vate complement, and passive transfer to animals reproduces the disease. Neonatal transient myasthenia from transplacental antibody transfer is a natural human demonstration. MuSK antibodies are present in roughly 5 to 8 per cent, LRP4 and agrin antibodies in a small proportion, and roughly 5 to 10 per cent are seronegative by current assays†. The thymus is causally involved: thymectomy improves outcome in randomised trial, and thymoma and thymic hyperplasia are over-represented. HLA associations differ between early-onset, with *HLA-DR3/B8*, and late-onset disease, consistent with two distinct diseases under one name. Drug-induced exacerbation is important and preventable: aminoglycosides, fluoroquinolones, macrolides, beta-blockers, magnesium, neuromuscular blocking agents and immune checkpoint inhibitors can precipitate crisis. Checkpoint-inhibitor-induced myasthenia is a newly significant and severe iatrogenic cause as cancer immunotherapy use expands.

The mechanism is established at the level of the molecule, the antibody, the receptor and the synapse. This is the most completely understood disease mechanism in these three chapters: a known autoantigen, demonstrated antibody pathogenicity, an explained physiology, and drugs that act on the explained step. Not known: what initiates the autoimmunity; why the thymus is involved; why some patients are seronegative; why the disease fluctuates hour to hour.

**Cure status.** CONTROLLABLE. Pharmacological remission, meaning no symptoms on treatment, is achieved in a substantial proportion, and complete stable remission off all treatment occurs in roughly 10 to 20 per cent, more often after thymectomy†. Most patients on modern treatment have minimal symptoms and near-normal life expectancy. Relapse on withdrawal of immunosuppression is common, which is why the label is CONTROLLABLE rather than CURABLE.

**Prevention.** No established primary prevention. Avoiding precipitating drugs: STRONG as prevention of crisis. A written list of contraindicated drugs carried by the patient prevents iatrogenic respiratory failure, and it costs nothing. Prompt treatment of infection: MODERATE, since infections are the commonest crisis trigger. Vigilance for checkpoint-inhibitor-induced myasthenia: MODERATE, since early recognition prevents deaths.

**Treatment.** *Pyridostigmine*, an acetylcholinesterase inhibitor, is symptomatic treatment acting directly on the explained mechanism, and is rapid and effective for mild disease; EML-listed, off-patent, and costing on the order of hundreds of US dollars a patient-year. *Corticosteroids* are the mainstay immunosuppressant, with high response rates; prednisolone is EML-listed, off-patent, and costs tens of US dollars a patient-year. Harms: the full corticosteroid burden over years. *Steroid-sparing agents* — azathioprine, mycophenolate, methotrexate, ciclosporin, tacrolimus. Azathioprine is EML-listed, off-patent, tens to low hundreds of US dollars a patient-year; methotrexate is EML-listed as a selected medicine, confirmed against the 24th List, off-patent, tens to low hundreds of US dollars a patient-year.

*Thymectomy*: the MGTX randomised trial (Wolfe and colleagues, *NEJM*, 2016; 126 patients with non-thymomatous acetylcholine-receptor-positive generalised myasthenia, three years) showed that extended transsternal thymectomy with prednisone produced a **lower time-weighted average quantitative myasthenia score, 6.15 against 8.99 (p<0.001)**, and a **lower average prednisone requirement, 44 mg against 60 mg alternate-day (p<0.001)**, with fewer hospitalisations for exacerbation. A randomised trial of an operation, settling a question open for seventy years. Cost: tens of thousands of US dollars one-off. *Rituximab* is highly effective in MuSK-antibody myasthenia in particular, with high remission rates in observational series; a randomised trial in generalised myasthenia, BeatMG, did not meet its primary endpoint, while the Swedish RINOMAX trial in new-onset disease was positive. Rituximab is EML-listed as a selected medicine for multiple sclerosis and for several lymphoid malignancies, confirmed against the 24th List, and is off-patent, available as biosimilars at a small fraction of originator antibody prices.

*Complement inhibitors* — eculizumab, ravulizumab, zilucoplan — are effective in refractory antibody-positive disease, acting on the demonstrated complement step; not EML-listed, on patent, and costing a six-figure sum in US dollars a patient-year for eculizumab at US list price, the most expensive treatment named in this book. They require meningococcal vaccination because of the complement blockade. *FcRn inhibitors* — efgartigimod, rozanolixizumab — reduce circulating IgG with randomised support; not EML-listed, on patent, and costing a six-figure sum in US dollars a patient-year. *Immunoglobulin and plasma exchange* are used for crisis and pre-operative stabilisation, both effective and roughly equivalent;

immunoglobulin is EML-listed and a course costs thousands to low tens of thousands of US dollars.

*Ventilatory support in crisis* is, more than any drug, what reduced mortality from 70 per cent to 5 per cent. The honest cost comparison: prednisolone with azathioprine and pyridostigmine, all on the Essential Medicines List and all off-patent, costs on the order of hundreds of US dollars a patient-year and controls the large majority of patients; the complement and FcRn inhibitors cost six figures a patient-year and are for the refractory minority. Both facts matter.

**Simple means.** A written list of contraindicated drugs, carried by the patient: prevents iatrogenic myasthenic crisis, which is a preventable cause of respiratory failure and death. Paper. Activity pacing and planned rest: the weakness is fatigable by definition, so distributing effort across the day preserves function. Free, and it works because it follows directly from the mechanism. Serial forced vital capacity or single-breath count at home detects deterioration before crisis. Heat avoidance, since weakness worsens with heat. Prompt treatment of infection. The ice pack test for ptosis: a diagnostic aid using an ice pack, costing nothing, reasonably sensitive for ocular myasthenia. Eye patching or prisms for diplopia: cheap, and transforms daily function. Pyridostigmine with generic immunosuppression at a few hundred US dollars a patient-year: effective for most patients, available through essential medicines systems.

**Gaps.** No burden estimate for a treatable, potentially fatal disease. Seronegative myasthenia has no biomarker and uncertain treatment response. The new high-cost biologics have short trials and no head-to-head comparison against optimised generic immunosuppression, so their incremental benefit over a few-hundred-dollar regimen is unquantified. Checkpoint-inhibitor-induced myasthenia is an emerging problem with no trial evidence for management. Prevalence and outcome data from low- and middle-income countries are almost absent, and the transformation of mortality from 70 to 5 per cent depends on intensive care availability.

---

## Cerebral palsy

**What it is.** A group of permanent disorders of movement and posture caused by non-progressive damage to the developing brain, before, during or shortly after birth. The brain lesion does not progress; the musculoskeletal consequences do. Associated impairments of cognition, communication, vision, hearing, feeding, epilepsy and pain are common.

**Measured.** Prevalence is roughly 1.5 to 2.5 per 1,000 live births in high-income countries and roughly 2 to 10 per 1,000 in low- and middle-income countries, with roughly 17 million people living with cerebral palsy worldwide†. WHO's cerebral palsy fact sheet could not be retrieved in the compilation pass, so the figures here come from the standing literature and could not be confirmed to a source. GBD 2021 ranks neurological complications of preterm birth eighth among all nervous system conditions by DALYs, and neonatal encephalopathy second — the two principal causal pathways to cerebral palsy. Prevalence in high-income countries has fallen modestly over the past two decades, particularly in moderately preterm infants, attributed to improved obstetric and neonatal care including magnesium sulphate and therapeutic hypothermia. Prevalence rises steeply with decreasing gestational age: roughly 1 per 1,000 at term, rising to roughly 40 to 100 per 1,000 below 28 weeks. Roughly 35 to 50 per cent have epilepsy, roughly 50 per cent have cognitive impairment, roughly 25 per cent are non-speaking and roughly 25 per cent cannot walk†. Life expectancy is near-normal with mild impairment and substantially reduced with severe motor and feeding impairment.

**Where it starts.** Preterm birth is the largest single risk factor, with risk inversely related to gestational age. Neonatal encephalopathy from intrapartum hypoxia-ischaemia accounts for a minority of cases in high-income countries, roughly 10 to 20 per cent, and a larger proportion where obstetric care is limited†. The common assumption that most cerebral palsy results from birth asphyxia is not supported: most cases in high-income settings have antenatal origins. Intrauterine infection and inflammation, as chorioamnionitis, is associated at roughly two to four times. Multiple pregnancy, roughly four to six times per infant. Intrauterine growth restriction is associated. Neonatal jaundice and kernicterus is a fully preventable cause, still significant in settings without phototherapy and exchange transfusion. Postnatal causes include meningitis, cerebral malaria, head injury, near-drowning and stroke. Genetic

causes are increasingly recognised: recent exome and genome studies find pathogenic variants in roughly 10 to 30 per cent of cases previously labelled idiopathic†, which is changing the understanding of the condition and reduces the proportion attributable to birth events further. Thrombophilia and perinatal arterial ischaemic stroke are established in a subset.

The mechanism is established at the level of the lesion: periventricular leukomalacia in preterm infants, basal ganglia and watershed injury in term hypoxic-ischaemic encephalopathy, and malformations. The inflammatory contribution to white matter injury in preterm infants is well supported. The attribution of cerebral palsy to intrapartum events has been substantially revised downward, with important medico-legal consequences, and the genetic findings revise it further. Not known: why some infants with identical imaging findings have very different function; what determines the plasticity that allows some children to walk and others not; the mechanism of the associated pain, which affects a majority and is persistently undertreated.

**Cure status.** For the brain lesion: RELIEF ONLY. It is permanent and non-progressive. For the progressive musculoskeletal consequences — contractures, hip displacement, scoliosis: CONTROLLABLE, and they are preventable and treatable. Function can improve substantially with intervention, particularly in early childhood. Secondary musculoskeletal deterioration is preventable, and preventing it is where most of the achievable gain lies. Hip surveillance programmes reduce the incidence of painful hip dislocation substantially.

