults. Tension-type headache affects 50 per cent more women than men. It is the most prevalent single neurological disorder by headcount and has a far lower DALY weight per case than migraine, so its DALY total is substantial and its rank lower. Onset is typically in the twenties to forties.

**Where it starts.** Heritability of the chronic form is roughly 40 per cent, and the episodic form has lower familial aggregation†. Pericranial muscle tenderness is the most consistent clinical finding, and whether it is cause or consequence is unresolved. Central sensitisation is supported for the chronic form: lowered pain thresholds at sites distant from the head suggest a generalised change in pain processing. Medication overuse converts the episodic to the chronic form, as in migraine. Stress, sleep deprivation, poor posture and prolonged static work are commonly reported associations with weak formal evidence. Depression and anxiety are strongly associated with the chronic form, with mixed direction of causation.

The muscle contraction headache model that gave the disorder its original name is not supported, since electromyographic studies did not confirm sustained muscle contraction as the cause. Peripheral nociceptive input from pericranial muscle plus central sensitisation is the current model for the chronic form: a reasonable synthesis rather than a demonstrated mechanism. Not known: whether tension-type headache and migraine are distinct disorders or ends of a continuum — a genuine and long-running disagreement in the field, with the frequent coexistence in individuals and the shared treatment response supporting the continuum view.

**Cure status.** Episodic form: SELF-LIMITING. Individual attacks resolve in hours, the disorder is intermittent, and most people never seek care. Chronic form: CONTROLLABLE. Chronic form with medication overuse: CURABLE.

**Prevention.** Avoiding medication overuse: STRONG, and the main preventable cause of the chronic form. Regular sleep: MODERATE. Exercise: MODERATE; randomised trials of exercise show reduced frequency. Workstation and posture modification: WEAK, widely recommended and poorly evidenced. Stress management: MODERATE, with randomised support for relaxation training.

**Treatment.** *Simple analgesics for acute episodes* — ibuprofen, aspirin, paracetamol, naproxen — are effective, with numbers needed to treat of roughly 5 to 9 for two-hour pain relief†. All are EML-listed and off-patent, and the UNICEF Supply Catalogue gives ibuprofen 400 mg at US$2.23 a pack, with US$1.43 for the same material number on another page, read 19 October 2026. These are the cheapest effective treatments in the book. *Limiting analgesic use to fewer than 15 days a month* prevents the chronic iatrogenic form. *Amitriptyline* is the best-evidenced preventive for the chronic form, with roughly 30 per cent reduction in headache index against placebo; EML-listed, off-patent, a few US dollars a patient-year.

*Mirtazapine and venlafaxine* are second-line preventives with some randomised support. *Physiotherapy, manual therapy and exercise* reduce headache frequency in randomised trials, with effect sizes comparable to amitriptyline in some comparisons and better tolerability. *Relaxation training, biofeedback and CBT* have moderate effect sizes in meta-analysis, durable after treatment ends, and combination with amitriptyline outperformed either alone in a randomised trial. *Acupuncture*: Cochrane review found a small benefit over sham and over no treatment for frequent tension-type headache, and interpretation of the sham comparison remains contested.

*Botulinum toxin* is **not** effective for tension-type headache in randomised trials, in contrast to chronic migraine — a clear negative result worth recording because it is sometimes offered.

**Simple means.** Exercise and physiotherapy: trial evidence comparable to amitriptyline, with fewer adverse effects. Another condition where a simple means matches the standard drug. Relaxation and biofeedback: meta-analytic effect sizes comparable to drug prevention, durable after treatment stops, deliverable from recordings. Limiting analgesic days: prevents and reverses the chronic form. Free. Regular sleep and adequate hydration. Aspirin or ibuprofen at a few US dollars a year: for the most prevalent neurological disorder in the world, the effective acute treatment costs less than a cup of coffee a month and is on the Essential Medicines List. There is no access case to make here beyond basic analgesic availability.

**Gaps.** No specific WHO prevalence figure for the world's most common neurological disorder. Whether it is distinct from migraine is unresolved after decades. The chronic form

is understudied relative to chronic migraine, with far fewer trials and no modern targeted treatment. Posture and ergonomic advice is universal and essentially unevidenced.