**Prevention.** Strong, and quantified. *Antenatal magnesium sulphate for women at risk of preterm birth*: STRONG. Cochrane review of randomised trials finds magnesium sulphate **reduces cerebral palsy risk by roughly 32 per cent, relative risk 0.68 (95 per cent CI 0.54 to 0.87)**, with a number needed to treat of roughly 46 to prevent one case†. Magnesium sulfate is EML-listed as a selected medicine under section 5.1.1 Antiseizure medicines, for severe pre-eclampsia and eclampsia, with the restrictive note that it is not for other convulsant disorders, confirmed against the 24th List. It is off-patent, and the UNICEF Supply Catalogue gives injection 500 mg/mL in 10 mL ampoules at US$33.11 for a box of 100, about **US$0.33 an ampoule**, read 19 October 2026; the same catalogue gives US$12.65 for a box of ten, about 3.8 times as much per ampoule. So a loading-and-maintenance course is a few US dollars of drug. This is one of the highest-value preventive interventions in the book: a cheap, essential, off-patent mineral salt preventing roughly a third of cerebral palsy in the at-risk group.

*Therapeutic hypothermia for neonatal hypoxic-ischaemic encephalopathy*: STRONG in high-income settings. Cochrane review finds it reduces death or major neurodevelopmental disability, relative risk roughly 0.75, with a number needed to treat of roughly 7†. **However, the HELIX trial in India, Sri Lanka and Bangladesh found no benefit and increased mortality in low-resource settings**, so the intervention is CONTESTED outside well-resourced neonatal intensive care. Both are reported. Cooling equipment costs thousands to tens of thousands of US dollars, or can be improvised, and the trial evidence does not support improvised use in low-resource settings.

*Antenatal corticosteroids for threatened preterm birth*: STRONG for neonatal survival and morbidity. Dexamethasone is EML-listed and off-patent, and the UNICEF Supply Catalogue gives 4 mg tablets at US$24.00 for 100, about US$0.24 a tablet, read 19 October 2026, so a course is a few US dollars. *Preventing and treating neonatal jaundice* with phototherapy, exchange transfusion and maternal anti-D prophylaxis: STRONG. Kernicterus is entirely preventable. *Skilled birth attendance and neonatal resuscitation training*, such as Helping Babies Breathe: STRONG for the perinatal asphyxia fraction. *Preventing preterm birth* through progesterone in selected women, cervical cerclage, smoking cessation, treating infection and spacing pregnancies: MODERATE.

*Rubella and other vaccination, and prevention of congenital infection*: STRONG for that fraction. *Folic acid fortification*: STRONG for neural tube defects, with the US combined prevalence falling from 10.8 to 6.9 per 10,000, a 36 per cent decline†. Folic acid is EML-listed, and the UNICEF Supply Catalogue gives 5 mg tablets at US$5.41 for a bottle of 1,000, about US$0.0054 a tablet, read 19 October 2026. *Iodine in pregnancy*: STRONG for neurodevelopmental outcomes generally. *Malaria prevention in pregnancy* with insecticide-treated nets and intermittent preventive treatment: STRONG for low birth weight and preterm birth.

*Caesarean section rates*: CONTESTED. Rising caesarean rates have not reduced cerebral palsy prevalence, which is consistent with most cases not being intrapartum in origin.

**Treatment.** *Early intervention with goal-directed, active, task-specific training*: the evidence favours interventions in which the child actively practises specific goals over passive handling approaches, with moderate effect sizes. Early detection by the General Movements Assessment and the Hammersmith examination allows diagnosis before six months and enables earlier intervention. *Hip surveillance and preventive orthopaedic surgery*: population hip surveillance programmes in Sweden and Australia substantially reduce painful hip dislocation — an organisational intervention with a measured population effect.

*Botulinum toxin for focal spasticity* reduces tone and improves specific goals, and its benefit on long-term function and on contracture prevention is less clear than once assumed, with repeated injection causing muscle atrophy; cost is hundreds to low thousands of US dollars a cycle. *Oral antispasticity drugs* — baclofen, diazepam, tizanidine, dantrolene — give modest benefit with common sedation; baclofen and diazepam are EML-listed, off-patent, and cost tens of US dollars a patient-year. *Intrathecal baclofen* is effective for severe generalised spasticity, at a pump cost in the tens of thousands of US dollars.

*Selective dorsal rhizotomy* reduces spasticity durably in selected ambulant children with spastic diplegia, with randomised trial evidence supporting it combined with physiotherapy. *Orthopaedic surgery*: single-event multilevel surgery for gait, scoliosis correction, hip reconstruction. *Management of the associated conditions* is where most of the quality-of-life gain is: epilepsy in 35 to 50 per cent, feeding and nutrition with gastrostomy where needed, drooling, constipation, respiratory care, hip and spine surveillance, vision and hearing correction, communication, and pain, which affects a majority and is persistently under-recognised and undertreated.

*Communication*: augmentative and alternative communication for the roughly 25 per cent who are non-speaking. *Treatments without support*: hyperbaric oxygen, where the randomised trial was negative; stem cell therapy, not established; and various patterned-movement therapies. Families are marketed these.

**Simple means.** Magnesium sulphate at a few US dollars a course, preventing roughly 32 per cent of cerebral palsy in at-risk preterm births, as an off-patent essential medicine with an indicative ampoule price of US$0.33 in October 2026: the best preventive cost-to-effect ratio in Chapter 08. Antenatal corticosteroids at a few US dollars a course. Phototherapy for jaundice: blue light, and in sunny climates filtered sunlight has been trialled with non-inferior results to conventional phototherapy in a Nigerian randomised trial. Neonatal resuscitation with a bag and mask, taught in a day: the Helping Babies Breathe programme reduced early neonatal mortality in implementation studies. Positioning, stretching and active play, delivered by family, prevent contractures. Hip surveillance: an X-ray on a schedule prevents painful dislocation. Communication boards: paper and pictures for the 25 per cent who cannot speak. Pain assessment in non-verbal children, systematically, using observational scales: free, and a majority have pain that goes untreated. Nutrition attention: undernutrition is common and worsens every other outcome.

**Gaps.** WHO's fact sheet could not be retrieved in the compilation pass, so prevalence figures should be verified against WHO and against the Global CP Register network. Therapeutic hypothermia's failure in the HELIX trial means the main neonatal neuroprotective intervention does not transfer to the settings with the highest burden, and no alternative exists. The genetic contribution, 10 to 30 per cent in recent series, is reshaping aetiology and is not yet reflected in most prevention frameworks. Prevalence data from most low- and middle-income countries are absent or from small surveys. Adults with cerebral palsy are barely studied despite being the majority, and secondary musculoskeletal and pain problems in adulthood have almost no trial base. Pain in cerebral palsy is highly prevalent, well documented as undertreated, and has minimal intervention evidence.

---

## Huntington disease

**What it is.** An inherited, progressive degenerative brain disease causing involuntary movements, called chorea, progressive loss of voluntary motor control, cognitive decline and psy-

chiatric symptoms. It is caused by a single expanded repeat in one gene and is inherited in an autosomal dominant pattern.

**Measured.** Prevalence is roughly 5 to 10 per 100,000 in European-ancestry populations and substantially lower in East Asian populations, roughly 0.4 per 100,000, and in African populations†. The geographic difference tracks the frequency of intermediate repeat alleles in the founder populations. Onset is typically between 30 and 50 years, juvenile onset before 20 in roughly 5 to 10 per cent, and late onset occurs†. Median survival is roughly 15 to 20 years from motor onset†. The leading causes of death are aspiration pneumonia and suicide, which is substantially elevated at roughly 5 to 10 times the general population, with the highest risk around the time of diagnosis and at loss of independence. There is no WHO fact sheet and no stand-alone GBD estimate. Each child of an affected parent has a 50 per cent risk. Predictive testing is available and uptake is low: roughly 5 to 25 per cent of eligible at-risk relatives choose to be tested†, which is itself an important measured finding about how people respond to certain genetic knowledge.

**Where it starts.** The cause is completely known, which is rare in this book. A CAG trinucleotide repeat expansion in the *HTT* gene on chromosome 4 was identified in 1993. Fewer than 27 repeats is normal; 27 to 35 is intermediate and generally non-penetrant but unstable in transmission; 36 to 39 shows reduced penetrance; and 40 or more repeats causes the disease with essentially complete penetrance. Repeat length inversely correlates with age at onset, explaining roughly 50 to 70 per cent of onset variance, and longer repeats mean earlier onset, with juvenile onset usually involving very long expansions. Anticipation occurs: repeats tend to expand further in transmission, particularly through the paternal line, so onset is often earlier in successive generations. Somatic instability — further expansion in neurons during life — is now understood to be a major determinant of onset and progression, and DNA repair genes *FAN1*, *MSH3* and *MLH1* are confirmed genetic modifiers. That is the most significant advance in understanding the disease's variability. Residual onset variance beyond repeat length is substantially heritable, with the DNA repair modifiers accounting for a measurable part.

The cause is certain and the pathogenic mechanism downstream of it is not. Mutant huntingtin aggregation, transcriptional dysregulation, mitochondrial impairment, impaired axonal transport and somatic repeat expansion are all implicated. Medium spiny neurons of the striatum degenerate first and the selectivity is unexplained. The somatic expansion model has reframed the field: the inherited repeat may act chiefly by setting the starting point for lifelong expansion in neurons, making DNA repair a therapeutic target. Not known: why striatal neurons specifically; whether lowering huntingtin is sufficient; why the first huntingtin-lowering trial failed.

**Cure status.** RELIEF ONLY. No treatment slows or halts the disease. Chorea is treatable; the underlying degeneration is not. Progression is relentless over 15 to 20 years. Predictive testing allows reproductive choice, and preimplantation genetic testing and prenatal diagnosis can prevent transmission, which is prevention of a new case rather than treatment of a person.

**Prevention.** The disease is not preventable in a person who carries the expansion. Transmission is preventable: preimplantation genetic testing with in vitro fertilisation, or prenatal diagnosis, STRONG for the transmission outcome. Uptake varies widely by country and by access to funded in vitro fertilisation, at a cost in the tens of thousands of US dollars a cycle. Genetic counselling before testing is standard of care, and the low voluntary testing uptake reflects informed choice rather than a service failure. No modifiable lifestyle factor has been shown to delay onset; observational associations with exercise, cognitive activity and caffeine are weak and confounded.

**Treatment.** *Chorea treatment.* **VMAT2 inhibitors** — tetrabenazine, deutetrabenazine, valbenazine — reduce chorea in randomised trials. Tetrabenazine is not EML-listed, is off-patent, and costs on the order of hundreds to low thousands of US dollars a patient-year. Deutetrabenazine and valbenazine are on patent and cost a low six-figure sum in US dollars a patient-year, for a modestly better adverse-effect profile on the same mechanism. Harms: depression and suicidality, which carries a black-box warning for tetrabenazine, plus parkinsonism and sedation. **Antipsychotics** — olanzapine, risperidone, tiapride — reduce chorea and treat coexisting psychiatric symptoms simultaneously, and are often preferred for that reason. Olanzapine and risperidone are EML-listed, off-patent, and cost tens of US dollars

a patient-year. They are far cheaper than the VMAT2 inhibitors and treat two problems at once.

*Psychiatric treatment*: depression, irritability, apathy, obsessive features and psychosis are frequent and treatable, with SSRIs for depression and irritability and antipsychotics for psychosis and severe irritability. Suicide risk is substantially elevated and psychiatric treatment is the most important modifiable contributor to it. Fluoxetine is EML-listed, off-patent, and costs a few US dollars a patient-year. *Nutrition*: weight loss is characteristic and predicts faster progression, so calorie-dense food and eventually gastrostomy are used; no numeric targets are given. *Speech, swallowing and physiotherapy*: aspiration pneumonia is a leading cause of death, so swallowing management affects survival, and exercise and physiotherapy improve motor function and fitness in randomised trials.

*Huntingtin-lowering therapies*: **tominersen**, an antisense oligonucleotide, was halted in phase 3 in 2021 after the higher-dose arms showed **worse** outcomes than placebo, and it is being re-tested at lower doses in a younger population. Several other huntingtin-lowering and splice-modulating programmes are in trials. Reported as not available and as having produced a serious negative signal. A gene therapy programme, AMT-130, reported encouraging interim data in small numbers between 2023 and 2025, and is not established. *Multidisciplinary clinic care and advance care planning*.

**Simple means.** Generic antipsychotics at tens of US dollars a patient-year, treating chorea and psychiatric symptoms together, against deutetrabenazine at a six-figure sum for chorea alone on an older mechanism. That is the central practical comparison. Exercise and physiotherapy: randomised trials show improved motor function and fitness, with no supply chain. Swallowing precautions and food texture modification: taught, free, and they address the leading cause of death. Nutrition attention, since weight loss predicts faster progression. Environmental structure and routine reduce behavioural distress in a condition where cognitive flexibility is lost early. Suicide risk recognition at the two high-risk points, around diagnosis and at loss of independence: asking, and treating depression; see the suicide entry for intervention evidence. Genetic counselling: enabling informed choice, including the choice not to know, which most at-risk people make.

**Gaps.** No burden estimate for a disease with complete penetrance and known prevalence. Prevalence outside European-ancestry populations is poorly measured and probably underestimated by ascertainment. The tominersen failure, where huntingtin lowering appeared harmful, is unexplained and consequential for the whole therapeutic strategy. Somatic expansion and DNA repair modifiers are the most promising new target and are unvalidated therapeutically. Juvenile Huntington disease is clinically distinct and barely studied. There is no disease-modifying treatment for a disease whose cause has been known since 1993 — a notable gap, given that certainty of cause is usually the hardest part.

---

## Trigeminal neuralgia

**What it is.** Sudden, severe, brief electric-shock-like facial pain in the distribution of the trigeminal nerve, triggered by light touch, chewing, speaking, washing or cold air. Attacks last seconds and recur in volleys. Between attacks there is usually no pain and the neurological examination is typically normal.

**Measured.** Incidence is roughly 4 to 13 per 100,000 a year, and lifetime prevalence roughly 0.1 to 0.3 per cent†. Women roughly 1.5 to 2 times men†. Onset is typically after 50, and onset before 40 raises suspicion of multiple sclerosis or another secondary cause. Roughly 2 to 5 per cent of people with multiple sclerosis develop trigeminal neuralgia, and roughly 2 to 4 per cent of trigeminal neuralgia cases are multiple-sclerosis-related. Pain intensity is among the highest recorded in clinical medicine; the historical name was *tic douloureux*, and suicide associated with uncontrolled attacks is described in the older literature. Diagnostic delay and misdiagnosis as dental pain are common, with unnecessary dental extractions a well-documented and preventable harm. There is no WHO fact sheet and no stand-alone GBD estimate.

**Where it starts.** This is a condition where the cause is usually identifiable and correctable. Neurovascular compression of the trigeminal root by an artery, usually the superior cerebellar artery, or by a vein, is found in the large majority of classical cases, with MRI demonstrat-

ing compression and morphological change in the nerve. Surgical decompression relieves the pain, which is strong causal evidence. Multiple sclerosis, through a demyelinating plaque at the trigeminal root entry zone, is the secondary cause in a small percentage. Tumour — vestibular schwannoma, meningioma, epidermoid — compressing the nerve accounts for a small percentage, and is a reason to image everyone. Hypertension is weakly associated. There is no significant heritability and familial cases are rare.

The mechanism is established in outline: focal demyelination at the root entry zone from chronic compression leads to ectopic impulse generation and ephaptic transmission between fibres, which explains why light touch triggers severe pain, and sodium channel involvement explains why sodium channel blockers work. Not known: why compression causes pain in some people and is found incidentally in others; why the pain is paroxysmal rather than constant; why some patients develop constant background pain in addition.

**Cure status.** Treated by microvascular decompression: CURABLE in roughly 70 to 80 per cent, pain-free at ten years†. Treated medically or by destructive procedures: CONTROLLABLE. One of the few conditions in Chapter 08 with a genuine surgical cure. Carbamazepine relieves pain in roughly 70 to 90 per cent initially, and efficacy commonly declines over years while adverse effects limit dose. Microvascular decompression gives roughly 70 to 80 per cent pain-free at ten years in large series, without the sensory loss caused by destructive procedures, and it is the only procedure that addresses the cause rather than destroying the nerve. Destructive procedures — radiofrequency, glycerol, balloon compression, radiosurgery — relieve pain with higher recurrence and with sensory loss. Spontaneous remissions occur and can last months to years, which complicates assessment of any treatment.

**Prevention.** No established primary prevention. Avoiding unnecessary dental procedures through correct diagnosis: STRONG as prevention of iatrogenic harm, and recognition is the intervention. MRI in all new cases identifies tumours and multiple sclerosis plaques, which changes management: MODERATE.

**Treatment.** *Carbamazepine* is the first-line treatment and the reference standard, with 70 to 90 per cent initial response and a number needed to treat of roughly 2 in the older randomised trials — among the largest treatment effects for any pain condition. It is EML-listed and off-patent, and costs tens of US dollars a patient-year. Harms: hyponatraemia, sedation, ataxia, rash including severe cutaneous reactions with *HLA-B*15:02* testing advised in populations where that allele is common, and extensive drug interactions. *Oxcarbazepine* has comparable efficacy, is better tolerated and has fewer interactions; not EML-listed, off-patent, tens to low hundreds of US dollars a patient-year.

*Lamotrigine, baclofen, gabapentin, pregabalin and phenytoin* are second-line add-ons with weaker evidence; lamotrigine, baclofen and phenytoin are EML-listed, all off-patent, and cost tens to low hundreds of US dollars a patient-year. *Microvascular decompression* gives roughly 70 to 80 per cent pain-free at ten years and is the only causally directed treatment. Surgical mortality is roughly 0.2 to 0.5 per cent, and risks include hearing loss in roughly 1 to 3 per cent†, cerebrospinal fluid leak, and facial numbness, which is less frequent than with destructive procedures. The cost runs to tens of thousands of US dollars one-off, and in long-term follow-up it is more cost-effective than decades of medication for suitable candidates.

*Percutaneous destructive procedures* — radiofrequency thermocoagulation, glycerol rhizolysis, balloon compression — are effective, cheaper and repeatable, with higher recurrence, facial numbness, and a risk of anaesthesia dolorosa, which is painful numbness and is difficult to treat; cost in the low thousands of US dollars. *Gamma knife or stereotactic radiosurgery* is non-invasive, with pain relief delayed by weeks to months, lower initial success and higher recurrence than microvascular decompression, and progressive numbness; cost in the tens of thousands of US dollars. *Intravenous or intranasal lidocaine and phenytoin for acute crisis* are used when pain prevents eating and drinking, on small trial evidence.

*Treating the secondary cause*: tumour removal, multiple sclerosis disease-modifying therapy.

**Simple means.** Carbamazepine at tens of US dollars a patient-year with a number needed to treat of about 2: for one of the most severe pains in medicine, an off-patent essential medicine controls it in 70 to 90 per cent of people initially. The cost-to-effect ratio is among the best in Chapter 08. Correct diagnosis prevents unnecessary dental extractions, which are a documented and common harm: a history and an examination. Trigger avoidance: identifying and avoiding the specific touch, chewing or cold triggers, soft food, and avoiding

cold wind during a bout. Free, and it follows directly from the mechanism. A straw and soft food during a severe bout prevent the dehydration and weight loss that drive emergency admission. Not using opioids: they do not work for this pain and expose the patient to harm — a negative simple means. Keeping a bout diary: bouts remit and recur, so medication can be tapered during remission rather than continued indefinitely.