---

## Cluster headache

**What it is.** Attacks of extremely severe, strictly one-sided pain around the eye or temple, lasting 15 minutes to 3 hours, with tearing, nasal congestion, eyelid drooping and marked restlessness on the same side. Attacks recur once to eight times daily in bouts lasting weeks to months, often at the same time of year and the same time of night.

**Measured.** Cluster headache affects fewer than 1 in 1,000 adults and affects six men to each woman (WHO headache disorders fact sheet, 24 October 2025) — the most male-skewed condition in the book. Onset is typically between 20 and 40 years. Roughly 10 to 15 per cent have the chronic form without remission periods. Pain intensity is rated among the most severe in clinical medicine, and suicidal ideation during attacks is frequently reported. Diagnostic delay is long, commonly years, with frequent misdiagnosis as sinus or dental disease and unnecessary procedures. There is no stand-alone GBD estimate: low prevalence and high per-case severity.

**Where it starts.** Circadian and circannual periodicity is the defining epidemiological feature: attacks cluster at fixed times of day and bouts at fixed times of year. That points to the hypothalamus, and functional imaging shows posterior hypothalamic activation during attacks — among the strongest localisation findings for any headache disorder. Smoking: the great majority of patients are current or former smokers, a much stronger association than in migraine; whether it is causal is unresolved, and stopping smoking does not reliably stop the attacks. Alcohol triggers attacks reliably during a bout and not during remission — a striking, well-described and unexplained pattern. First-degree relatives carry roughly 5 to 18 times the risk, and heritability is present with no major gene identified. Male sex, 6 to 1, and the ratio appears to have narrowed over decades.

Hypothalamic involvement is established by imaging and by the circadian pattern, and the trigeminal-autonomic reflex explains the autonomic features. CGRP is involved: levels rise during attacks, and galcanezumab reduces episodic cluster attacks. Not known: what drives the periodicity; why the male predominance; why alcohol triggers only during bouts; why oxygen works.

**Cure status.** Individual bouts in the episodic form: SELF-LIMITING, since they remit spontaneously. The disorder itself: CONTROLLABLE. Acute treatment aborts individual attacks highly effectively and preventive treatment shortens bouts, which is control; no treatment prevents future bouts permanently. Spontaneous long-term remission occurs in a minority with age.

**Prevention.** No established primary prevention. Smoking cessation is justified and does not reliably alter the disorder: WEAK. Alcohol avoidance during a bout prevents individual attacks reliably: STRONG for that narrow outcome, and free. Starting preventive treatment early in a bout shortens the bout: MODERATE.

**Treatment.** *High-flow oxygen* aborts attacks in roughly 70 to 80 per cent within fifteen minutes, with randomised trial support (Cohen and colleagues, *JAMA*, 2009). It is an inhaled gas, not a drug: there is no patent, no EML entry as such, and a cylinder costs a few US dollars a fill. It is one of the most effective acute treatments in all of neurology, and it is frequently unavailable to patients because of supply and reimbursement rules rather than cost. That is recorded. *Subcutaneous sumatriptan* aborts attacks in roughly 75 per cent within fifteen minutes and is the fastest pharmacological option; sumatriptan is EML-listed and off-patent, and the injectable form costs from low hundreds to low thousands of US dollars a year depending on attack frequency and market. Intranasal zolmitriptan is also effective.

*Verapamil* is the first-line preventive and reduces attack frequency substantially; not EML-listed, off-patent, tens of US dollars a patient-year at most, and it requires ECG monitoring at higher doses. *Corticosteroid bridging* with prednisolone, or a greater occipital nerve block with steroid, rapidly suppresses attacks while verapamil takes effect; prednisolone is EML-listed, off-patent, a few US dollars a course, and the nerve block is cheap, quick and

effective in randomised trials. *Lithium* is an effective preventive, particularly in chronic cluster headache; EML-listed, off-patent, a few tens of US dollars a patient-year at most plus monitoring.

*Galcanezumab* reduced weekly attack frequency in episodic cluster headache in a randomised trial and failed in chronic cluster headache; not EML-listed, on patent, thousands to tens of thousands of US dollars a patient-year. *Topiramate, melatonin and warfarin* are second-line with weaker evidence, and melatonin at night has small randomised support, costs tens of US dollars a year, and fits the circadian mechanism. *Non-invasive vagus nerve stimulation* gives modest benefit for episodic cluster, at a device cost in the hundreds of US dollars. *Sphenopalatine ganglion stimulation and occipital nerve stimulation* are used for refractory chronic cases at device costs in the tens of thousands of US dollars.

**Simple means.** Oxygen: the single most striking cost-to-effect ratio in Chapter 08 — 70 to 80 per cent attack abortion from an inhaled gas that costs a few dollars a cylinder and cannot be patented. The barrier is prescribing and supply, not price. Alcohol avoidance during a bout prevents attacks reliably, and it is free. Regular sleep timing: attacks are nocturnally clustered and sleep disruption is implicated, and melatonin at tens of US dollars a year fits the circadian mechanism. Keeping a bout diary identifies the bout pattern, which allows preventive treatment to be started early and stopped when the bout ends. Paper. Greater occipital nerve block: a few US dollars of steroid and local anaesthetic, administered in minutes, with randomised support. Correct and early diagnosis: years of delay and unnecessary sinus and dental procedures are a large part of the measured harm, and the remedy is recognition rather than a product.

**Gaps.** No burden estimate for a condition with extreme per-case severity. The periodicity is the disorder's most distinctive feature and is unexplained. Oxygen's mechanism is unknown and its availability is poor relative to its efficacy. The 6-to-1 male predominance and its apparent narrowing are unexplained. Chronic cluster headache has fewer effective options and galcanezumab failed in it. Most preventive evidence is from small trials, and verapamil, the first-line agent, has a thin randomised base for its wide use.

---

## Diabetic neuropathy

**What it is.** Damage to the peripheral nerves from chronic hyperglycaemia, typically beginning in the feet and progressing proximally, causing numbness, tingling, burning pain and loss of protective sensation.

**Measured.** 206 million cases globally, having more than tripled since 1990 (GBD 2021, *Lancet Neurology*, 2024). It ranked fifth among all nervous system conditions by DALYs on that analysis — higher than meningitis, epilepsy or autism. Roughly 50 per cent of people with diabetes develop neuropathy over their lifetime, and roughly 20 per cent have painful neuropathy. Diabetic neuropathy underlies the majority of diabetic foot ulcers, which precede the majority of non-traumatic lower limb amputations, and amputation and ulcer rates are the measurable downstream harm. It is rising faster than almost any condition in the book, tracking the global diabetes epidemic: 830 million people were living with diabetes in 2022, up from 200 million in 1990, and more than half of all people with diabetes were untreated in 2022 (WHO diabetes fact sheet, 14 November 2024).

**Where it starts.** Duration and degree of hyperglycaemia are the primary determinants. In type 1 diabetes, intensive glycaemic control reduces neuropathy incidence substantially — roughly 60 to 69 per cent in the DCCT trial†. In type 2 diabetes, intensive glycaemic control produces only a small, non-significant reduction in clinical neuropathy in meta-analysis: a major and under-communicated difference between the two diseases. Additional factors in type 2: height, smoking, hypertension, dyslipidaemia, obesity and alcohol.

Polyol pathway flux, advanced glycation end products, oxidative stress, microvascular ischaemia and impaired nerve regeneration are all implicated. No single mechanism is established, and every mechanism-targeted drug has failed in trials — aldose reductase inhibitors, protein kinase C inhibitors, alpha-lipoic acid and others. The failure is as informative as the hypotheses. Not known: why intensive glycaemic control works in type 1 and barely in type 2, which is the single most important unanswered question here; why some people get painful and others painless neuropathy; why no neuroprotective agent has worked.

**Cure status.** RELIEF ONLY for established neuropathy. Nerve damage does not reverse. Glycaemic control prevents progression in type 1 and has limited effect in type 2. Curable causes of neuropathy exist and must be excluded in anyone presenting with it: B12 deficiency, where replacement reverses it if treated early; hypothyroidism; leprosy; HIV; vasculitis; and alcohol-related neuropathy with abstinence and thiamine.