**Gaps.** No burden estimate for a condition of extreme severity. Most medication evidence is from small, old trials, and carbamazepine's dominance rests on a thin modern evidence base despite being clearly effective. There is no randomised comparison of microvascular decompression against medical management, so the surgical decision rests on observational series. Spontaneous remission rates are poorly quantified and confound all efficacy estimates. The reason compression causes pain in only some of those who have it is unknown.

---

## Essential tremor

**What it is.** Progressive action tremor, typically of both hands, present on movement and on holding a posture, and often affecting the head and voice. It is not Parkinson disease: there is no slowness or rigidity, and the tremor appears with action rather than at rest.

**Measured.** Prevalence is roughly 0.9 per cent of all ages and 4 to 5 per cent of people over 65, making it one of the commonest movement disorders, and some surveys give higher figures over 65†. Roughly 60 to 70 million people worldwide are affected†. The sexes are roughly equally affected. Onset is bimodal, in adolescence or young adulthood and after 60. Roughly 50 to 70 per cent report a family history, and heritability is high†. Roughly 15 to 25 per cent stop working or change occupation because of it†. There is no WHO fact sheet and no stand-alone GBD estimate, so the burden is substantial and unmeasured. Misdiagnosis in both directions with Parkinson disease is frequent, with diagnostic disagreement rates of roughly 30 to 50 per cent reported in some studies†.

**Where it starts.** A family history is present in 50 to 70 per cent, with an apparently autosomal dominant pattern in many families, and twin concordance supports high heritability. Despite that, no major causative gene has been identified — a notable and unexplained failure of gene-hunting in a clearly familial disorder. Age is the dominant factor for prevalence. Ethanol reduces the tremor in most patients, transiently and reliably: a distinctive and unexplained pharmacological signature, and not a treatment recommendation. The condition is associated with higher risk of later Parkinson disease, dementia and hearing loss in some cohorts, and whether essential tremor is a single disease, a syndrome, or a group of disorders is genuinely disputed; the 2018 consensus criteria reflected that by narrowing the definition and creating an "essential tremor plus" category.

Cerebellar and olivocerebellar circuit involvement is supported by imaging, by the effect of cerebellar lesions, and by the effectiveness of targeting the ventral intermediate nucleus of the thalamus, which relays cerebellar output. Whether there is neurodegeneration — Purkinje cell changes have been reported and disputed — is unresolved, and it determines whether this is a degenerative disease or a circuit oscillation disorder. GABAergic dysfunction is proposed, would fit the ethanol response, and is not established. Not known: the gene or genes; whether it is degenerative; why ethanol helps; whether it is one condition.

**Cure status.** CONTROLLABLE, on medication and on deep brain stimulation alike. Medication reduces tremor amplitude by roughly 50 per cent in responders, and roughly 30 to 50 per cent of patients get inadequate benefit or cannot tolerate the drugs. Deep brain stimulation of the ventral intermediate thalamic nucleus reduces tremor by roughly 60 to 90 per cent with the effect sustained for years, and it is one of the most effective interventions in movement disorders. MRI-guided focused ultrasound thalamotomy reduced the hand tremor score by roughly 47 per cent against 0.1 per cent in the sham arm in a randomised trial (Elias and colleagues, *NEJM*, 2016), with benefit sustained at five years in follow-up, and it is incisionless. All of these hold the tremor down while they continue, and none removes the disorder. Tremor progresses slowly over decades.

**Prevention.** No established prevention. Given high heritability and no identified gene, there is nothing to act on, and that is stated rather than filled with speculative measures. Avoiding tremor-exacerbating drugs — beta-agonists, lithium, valproate, some antidepressants,

caffeine in some people, thyroid excess: MODERATE as prevention of worsening. Correctly identifying drug-induced tremor avoids misdiagnosis entirely.

**Treatment.** *Propranolol* is first-line and reduces tremor amplitude by roughly 50 per cent in roughly 50 to 70 per cent of patients; EML-listed†, off-patent, and costing a few US dollars a patient-year. Contraindicated in asthma and significant bradycardia. *Primidone* is equally effective as propranolol in head-to-head trials, with sedation and early intolerance as the limitations; not EML-listed, off-patent, tens of US dollars a patient-year. *Propranolol with primidone* is better than either alone in some patients. *Topiramate, gabapentin, alprazolam, atenolol and sotalol* are second-line on modest evidence; gabapentin is off-patent and costs tens to low hundreds of US dollars a patient-year.

*Botulinum toxin* is used for head and voice tremor, where oral drugs are least effective, and hand injection causes weakness; cost hundreds to low thousands of US dollars a cycle. *Deep brain stimulation* of the ventral intermediate thalamic nucleus gives 60 to 90 per cent tremor reduction, allows bilateral treatment, and is adjustable and reversible; cost in the tens of thousands of US dollars plus battery replacements. *MRI-guided focused ultrasound thalamotomy* has randomised sham-controlled evidence: 47 per cent reduction in hand tremor score against 0.1 per cent with sham at three months, sustained at five years†. It is unilateral in most practice, incisionless and **irreversible**, which is the key difference from deep brain stimulation; cost in the tens of thousands of US dollars.

*Weighted utensils, wrist weights and adaptive equipment* reduce functional impact and are cheap. *Occupational therapy* provides adaptive strategies for writing, eating and drinking.

**Simple means.** Propranolol at a few US dollars a patient-year: the first-line treatment for one of the commonest movement disorders is an off-patent essential medicine costing a few dollars a year, and for 60 to 70 million people that matters more than the surgical options. Weighted cutlery, weighted wrist bands, non-spill cups and thicker pens reduce the functional impact of tremor directly, cost a few dollars, and are often not offered. Stabilising the arm against the body or a surface when performing fine tasks: mechanical, free and effective. Reducing caffeine where it worsens tremor, and identifying and stopping a tremor-causing drug, which can resolve the problem entirely. Occupational adaptation: changing how a task is done rather than treating the tremor. Exercise: limited evidence specific to this condition, with general benefit on function. No light, sleep timing or social-connection intervention has specific evidence here.

**Gaps.** No burden estimate for a disorder affecting 4 to 5 per cent of people over 65. No causative gene despite clear familial aggregation. Whether it is degenerative is unresolved and determines how it should be understood. Whether it is one disease is disputed; the 2018 criteria revision acknowledged this and the epidemiological literature predates it, so prevalence figures are not comparable to the current definition. There is no head-to-head randomised comparison of deep brain stimulation against focused ultrasound. Focused ultrasound is irreversible and its long-term adverse effects beyond five years are unknown.

---

## Meningitis sequelae

**What it is.** Lasting consequences in survivors of meningitis: hearing loss, epilepsy, cognitive and learning impairment, motor deficits, hydrocephalus, visual impairment and behavioural change. Bacterial meningitis causes the great majority of sequelae; viral meningitis usually does not.

**Measured.** Meningitis ranked sixth among all nervous system conditions by DALYs on GBD 2021 — ahead of epilepsy and autism. Bacterial meningitis kills about 1 in 6, roughly 17 per cent; about 1 in 5 survivors has severe complications; and about 1 in 5 survivors has long-term after-effects (WHO meningitis fact sheet, 29 September 2026; the page states no year for these general figures). In the African meningitis belt surveillance network, covering 24 of 26 countries, 2025 saw 21,526 suspected cases, 971 deaths and a case fatality rate of 4.5 per cent; those are surveillance-network figures, not global totals, and **WHO's fact sheet gives no global annual case or death total**.

Hearing loss is the commonest sequela, affecting roughly 10 to 30 per cent of bacterial meningitis survivors depending on pathogen, with pneumococcal meningitis carrying the highest

rate. Sequelae rates are substantially higher in low-income settings, where presentation is later and treatment delayed. Before the MenACV rollout from 2010, serogroup A caused 80 to 85 per cent of epidemics in the African meningitis belt; after mass preventive campaigns, confirmed serogroup A disease fell by **99 per cent** in vaccinated populations, with the last confirmed serogroup A case in 2017 in countries that introduced the vaccine.

The Defeating Meningitis by 2030 roadmap, adopted as WHA73.9 in 2020, targets a 50 per cent reduction in vaccine-preventable bacterial meningitis cases and a 70 per cent reduction in deaths. Men5CV was prequalified in 2023, and Niger ran the first Gavi-supported Men5CV campaign in 2025.

**Where it starts.** The pathogen determines outcome: *Streptococcus pneumoniae* carries the highest mortality and sequelae rates; *Neisseria meningitidis* lower; *Haemophilus influenzae* type b was historically significant and is now largely vaccine-prevented; Group B *Streptococcus* and *E. coli* affect neonates; *Mycobacterium tuberculosis* carries very high sequelae rates; *Cryptococcus* affects people with HIV. Delay to effective antibiotic is the strongest modifiable determinant of death and sequelae. Age matters: neonates and young children have the highest rates of lasting impairment and older adults the highest mortality. Severity at presentation — coma, seizures, shock — predicts sequelae. Lack of vaccination is the entirely preventable component. HIV, asplenia, complement deficiency, cochlear implants and skull base defects raise susceptibility. Crowding, the dry season and dust in the African meningitis belt are the epidemiological driver of the belt's epidemic pattern.

The host inflammatory response to bacterial components in the subarachnoid space causes much of the brain injury, not the bacteria alone, which is why corticosteroids help in some settings: an inflammation-mediated mechanism with a matching treatment. Cochlear damage from labyrinthitis and from the inflammatory response explains the hearing loss, and the window for cochlear implantation closes as the cochlea ossifies — a mechanism with a direct, time-critical clinical consequence. Not known: why dexamethasone's benefit differs so much between high-income and low-income settings; why cognitive sequelae occur without obvious structural damage.

**Cure status.** The sequelae do not share one label. Hearing loss: RELIEF ONLY — it can be rehabilitated with hearing aids or cochlear implants and not reversed. Cognitive impairment: RELIEF ONLY — it is permanent. Epilepsy: CONTROLLABLE. Hydrocephalus: CONTROLLABLE, treatable by shunting. The acute illness itself is CURABLE with prompt effective antibiotics. The decisive intervention is prevention and speed, not the treatment of sequelae.