**Prevention.** Glycaemic control in type 1 diabetes: STRONG, roughly 60 to 69 per cent reduction in incidence in DCCT†. Glycaemic control in type 2 diabetes: CONTESTED for neuropathy specifically, since meta-analysis shows a small, non-significant reduction. This contradicts common assumption and is stated plainly. Multifactorial risk management in type 2 — blood pressure, lipids, smoking, weight: MODERATE; the Steno-2 trial showed reduced autonomic neuropathy with multifactorial intervention. Diabetes prevention itself: STRONG. The Diabetes Prevention Program randomised 3,234 participants — 1,082 to placebo, 1,073 to metformin, 1,079 to intensive lifestyle intervention — over an average 2.8 years.

Three-year cumulative diabetes incidence was **28.9 per cent on placebo, 21.7 per cent on metformin and 14.4 per cent on lifestyle intervention**. The published relative reductions are 58 per cent (95 per cent CI 48 to 66) for lifestyle and 31 per cent (17 to 43) for metformin. The published numbers needed to treat for three years are 6.9 (5.4 to 9.5) for lifestyle and 13.9 (8.7 to 33.9) for metformin. Those numbers needed to treat follow exactly from the cumulative incidences: 28.9 minus 14.4 gives 14.5 percentage points and a reciprocal of 6.90, and 28.9 minus 21.7 gives 7.2 points and 13.89, both recomputed.

Preventing diabetes prevents its neuropathy. Annual foot examination and protective footwear: STRONG for the ulcer and amputation outcome — not for the neuropathy, but for the harm the neuropathy causes; structured foot care reduces amputation rates substantially in programme evaluations. Vitamin B12 monitoring in long-term metformin users: MODERATE, because it prevents a reversible cause.

**Treatment.** *Tricyclic antidepressants*, amitriptyline and nortriptyline, give a number needed to treat of roughly 3 to 5 for 50 per cent pain reduction — the best effect size of any class — with anticholinergic and cardiac limitations in older people. Amitriptyline is EML-listed, off-patent, and costs a few US dollars a patient-year: the most effective and the cheapest option simultaneously. *Gabapentinoids*, gabapentin and pregabalin, give a number needed to treat of roughly 6 to 8†; neither is EML-listed†, both are off-patent, and they cost tens to low hundreds of US dollars a patient-year. Harms: sedation, dizziness, oedema, weight gain, misuse potential, and respiratory depression risk with opioids.

*SNRIs*, duloxetine and venlafaxine, give a number needed to treat of roughly 5 to 7, and duloxetine has the best evidence in diabetic neuropathy†; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year. *Topical capsaicin 8 per cent patch and topical lidocaine* are useful for localised pain, and the high-concentration capsaicin patch has randomised support; costs vary widely. *Opioids and tramadol* have modest efficacy and substantial harms, and guidelines now place them last or advise against them for chronic neuropathic pain. *Treating the cause*: glycaemic control; B12 replacement, EML-listed†, off-patent, a few US dollars a year; thyroxine; alcohol abstinence with thiamine.

*Foot care, offloading and podiatry*: for the diabetic foot this is the intervention that prevents amputation, and therapeutic footwear, regular inspection, prompt ulcer treatment and total contact casting have strong evidence for the ulcer outcome. *Exercise*: randomised trials show improved nerve function measures, reduced pain and improved balance. No disease-modifying treatment exists.

**Simple means.** Amitriptyline at a few US dollars a patient-year with a number needed to treat of 3 to 5: the most effective neuropathic pain drug in the world is also one of the cheapest and is on the Essential Medicines List. For a condition affecting 206 million people, that is the central practical fact. Daily foot inspection, well-fitting shoes, and never walking barefoot prevent the ulcers that cause the amputations: a mirror and a pair of shoes, with a large measured effect on amputation rates in structured foot-care programmes. Exercise: trial evidence for improved nerve function, pain and balance. Free. Vitamin B12 at a few US dollars a year reverses a cause if caught early. Weight loss and diabetes prevention: the Diabetes Prevention Program's 58 per cent reduction came from diet and physical activity, outperforming metformin's 31 per cent — a simple means with trial evidence superior to the

medication it was compared against. Balance and falls prevention: loss of proprioception causes falls, and balance training has randomised support.