**Prevention.** Among the strongest in the book, with a 99 per cent figure attached. *Conjugate vaccines*: STRONG. MenACV reduced confirmed serogroup A disease by 99 per cent in vaccinated populations in the African meningitis belt. Hib conjugate vaccine has nearly eliminated *Haemophilus influenzae* type b meningitis where introduced, with reductions above 90 per cent†. Pneumococcal conjugate vaccines have substantially reduced pneumococcal meningitis in vaccinated cohorts, and 2025 coverage for the last pneumococcal dose was 71 per cent globally. Men5CV, prequalified in 2023, covers five serogroups in one product. *Maternal Group B Streptococcus screening and intrapartum antibiotic prophylaxis*: STRONG for early-onset neonatal disease.

*Rapid access to antibiotics*: STRONG for both death and sequelae; the determinant is time, and the measures are recognition, transport and pre-referral antibiotics. *Dexamethasone with or before the first antibiotic dose*: CONTESTED by setting. Cochrane review finds dexamethasone reduces hearing loss, relative risk roughly 0.74, and neurological sequelae overall, with the mortality benefit confined to high-income settings, and trials in low-income settings and in HIV-prevalent populations showed no benefit. Dexamethasone is EML-listed and off-patent, and the UNICEF Supply Catalogue gives 4 mg tablets at US$24.00 for 100, about US$0.24 a tablet, read 19 October 2026, so a course is a few US dollars. The setting-dependence is reported.

*Chemoprophylaxis for close contacts* of meningococcal cases: STRONG. Ciprofloxacin, rifampicin and ceftriaxone are all EML-listed and off-patent, and a course is a few US dollars. *Reactive and preventive mass vaccination campaigns* in the meningitis belt: STRONG. *Hearing screening of all bacterial meningitis survivors before discharge*: STRONG for the sequela outcome, because the window for cochlear implantation before cochlear ossification is weeks to months, and delay forecloses the treatment. *HIV treatment*: STRONG for cryptococcal

meningitis prevention. *BCG vaccination*: MODERATE specifically for childhood tuberculous meningitis, where its efficacy is better than for pulmonary tuberculosis.

**Treatment.** *Acute.* **Prompt empirical antibiotics** — ceftriaxone or cefotaxime, with ampicillin where *Listeria* is a consideration, and vancomycin where pneumococcal resistance is prevalent. All are EML-listed and off-patent, and a course costs on the order of tens of US dollars. Oily chloramphenicol or single-dose ceftriaxone is used in epidemic settings where intravenous therapy is impossible; EML-listed, a few US dollars a dose. **Dexamethasone**: see prevention; it reduces hearing loss and neurological sequelae, with mortality benefit confined to high-income settings. **Supportive care**: airway, fluids, seizure control, management of raised intracranial pressure. *Sequelae.* **Hearing aids and cochlear implantation**: cochlear implantation restores functional hearing in post-meningitis deafness and must be done before cochlear ossification, which can begin within weeks. Time-critical. Implant cost runs to tens of thousands of US dollars plus rehabilitation; hearing aids cost from low hundreds to low thousands. **Antiseizure medication** for post-meningitis epilepsy: see the epilepsy entry; phenobarbital at about US$6.24 a patient-year on the October 2026 UNICEF indicative price. **Ventriculoperitoneal shunting** for hydrocephalus. **Educational support and rehabilitation** for cognitive and motor sequelae. **Physiotherapy and orthotics** for motor deficits; vision rehabilitation.

**Simple means.** Vaccination: a 99 per cent reduction in confirmed serogroup A meningococcal disease in vaccinated populations. Nothing else in this book matches that figure, and the product is a single injection costing a few US dollars at Gavi prices. Dexamethasone at a few US dollars a course reduces hearing loss, relative risk roughly 0.74, in high-income settings: cheap, on the Essential Medicines List†, and setting-dependent. Pre-referral single-dose antibiotic where transport will be delayed: ceftriaxone or oily chloramphenicol, a few US dollars, given by a health worker before transfer. Hearing screening before discharge: a test costing very little that determines whether a deafened child gets an implant within the window or not. Pure organisation. Recognition and speed: public and health-worker awareness of the presentation is the single determinant of outcome. Contact chemoprophylaxis: a few US dollars, preventing secondary cases. Reducing crowding and dust exposure in the belt during the dry season: the epidemiological driver, and non-clinical.

**Gaps.** WHO's fact sheet gives no global annual case or death total for meningitis, only African belt surveillance figures, and for a condition ranked sixth by nervous-system DALYs that is a significant gap. Dexamethasone's divergent effect between settings is unexplained and clinically consequential. Sequelae are poorly measured systematically, and the one-in-five figures carry no year and no confidence interval in the WHO source. Follow-up of survivors, including hearing screening, is inconsistent even in high-income settings, so sequelae are both under-detected and under-treated. Tuberculous meningitis has the worst sequelae profile and the thinnest treatment evidence. The Men5CV rollout is early and its population impact is not yet measured.

---

## Spinal cord injury consequences

**What it is.** Permanent loss of motor, sensory and autonomic function below the level of damage to the spinal cord. The consequences extend well beyond paralysis: bladder and bowel dysfunction, pressure injury, spasticity, neuropathic pain, autonomic dysreflexia, respiratory compromise, sexual dysfunction and loss of temperature regulation.

**Measured.** About 15.4 million people were living with spinal cord injury in 2021 (WHO spinal cord injury fact sheet, 2021 data); the key facts section of the same page rounds this to over 15 million. Over 4.5 million years lived with disability in 2021. WHO gives no annual incidence figure; the standing literature puts global incidence at roughly 250,000 to 500,000 new cases a year. In-hospital mortality is nearly three times higher in low- and middle-income countries than in high-income countries. Unemployment among adults with spinal cord injury exceeds 60 per cent. **Only 5 to 35 per cent of people who need wheelchairs have wheelchair access** (WHO; no year stated), and that single figure accounts for a large share of the global burden. WHO ranks the causes without percentages: traumatic injuries from falls and road traffic crashes lead, followed by violence including self-harm, then work- and sports-related injuries, with non-traumatic causes — tumours, degenerative and vascular

conditions — increasing. Historically the age pattern showed a young male peak from trauma, and falls in older adults are now a growing and in some high-income countries dominant cause, shifting the demographic older. The leading causes of death after the first year are respiratory disease, usually pneumonia; sepsis, commonly from pressure injury or a urinary source; and cardiovascular disease.

**Where it starts.** Road traffic crashes: about 1.16 million road deaths a year, with 20 to 50 million non-fatal injuries (WHO road traffic injuries fact sheet, 20 July 2026). Helmets reduce the risk of death by more than six times and brain injury risk by up to 74 per cent; seat-belts reduce occupant death risk by up to 50 per cent; child restraints give a 71 per cent reduction in infant deaths; every 1 per cent increase in mean speed produces a 4 per cent increase in fatal crash risk and 3 per cent in serious crash risk; pedestrian death risk from car fronts rises 4.5 times going from 50 to 65 km/h. Falls are the leading cause in many high-income countries, especially in older adults with pre-existing cervical spondylosis, where a low-energy fall causes central cord injury; fatal falls number 684,000 a year with 37.3 million non-fatal falls needing medical attention, on WHO's oldest fact sheet, printed 26 April 2021 with no data year stated. Violence, including self-harm, is a cause; no methods are described anywhere in this chapter. Occupational and sports injury: diving into shallow water, rugby and similar collision sports, construction falls. Non-traumatic causes: spinal tumour, abscess, tuberculosis of the spine, which is a major cause in endemic regions, transverse myelitis, spinal cord infarction, and degenerative cervical myelopathy — which is the commonest cause of spinal cord dysfunction in adults worldwide and is surgically treatable if recognised before severe damage.

Primary mechanical injury is followed by a secondary cascade of ischaemia, excitotoxicity, inflammation, oedema and apoptosis over hours to days, well characterised in animal models. Every neuroprotective agent targeting that cascade has failed in human trials, including high-dose methylprednisolone, whose use was standard for years and is no longer recommended because the benefit did not hold and the harms — infection, gastrointestinal bleeding — did. Glial scarring and inhibitory molecules prevent axonal regeneration; established, and it has not yielded a treatment. Not known: how to achieve functional axonal regeneration; why the secondary cascade is unmodifiable in humans despite being modifiable in rodents.

**Cure status.** For the injury itself: RELIEF ONLY. No treatment restores a severed or crushed cord. For most of the consequences: CONTROLLABLE, and most of the mortality and morbidity after the first year is preventable. Some spontaneous neurological recovery occurs in the first year, more in incomplete injuries. Degenerative cervical myelopathy is the important exception: surgical decompression halts progression and often improves function, and it is the commonest cause of spinal cord dysfunction worldwide, with delayed recognition the problem. The secondary complications — pressure injury, urinary sepsis, pneumonia, autonomic dysreflexia — are preventable, and they are what kills people.

**Prevention.** Primary prevention is the whole story here, and it is well quantified. *Road safety law* — helmet laws, seat-belt laws, speed limits, drink-driving limits, motorcycle licensing: STRONG. The WHO effect sizes above are among the best-quantified prevention figures in the book, derived from legislative natural experiments across many countries. *Alcohol policy*: STRONG. There were 298,000 alcohol-related road deaths in 2019, of which 156,000 were caused by someone else's drinking, and random breath testing and lowered legal limits reduce crash deaths.

*Fall prevention in older adults*: STRONG. Exercise programmes with balance and strength components reduce falls by roughly 20 to 25 per cent in Cochrane review†, and multifactorial assessment, medication review, home hazard removal and vision correction add further. For the growing older-adult share of spinal cord injury this is now the main preventive lever. *Safe water entry and diving education, sports rule changes*: MODERATE; rugby scrum law changes in several countries were followed by reductions in catastrophic cervical injury. *Occupational safety law*, fall protection and scaffolding standards: STRONG.

*Violence reduction*: MODERATE. *Tuberculosis treatment and control*: STRONG for the spinal tuberculosis fraction in endemic regions. *Early recognition and decompression of degenerative cervical myelopathy*: STRONG for preventing the permanent injury. *Secondary prevention of complications*: see treatment, and this is where the preventable deaths are. *High-dose methylprednisolone is no longer recommended*: the negative result is recorded.

**Treatment.** *Acute spinal immobilisation, timely surgical decompression and stabilisation*: early decompression within 24 hours is associated with better neurological recovery in prospective cohort studies and one randomised trial signal; the evidence is observational-dominant and consistent. *Specialist spinal injury unit care* is associated with fewer complications and better outcomes than general ward care: organisational, like stroke units. *Bladder management*: intermittent catheterisation is the reference standard, with lower infection and renal damage rates than indwelling catheters. Catheters cost a few US dollars each, and renal failure from poor bladder management was historically the leading cause of death after spinal cord injury and is now largely preventable. Anticholinergics or botulinum toxin are used for detrusor overactivity.

*Pressure injury prevention*: repositioning schedules, pressure-redistributing cushions and mattresses, daily skin inspection. Pressure injury is a leading cause of hospitalisation, sepsis and death, and is almost entirely preventable by routine. *Bowel management*: a regular routine prevents impaction and autonomic dysreflexia. *Autonomic dysreflexia recognition and management*: a medical emergency triggered by bladder or bowel distension or skin stimulation below the injury level, which can cause stroke and death. The treatment is sitting the person up, removing the trigger, and loosening constrictions — free actions, and recognition is the whole intervention. A card carried by the patient explaining it to emergency staff prevents deaths.

*Respiratory care*: assisted cough, secretion clearance, vaccination against influenza and pneumococcus, and ventilation for high cervical injuries. Pneumonia is a leading cause of death. *Spasticity management*: baclofen, which is EML-listed, off-patent, and costs tens of US dollars a patient-year; tizanidine; botulinum toxin; intrathecal baclofen. *Neuropathic pain*: amitriptyline, EML-listed, off-patent, a few US dollars a patient-year, and gabapentinoids; pain affects a majority and is frequently undertreated. *Wheelchairs, seating and assistive technology*: only 5 to 35 per cent of people who need wheelchairs have access. A basic appropriate wheelchair costs on the order of a few hundred US dollars, and an inappropriate one causes pressure injury and deformity. This is the largest single gap between need and provision in Chapter 08.

*Rehabilitation, vocational rehabilitation and supported employment*: unemployment exceeds 60 per cent, and supported employment improves it. *Functional electrical stimulation, epidural stimulation, exoskeletons, brain-computer interfaces*: research-stage for function restoration, with striking individual results in small numbers and no established population benefit, at costs from tens of thousands to hundreds of thousands of US dollars. Reported as not established. *Mental health care*: depression prevalence is high and suicide risk elevated; see the suicide entry for intervention evidence.

**Simple means.** Repositioning and daily skin inspection prevent the pressure injuries that cause sepsis and death: a schedule, a mirror and a pair of hands, with no supply chain. Intermittent catheterisation with clean technique, at a few US dollars a catheter, prevents the renal failure that was once the leading cause of death. A bowel routine prevents impaction and the autonomic dysreflexia it triggers. An autonomic dysreflexia card: a piece of paper that tells an unfamiliar emergency clinician what to do, and it prevents deaths. Sitting the person up and removing the trigger in dysreflexia: free, and it is the treatment. Assisted cough, taught to a family member, prevents pneumonia. An appropriate wheelchair at a few hundred US dollars: for the 65 to 95 per cent without access† this is the difference between participation and confinement, measured by WHO, and the largest avoidable gap here. Helmets, seat-belts and speed limits: legislation, with the six-fold, 50 per cent and 4-per-cent-per-1-per-cent effect sizes above. Prevention beats everything that follows. Exercise for falls prevention in older adults: roughly 20 to 25 per cent fall reduction, free, and it now addresses the leading cause in high-income countries.

**Gaps.** WHO gives no incidence figure, so the annual new-case number rests on literature estimates with wide ranges. No percentages are given for causes in the WHO source, only a ranking. The 5-to-35-per-cent wheelchair access figure has no stated year and a very wide range. There is no neuroprotective or regenerative treatment despite decades of work and clear animal-model targets. Early surgery evidence is observational-dominant, and the randomised base is thin for an intervention now widely standard. Outcome data from low- and middle-income countries, where in-hospital mortality is three times higher, are sparse.

Long-term outcomes of the growing older, fall-related, non-traumatic population are poorly described, because the literature describes a younger traumatic population.

---

# What no longer holds

A reference work that records only what is currently believed passes on retired certainties as though they were live. The claims below were once standing positions in these three chapters. Each was overturned, failed to replicate, or was reversed in guidelines. They are listed because readers will still meet them in older textbooks, in clinical habit, and in current marketing.

| Claim | Status |
|---|---|
| Low serotonin causes depression | **Not supported.** An umbrella review across six areas of research found no consistent evidence (Moncrieff, *Molecular Psychiatry*, 2022). Drug efficacy is a separate and better-established fact. |
| Low cortisol or HPA-axis dysfunction characterises post-traumatic stress disorder | **Did not replicate** consistently; meta-analyses find no reliable group difference in basal cortisol. |
| Psychological debriefing prevents post-traumatic stress disorder | **Does not work**; some trials show harm. WHO and NICE advise against routine use. |
| The MMR vaccine causes autism | **Settled: it does not.** A Danish cohort of over 650,000 children found no increased risk overall, in any subgroup, or in any post-vaccination time window (Hviid, *Annals of Internal Medicine*, 2019). The original paper was retracted. |
| Secretin, gluten-free and casein-free diet, or chelation treat autism | **Tested and not supported**; chelation is harmful. |
| Cognitive and working-memory training transfers to ADHD symptoms | **Does not transfer** in blinded-rated trials. Heavily marketed regardless. |
| Maternal smoking causes ADHD | **Substantially attenuated** in sibling-comparison and genetically informed designs. |
| Elimination diets treat ADHD | Effects **do not survive blinding**. |
| Vascular dilation causes migraine | **Abandoned.** Migraine is a disorder of brain excitability and of the trigeminovascular pain system. |
| Chocolate, cheese and red wine trigger migraine | **Blinded challenge studies largely negative**; premonitory-phase craving may explain the association. |
| Sustained muscle contraction causes tension-type headache | **Not confirmed** by electromyography. The disorder's original name is a misnomer. |
| Botulinum toxin helps tension-type headache | **Negative** in randomised trials, unlike chronic migraine. |
| CPAP reduces cardiovascular events in obstructive sleep apnoea | **Negative.** SAVE hazard ratio 1.10 (95 per cent CI 0.91 to 1.32, p=0.34); RICCADSA and ISAACC similarly null. |
| Adaptive servo-ventilation helps central apnoea in heart failure | **Increased mortality** (SERVE-HF, *NEJM*, 2015). Now contraindicated in heart failure with reduced ejection fraction and predominant central apnoea. |
| Dopamine agonists are the right first-line for restless legs syndrome | **Reversed.** Augmentation in roughly 7 to 8 per cent a year† led to a guideline change; alpha-2-delta ligands are now first-line. |
| Sleep hygiene education alone treats insomnia | **Fails as a standalone intervention**; it works only as a component of cognitive behavioural therapy for insomnia. |
| Hearing aids slow cognitive decline | **Primary outcome null** (ACHIEVE, *Lancet*, 2023; difference 0.002 SD, p=0.96). The circulating 48 per cent is a high-risk subgroup†. |
| Intensive blood pressure control prevents dementia | **Primary endpoint not significant** (SPRINT MIND; probable dementia hazard ratio 0.83, 95 per cent CI 0.67 to 1.04). Only mild cognitive impairment and the composite were significant. Frequently misreported. |
| Aducanumab treats Alzheimer disease | Approved against its own advisory committee's vote; **withdrawn from the market in 2024**. |
| Amyloid-beta*56 is a key Alzheimer species | **The 2006 paper was retracted in 2024** after image-manipulation findings. The amyloid hypothesis rests on other evidence. |
| Vitamin D supplementation prevents or treats multiple sclerosis | **Observational and Mendelian signal strong; randomised supplementation trials negative.** |
| Exercise is harmful in multiple sclerosis | **Reversed.** Exercise improves function and does not worsen the disease. |
| Fluoxetine improves motor recovery after stroke | **Negative** in FOCUS, AFFINITY and EFFECTS, with increased fracture risk. |
| High-dose methylprednisolone helps acute spinal cord injury | **No longer recommended.** The benefit did not hold; the harms did. |
| Intensive glycaemic control prevents neuropathy in type 2 diabetes | **Small and non-significant** in meta-analysis, unlike type 1, where DCCT gave roughly 60 to 69 per cent reduction†. |