**Gaps.** The type 1 and type 2 divergence in glycaemic control's effect on neuropathy is established and poorly communicated. Every mechanism-targeted drug has failed, and the field has no disease-modifying candidate. Pain trial outcomes are subjective and placebo responses large, so effect sizes across the class are modest and may be overstated by publication bias. The 206 million figure tripling since 1990 is a modelled estimate following diabetes prevalence rather than direct neuropathy measurement.

---

## Chemotherapy-induced peripheral neuropathy

**What it is.** Damage to the peripheral nerves from neurotoxic cancer drugs, typically beginning in the feet and hands, causing numbness, tingling, burning pain and loss of sensation, and often limiting the dose of the cancer treatment.

**Measured.** Incidence is roughly 68 per cent within the first month of treatment, roughly 60 per cent at three months, and **roughly 30 per cent persisting at six months or more**, on meta-analysis of platinum, taxane, vinca alkaloid and bortezomib regimens. It is the commonest dose-limiting toxicity of several curative cancer regimens, so it directly limits cancer treatment. There is no WHO fact sheet and no stand-alone GBD estimate.

**Where it starts.** Cumulative dose of the neurotoxic agent is the dominant determinant. Preexisting neuropathy, diabetes and specific pharmacogenetic variants increase susceptibility. Platinum agents cause a dorsal root ganglion sensory neuronopathy that can worsen for months after treatment stops, which is called coasting and is a distinctive and clinically important feature. Axonal transport disruption by taxanes, dorsal root ganglion accumulation by platinum agents, and mitochondrial injury are supported mechanisms. Not known: why some patients are affected severely and others not at the same cumulative dose.

**Cure status.** SELF-LIMITING in roughly 70 per cent, who resolve within months of stopping; RELIEF ONLY in roughly 30 per cent, whose neuropathy persists beyond six months, much of it permanently.

**Prevention.** Dose limitation and regimen selection: STRONG for the neuropathy outcome, with an obvious trade-off against cancer control. Cryotherapy and compression therapy during taxane infusion: MODERATE; randomised trials show reduced neuropathy incidence with limb cooling or compression, and the means are ice packs or compression stockings. Exercise during chemotherapy: MODERATE; randomised trials show reduced severity. Neuroprotective agents during chemotherapy: CONTESTED to negative. Calcium and magnesium infusions, glutathione, vitamin E and acetyl-L-carnitine have all been tested; none is established, and acetyl-L-carnitine **worsened** outcomes in a randomised trial.

**Treatment.** *Duloxetine* is the only agent with any support in chemotherapy-induced neuropathic pain, where a randomised trial showed modest benefit; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year. *Tricyclic antidepressants and gabapentinoids* are used on the shared neuropathic pain evidence base; amitriptyline is EML-listed, off-patent, a few US dollars a patient-year. *Exercise*: randomised trials show reduced severity and improved function. *Dose reduction or discontinuation of the offending agent* is the only intervention that halts progression, with the obvious trade-off. No disease-modifying treatment exists, and no preventive agent is established.

**Simple means.** Limb cooling or compression during taxane infusion: ice packs or compression stockings reduce neuropathy incidence in randomised trials, for pennies. Exercise during and after chemotherapy: randomised evidence for reduced severity and improved function. Amitriptyline at a few US dollars a patient-year for the pain. Balance training and falls prevention, since proprioceptive loss causes falls. Foot protection and inspection where sensation is lost.

**Gaps.** There is one modestly effective symptomatic drug and no preventive agent, and one tested supplement made the condition worse. No burden estimate exists for a condition affecting roughly 30 per cent of treated patients persistently. Why susceptibility varies at the same cumulative dose is unknown. Long-term outcomes beyond two years are sparse.

---

## Guillain-Barré syndrome

**What it is.** Acute immune attack on peripheral nerves, usually following an infection, causing rapidly progressive weakness that ascends from the legs over days to weeks, often with loss of reflexes and sometimes with respiratory and swallowing failure. It reaches its worst within four weeks and then recovers.

**Measured.** Incidence is roughly 1 to 2 per 100,000 a year, consistent across most studied populations, giving roughly 100,000 cases globally a year†. Incidence rises with age and is roughly 1.5 times higher in men†. Roughly 20 to 30 per cent require mechanical ventilation at some point†. Mortality is roughly 3 to 7 per cent in high-income settings with intensive care, and substantially higher where ventilation is unavailable. Roughly 20 per cent remain unable to walk unaided at six months, and roughly 10 to 20 per cent have persistent significant disability at one year, with fatigue and pain persisting in a majority. There is no WHO fact sheet of its own, and WHO publishes guidance in the context of outbreak-associated clusters. The 2015 to 2016 Zika virus outbreak in the Americas produced a marked rise in incidence, with case-control studies supporting a causal association and incidence rising several-fold in affected countries.

**Where it starts.** This is one of the clearest causal chains in Chapter 08. An antecedent infection is present in roughly two thirds of cases, typically one to four weeks before onset. *Campylobacter jejuni* is the commonest identified trigger, associated with the axonal form and with worse outcome. Molecular mimicry is demonstrated: *C. jejuni* lipo-oligosaccharide shares epitopes with peripheral nerve gangliosides GM1 and GD1a, and anti-ganglioside antibodies are found in those patients. That is a demonstrated autoimmune mechanism with an identified mimicked antigen — among the best-established mechanisms in the book. Other triggers: cytomegalovirus, Epstein-Barr virus, *Mycoplasma pneumoniae*, influenza, hepatitis E, Zika virus and SARS-CoV-2. On vaccines: the 1976 swine influenza vaccine in the United States was associated with roughly one additional case per 100,000 vaccinated — a real, measured, historically important signal. Subsequent seasonal influenza vaccines carry at most roughly one to two additional cases per million doses, and influenza infection itself carries a substantially higher risk than vaccination, so vaccination is net protective. Both the real historical signal and the current magnitude are reported accurately. The Miller Fisher variant is associated with anti-GQ1b antibodies, another specific antibody-syndrome correspondence.

The mechanism is established for the axonal forms: molecular mimicry between microbial and nerve glycolipids, with specific antibodies and complement-mediated nerve injury, and passive transfer models reproduce it. It is less established for the demyelinating form, which is commoner in Europe and North America and where the target antigen is not identified. Not known: why only roughly 1 in 1,000 to 5,000 people with *Campylobacter* infection develops the syndrome; what determines the demyelinating against the axonal form; why complement inhibition has given mixed trial results.

**Cure status.** SELF-LIMITING, with treatment that shortens the course. This is a monophasic illness that recovers. The natural history is recovery in the large majority, over weeks to many months. Treatment accelerates recovery and does not change the monophasic nature. Roughly 80 per cent walk independently at six months, 10 to 20 per cent have persistent significant disability, and 3 to 7 per cent die†. Recurrence is uncommon, roughly 2 to 5 per cent†. Distinguish from chronic inflammatory demyelinating polyradiculoneuropathy, which is CONTROLLABLE rather than self-limiting and requires maintenance immunotherapy.

**Prevention.** Food and water hygiene to prevent *Campylobacter* — poultry handling, cooking, water safety: MODERATE. It addresses the commonest trigger, with no trial using Guillain-Barré endpoints, and *Campylobacter* reduction programmes in poultry, notably in New Zealand, demonstrate the exposure is reducible. Vector control to prevent Zika: MODERATE, demonstrated by the outbreak-associated incidence rise and fall. Influenza vaccination: net protective on current evidence, since infection carries higher risk than vaccination, MODERATE. No other prevention is established.