| Claim | Status |
|---|---|
| Acetyl-L-carnitine prevents chemotherapy-induced neuropathy | **Worsened** outcomes in a randomised trial. |
| Corticosteroids help Guillain-Barré syndrome | **Ineffective**; oral steroids may delay recovery. |
| Combining immunoglobulin and plasma exchange helps Guillain-Barré syndrome | **No added benefit.** |
| Huntingtin lowering slows Huntington disease | **Tominersen phase 3 halted**: the higher-dose arms were worse than placebo. |
| Sodium phenylbutyrate with taurursodiol treats amyotrophic lateral sclerosis | Approved on a phase 2 trial, **failed phase 3, withdrawn from the market in 2024** (Relyvrio). |
| Therapeutic hypothermia helps neonatal encephalopathy everywhere | **No benefit and increased mortality in low-resource settings** (HELIX trial). |
| Most cerebral palsy results from birth asphyxia | **Substantially revised downward.** Most high-income cases are antenatal in origin, and 10 to 30 per cent are genetic†. |
| Antipsychotics help challenging behaviour in intellectual disability | **Not supported** by the largest randomised trial. Over-prescribing is a documented quality-of-care problem. |
| Drug treatment is indicated for borderline personality disorder itself | **Not supported**; NICE advises against it. |
| The categorical subtypes of personality disorder are valid | **Abandoned in ICD-11** because of poor construct validity, extensive overlap and poor inter-rater reliability. |
| Antiseizure drugs after head injury or stroke prevent later epilepsy | **Negative.** They prevent early provoked seizures only. |
| “Responsible gambling” information changes behaviour | **Little effect**, mirroring the alcohol and tobacco education findings. |
| Moderate alcohol protects the heart — the J-curve | **Not supported** by Mendelian randomisation. |
| Supply-side drug interdiction reduces stimulant prevalence | **No demonstrated sustained effect** on price, purity or prevalence. |
| Individual-level suicide risk prediction works | **It does not.** Risk-assessment scales lack the predictive accuracy needed for clinical allocation, and meta-analyses find positive predictive values too low to be useful. Guidelines in several countries have changed. Services still use the instruments. |
| The antipsychotic maintenance readmission number needed to treat is 5 | **Superseded.** The 2012 Lancet figure of 5 is correctly published and derives from the pooled risk ratio. The 2020 Cochrane update gives hospitalisation 7 against 18 per cent, risk ratio 0.43, number needed to treat 8, and **8 is the figure to quote as current.** |
| Pandemrix narcolepsy risk generalises to vaccines in general | **It does not.** The association was real, measured at roughly one additional case per 16,000 vaccinated, and confined to one adjuvanted formulation; other H1N1 vaccines showed no such signal, and H1N1 infection itself was associated with increased narcolepsy incidence. |

Two further reversals belong here as method rather than finding. The compilation this chapter was built from carried 178 drug prices that were order-of-magnitude guesses with no source consulted. And the international price source the book had relied on, the MSH International Medical Products Price Guide, turns out to have a last edition of 2017 and a website retired after 30 June 2024. Six of the 169 that printed digits have been replaced here with sourced, dated figures from the UNICEF Supply Catalogue and the NHS Drug Tariff, and two further medicines were priced from the same sources. The remaining 163 are given in words. Where this chapter says a drug costs a few dollars or several thousand, that is the honest extent of what is known, and the reader is not handed a number that was never measured.

---

*Chapter 13 covers 51 named conditions across ICD-11 Chapters 06, 07 and 08: 21 in Chapter 06, 10 in Chapter 07 and 20 in Chapter 08.*

# Chapter 14 — ICD-11 Chapters 09, 10 and 14: the visual system, the ear, the skin

Fifty entries. Nineteen for the visual system, twelve for the ear and mastoid process, nineteen for the skin.

Glaucoma and age-related macular degeneration each take two entries. Open-angle and angle-closure glaucoma have different mechanisms, different geography and different definitive treatments. Dry and wet macular degeneration differ in cure status, so one label would be false at one end.

---

## The widest gap in the book between what a thing costs and what it returns

This chapter holds the largest price-to-return spreads in the whole book, and they are measured, not inferred.

Cataract surgery at the Aravind Eye Care System in India cost **US$29.02** per operation in total direct and indirect cost in 2013, with the intraocular lens charged separately at **US$12.80 to 96.00**, giving an all-in **US$41 to 125** per case. Aravind's own manufacturing arm, Aurolab, brought the lens itself to **US$3**, against **US$4,000 to 6,000** quoted for a lens in the United States†. At that cost the measured outcomes were a complication rate of **1.5 per cent** and an endophthalmitis rate of **0.02 per cent**, reported at about half the United Kingdom National Health Service complication rate. The volume was **over 700,000 operations** and over 5.7 million outpatient visits in 2023. One cheap operation, performed at industrial scale, with a complication rate reported at about half that of the United Kingdom National Health Service, and a lens that costs a small fraction of the lens price quoted in the United States.

Reading glasses cost **a few US dollars per pair** in low-cost programmes. In the PROSPER randomised trial, 750 tea pickers in Assam given near-vision glasses raised their productivity by **21.7 per cent** overall and **31.6 per cent** among those over fifty, an extra **5.25 kg** of tea a day, with about **90 per cent** still wearing the glasses at three months. Presbyopia accounts for **826 million** people with near vision impairment. Cerumen impaction is on the World Health Organization's list of causes of hearing loss, and the Cochrane review of cerumenolytics found no clear difference between agents, including plain water and saline — so a World Health Organization listed cause of hearing loss is removed outright with water and a rubber bulb. The Epley manoeuvre for benign paroxysmal positional vertigo needs a couch and about two minutes, and cures roughly **80 per cent** of patients in one session†. Ivermectin mass drug administration took scabies prevalence from **32 per cent to under 2 per cent** in Fiji and from **18.7 to 2.3 per cent** in the Solomon Islands, with community impetigo down **60 to 88 per cent**, on two oral doses of a drug that is donated or costs cents.

The other half of the chapter is the half where nothing works, and it is the larger half by burden. Glaucomatous visual field loss has never been recovered by any treatment. Mammalian cochlear hair cells do not regenerate, so presbycusis, noise-induced loss and aminoglycoside

or cisplatin ototoxicity are permanent, and hearing aids and cochlear implants substitute rather than repair. Dry macular degeneration has licensed drugs that slow lesion growth on imaging without a demonstrated acuity benefit. An opaque cornea is cleared only by transplantation, which is scarcest where trachoma and keratitis are commonest. Amblyopia after roughly age seven does not respond. Deep burn scarring and contracture are improved and never restored.

The honest figure for the commonest of these is the Early Manifest Glaucoma Trial. Of 255 patients with early glaucoma, 129 were treated immediately and 126 were untreated controls. Mean intraocular pressure fell **25 per cent** in the treated group. At six years, **45 per cent** of treated patients had progressed against **62 per cent** of controls. That is a real effect, and it means nearly half of treated patients progressed anyway. Control here is partial even when it is achieved, which is why the label is CONTROLLABLE and cannot be raised.

Three structures recur and are worth naming before the entries. First, the binding constraint is rarely money. For cataract, trachoma, scabies and vitamin A it is delivery volume; for glaucoma, diabetic retinopathy and hearing aids it is sustained clinical contact over decades; for amblyopia, retinopathy of prematurity, retinal detachment and burns it is **timing**, a window after which the identical intervention achieves nothing; for pressure ulcers and positional vertigo it is simply whether anyone present knows what to do. Second, a recurring and well-evidenced category of intervention consists of **not doing something** — and those interventions save money as well as harm. Third, provenance in this chapter is uneven by design, and the daggers show it: more than three in four of the chapter’s figures carry daggers, and more than four in five in the skin block. The skin block in particular carries a large body of figures with daggers: reported as commonly carried, with the source not opened, because the Global Burden of Disease skin analyses and every Cochrane review were unreachable. Where a World Health Organization page was read off the page, the figure is printed plainly and the page is named with its printed date.

# ICD-11 Chapter 09 — Diseases of the visual system

## Global totals for vision

At least **2.2 billion** people have a near or distance vision impairment, and at least **1 billion** of those — “almost half” — have an impairment that could have been prevented or is still unaddressed (World Health Organization fact sheet, *Blindness and vision impairment*, 10 February 2026).

The named causes within that figure are cataract **94 million**, uncorrected refractive error **88.4 million**, age-related macular degeneration **8 million**, glaucoma **7.7 million** and diabetic retinopathy **3.9 million**. Those five sum to about **202 million**, not a billion: they are the main causes of distance impairment, not the full count. Presbyopia accounts for a further **826 million** people with near vision impairment. An earlier reading of this page added the near-vision and distance-vision figures into one total and produced a sum larger than its own denominator; the figures above are the published figures and the near and distance counts are not additive.

The Vision Atlas of the International Agency for the Prevention of Blindness gives **1.1 billion** people living with sight loss, projected to **over 1.7 billion by 2050**, and states that **90 per cent** of sight loss is preventable or treatable without attributing that percentage to a named study on the page. The two sets of headline figures differ and both are printed.

Global Burden of Disease 2023 places blindness and vision loss at **23.6 million** years lived with disability (95% uncertainty interval 16.3 to 33.5), the twelfth leading cause of years lived with disability.

Annual global productivity loss from vision impairment is about **US$411 billion** at purchasing power parity, against a **US$25 billion** cost gap to address the unmet need. The component split is **US$43.6 billion** for blindness and **US$367.1 billion** for moderate to severe impairment.

Access is the limiting factor. **One in two** people who need cataract surgery cannot get it, and **two in three** people in low-income countries who need spectacles lack them. Effective cataract surgical coverage — surgery performed and a good visual result obtained — is **44 per cent**, with female coverage 43 and male 45 per cent. Distance vision impairment prevalence is about **four times** higher in low- and middle-income regions than in high-income regions. Unaddressed near vision impairment is **above 80 per cent** in western, eastern and central sub-Saharan Africa and **below 10 per cent** in high-income North America, Australasia, western Europe and Asia-Pacific. The global eye care targets for 2030 and the SPECS 2030 initiative count **800 million** people in need of refractive error services.

---

### My-opia (short-sightedness)

**What it is.** The eye grows too long from front to back. Light focuses in front of the retina instead of on it, so distant things blur. Near vision stays clear.

**Measured.** Myopia sits inside the uncorrected refractive error figure of **88.4 million** people with distance vision impairment or blindness from uncorrected refractive error. That figure counts the uncorrected subset, not total myopia prevalence.

Holden and colleagues projected **4.758 billion** people with myopia by 2050, 49.8 per cent of the world population, and **938 million** with high myopia, 9.8 per cent, from 1.406 billion (22.9 per cent) and 163 million (2.7 per cent) in 2000†.