**Treatment.** *Intravenous immunoglobulin* shortens time to recovery, and Cochrane review finds it as effective as plasma exchange with better tolerability and easier administration. Normal immunoglobulin is EML-listed and off-patent, since it is a blood product rather than a patented molecule, and a course costs on the order of thousands to low tens of thousands of

US dollars, driven by plasma collection and processing cost. Supply is globally constrained and inequitably distributed. *Plasma exchange* is equally effective; Cochrane review of trials against supportive care shows improved outcome at four weeks and better recovery of walking. It requires apheresis equipment and trained staff, at a course cost on the order of thousands of US dollars.

*Combining immunoglobulin and plasma exchange*: no added benefit. A clear negative result. *Corticosteroids*: ineffective. Cochrane review finds corticosteroids alone do not hasten recovery and oral steroids may delay it. That is an important negative result in an inflammatory disease where steroids would be the intuitive treatment. *Supportive care and intensive care* — respiratory monitoring with forced vital capacity measurement, ventilation when needed, autonomic monitoring, venous thromboembolism prophylaxis, pain management, pressure area care — is what determines survival, not immunotherapy. In settings without ventilation, mortality is many times higher.

*Eculizumab and complement inhibitors*: trials have shown mixed results and nothing is established. *Rehabilitation*: multidisciplinary rehabilitation improves disability and quality of life in randomised and controlled studies, and fatigue and pain persist in a majority and are often undertreated. *Neuropathic pain treatment* with gabapentinoids and tricyclics: pain is present in roughly two thirds and is frequently missed in the acute phase.

**Simple means.** Serial forced vital capacity measurement with a handheld spirometer identifies impending respiratory failure before it becomes an emergency. A device costing tens of US dollars, used at the bedside, determines whether the patient is intubated electively or arrests. This is the highest-value simple means in this entry. Food and water hygiene prevents the commonest trigger. Pressure area care, joint positioning and passive movement prevent contractures, pressure ulcers and nerve compression palsies during the paralysed phase: nursing and family hands. Thromboembolism prophylaxis and early mobilisation. Pain recognition: asking about pain in a patient who cannot easily communicate. Graded exercise in recovery has randomised support for reducing the fatigue that persists in a majority. The honest comparison: supportive care determines survival and immunotherapy shortens the course, so in resource-limited settings excellent nursing and ventilation save more lives than immunoglobulin.

**Gaps.** No WHO fact sheet and no stand-alone GBD estimate for an acutely life-threatening condition. The demyelinating form’s target antigen is unidentified. There is no treatment for the residual disability in 10 to 20 per cent. Steroids’ ineffectiveness is established and counterintuitive, and steroids are still sometimes given. Immunoglobulin supply is globally constrained, equity of access is a major unaddressed issue, and the cost reflects plasma supply rather than intellectual property. Incidence data from low-income countries are sparse, and mortality there is likely substantially higher than published figures.

---

## Myasthenia gravis

**What it is.** An autoimmune disease in which antibodies block neuromuscular transmission, causing fluctuating, fatigable weakness — worse with use and better with rest. It typically affects eyelids, eye movements, speech, swallowing, and limb and respiratory muscles.

**Measured.** Prevalence is roughly 15 to 25 per 100,000 and incidence roughly 0.3 to 3 per 100,000 a year†. Prevalence has risen over decades, mainly from better recognition and longer survival. Onset is bimodal, with a female-predominant peak in the twenties and thirties and a male-predominant peak after 60, and the late-onset group is now the largest and growing, tracking population ageing. Myasthenic crisis, meaning respiratory failure requiring ventilation, occurs in roughly 15 to 20 per cent at some point†. **Mortality has fallen from roughly 70 per cent in the pre-1930s era to roughly 5 per cent or less today**† — one of the most dramatic prognostic transformations of any disease in the book, achieved by ventilation, immunosuppression and intensive care rather than by a targeted cure. There is no WHO fact sheet and no stand-alone GBD estimate. Thymoma is present in roughly 10 to 15 per cent†, and thymic hyperplasia in a substantial proportion of early-onset cases.

**Where it starts.** Among the best-characterised autoimmune diseases in medicine. Acetylcholine receptor antibodies are present in roughly 85 per cent of generalised cases†, and their pathogenicity is demonstrated: the antibodies block and cross-link the receptor, acti-