Onset and progression concentrate in school-age children, and progression largely stops in the late teens to early twenties. Prevalence in urban East and South-east Asia is far above Western levels, with reported school-leaver prevalence of 80 to 90 per cent in parts of China, Taiwan, Singapore and South Korea†. The trend is rising, fastest in East Asia. Children's uncorrected refractive error costs an esti-

---

**Where it starts.** Outdoor time is the best-evidenced modifiable factor, and the trial evidence is direct. The Guangzhou Outdoor Activity Longitudinal Trial was cluster-randomised across 12 primary schools, 1,903 grade-1 children, 952 intervention and 951 control, over three years, with one extra 40-minute outdoor class per school day plus encouragement of after-school outdoor activity.

Three-year cumulative incidence of myopia, defined as spherical equivalent of −0.5 D or more, was **30.4 per cent** in the intervention group (259 of 853) against **39.5 per cent** in controls (287 of 726). The absolute difference was **−9.1 per cent**, 95% CI −14.1 to −4.1, p<0.001.

The progression measures were weaker. Change in spherical equivalent refraction over three years was −1.42 D against −1.59 D, a difference of 0.17 D, 95% CI 0.01 to 0.33, p=0.04. Change in axial length was 0.95 mm against 0.98 mm, a difference of −0.03 mm, 95% CI −0.07 to 0.003, **p=0.07, not significant**. Both results belong in the same place: outdoor time cut the number of children who became

Years of education and near-work intensity associate strongly with myopia, and Mendelian randomisation studies support education as causal. Two myopic parents raise a child’s risk roughly two- to three-fold. Myopia is highly polygenic; genome-wide studies have found hundreds of loci that together explain a modest fraction of variance.

Genuinely not known: why outdoor time protects. Retinal dopamine release under bright light and the dioptric properties of outdoor scenes are the leading candidates, and neither has been demonstrated as the operative mechanism in humans. The light intensity threshold, the required daily duration, and whether the effect is light or simply the absence of near work are all unresolved. Why the incidence effect in

**Cure status.** CONTROLLABLE. The refractive error is fully correctable — spectacles restore normal vision the day they are worn — but no treatment reverses the eye's elongation. Refractive surgery removes the need for spectacles with high predictability and leaves the long eye, and with it the elevated lifetime risk of retinal detachment, myopic maculopathy and glaucoma that

---

**Prevention.**
- **Outdoor time, two or more hours a day, school-based.** Reduces myopia incidence by about 9 percentage points absolute over three years. **MODERATE** — consistent across several trials and settings, weaker on progression than on onset, and it costs a timetable change.
- **Low-dose atropine eye drops, 0.01 to 0.05 per cent.** Slows progression; 0.05 per cent was the most effective of the low doses tested

**Treatment.** 1. **Spectacles.** Complete correction of the refractive error. A device, so not on the Essential Medicines List; spectacles appear on the World Health Organization's assistive products list. Cost: see *Simple means*. 2. **Soft contact lenses.** Equivalent optical correction, higher recurring cost, a small keratitis risk. 3. **Low-dose atropine.** Atropine is on the Essential Medicines List as an ophthalmologi-

**Simple means.** Spectacles are the clearest case in this chapter of a near-zero-technology fix for a very large burden. Ready-made spectacles are supplied at roughly **a few US dollars per pair** in low-cost programmes. The World Health Organization fact sheet states only that spectacle correction is among the most cost-effective healthcare interventions.

The measured effect on earnings comes from the PROSPER randomised trial: 750 tea pickers in Assam, mostly female, aged 40 to over 50, over three months. Near glasses raised productivity by **21.7 per cent** overall and **31.6 per cent** in workers over fifty, an extra **5.25 kg** of tea per day, with nearly **90 per cent** still wearing the glasses at three months.

Added outdoor time costs nothing at all. It is a change to a school timetable with a measured 9-percentage-point effect on three-year incidence.

**Gaps.** Holden’s projections could not be verified against the journal page. School-leaver prevalence figures for East Asia are widely carried and unsourced here. The LAMP atropine figures and the orthokeratology effect sizes were not verified. The mechanism of the outdoor-time effect is unknown, so the dose — intensity and duration — cannot be specified. Whether childhood myopia control reduces adult retinal

## Hyperopia and astigmatism

**What it is.** In hyperopia the eye is too short, so light focuses behind the retina and near vision blurs first. In astigmatism the cornea or lens is not evenly curved, so one axis focuses differently from another and vision is blurred at every distance.

**Measured.** Both sit inside the **88.4 million** people with distance vision impairment or blindness from uncorrected refractive error. Separate global prevalence figures for hyperopia and for astigmatism were not retrievable.

Hyperopia is normal in infancy and usually reduces with growth (emmetropisation); clinically significant hyperopia then rises again with age as accommodative reserve falls. Astigmatism is present from childhood and is relatively stable. Unlike myopia, neither is reported as rising sharply.

**Where it starts.** Both are largely determined by the geometry of the growing eye and both are substantially heritable. Uncorrected hyperopia in childhood is a direct cause of amblyopia and of accommodative esotropia. Known risk factors for astigmatism include eyelid pressure, ptosis, and corneal disease including keratoconus and scarring from trachoma or keratitis.

Genuinely not known: why emmetropisation fails in some children and not others. There is no established modifiable risk factor for either condition. That is a sharp contrast with myopia, where an environmental intervention changes incidence.

**Cure status.** CONTROLLABLE. Fully correctable with spectacles; the underlying eye shape is unchanged. Refractive surgery and toric intraocular lenses remove the spectacle need. Nothing reshapes a short eye.

**Prevention.** Nothing demonstrably prevents either condition. What is preventable is the consequence: preschool vision screening followed by correction prevents the amblyopia that uncorrected childhood hyperopia and astigmatism cause — **MODERATE**.

**Treatment.** 1. **Spectacles.** Full correction. A device, not listed. 2. **Contact lenses**, including toric lenses for astigmatism. 3. **Refractive surgery, or a toric intraocular lens at cataract surgery.** Not listed. Cost in the hundreds to thousands of US dollars.

**Simple means.** Ready-made spectacles correct hyperopia and simple astigmatism at roughly **a few US dollars per pair** in low-cost programmes. The limit is specific: ready-made non-prescription spectacles cannot correct significant or oblique astigmatism, which needs a ground lens. That is the point at which the supply chain stops being simple. The PROSPER productivity result, **+21.7 per cent** overall and **+31.6 per cent** over fifty, is a near-correction result and applies directly here.

**Gaps.** No global prevalence figure for either condition was obtainable. The share of the 88.4 million uncorrected refractive error burden attributable to hyperopia against astigmatism against myopia is not reported on any source read. Thresholds for correcting childhood hyperopia to prevent amblyopia differ between guidelines.

---

## Presbyopia

**What it is.** The lens stiffens with age and stops changing shape, so the eye cannot focus on close things. It begins around age 40 and affects everyone who lives long enough. Reading glasses correct it completely.

**Measured. 826 million** people have near vision impairment from presbyopia (World Health Organization fact sheet, *Blindness and vision impairment*, 10 February 2026). That is the single largest cause of vision impairment of any kind in the published breakdown, and it is a modelled estimate.

The condition is universal. Onset is around 40, and by the mid-50s accommodative amplitude is effectively gone†. Unaddressed near vision impairment runs **above 80 per cent** in western, eastern and central sub-Saharan Africa and **below 10 per cent** in high-income North America, Australasia, western Europe and Asia-Pacific. The condition is universal; only its correction is unequally distributed. The burden rises with population ageing.

**Where it starts.** Age. The lens loses elasticity progressively from childhood, and the loss becomes symptomatic when accommodative amplitude falls below what reading distance requires. Earlier onset is reported with hyperopia, which has less reserve to spare, and in hotter climates and at lower latitudes.

Genuinely not known: whether lens stiffening can be slowed or reversed at all. Proposed pharmacological lens-softening agents have not shown a durable clinical effect. Why onset age varies by several years between individuals and populations is unexplained.

**Cure status.** CONTROLLABLE. The functional deficit is removed completely and immediately by a pair of reading glasses costing a dollar, which makes this the cheapest full functional correction in medicine. Nothing halts or reverses the lens change itself, and the glasses must be worn for the rest of the person's life — the day they are not worn the deficit is back in full. The asymmetry is worth stating: near-total functional restoration, zero disease modification.

**Prevention.** Nothing prevents presbyopia. It is a universal consequence of ageing and no intervention has been shown to delay its onset. Claims for eye exercises are **CONTESTED** at best and unsupported by trial evidence.

**Treatment.** 1. **Reading spectacles, ready-made or prescription.** Complete correction. A device, not listed. 2. **Multifocal or progressive spectacles.** Convenience; the same optical result. 3. **Multifocal contact lenses, monovision.** Lower satisfaction than spectacles in some wearers. 4. **Pilocarpine 1.25 per cent drops.** Pupil-constricting, with a transient effect and dim-light and headache side effects. Pilocarpine is on the Essential Medicines List as an antiglaucoma miotic, with carbachol as a therapeutic equivalent — not for this indication. 5. **Refractive lens exchange, corneal inlays.** Not listed; a surgical cost.

**Simple means.** This is the strongest simple-means case in the chapter. Ready-made reading glasses need no eye examination beyond a reading card, no prescription, no fitting and no power supply, and one of a handful of stock powers fits most presbyopes. Programme cost is roughly **a few US dollars per pair**.

The earnings effect is measured. PROSPER randomised 750 Assam tea pickers with presbyopia over three months: **+21.7 per cent** productivity overall, **+31.6 per cent** in those over fifty, **+5.25 kg** of tea per day, and about **90 per cent** still wearing the glasses at three months. The World Health Organization names spectacle correction for refractive error, with cataract surgery, as among the most cost-effective health-care interventions.

**Gaps.** The 826 million figure is a model estimate and its uncertainty interval is not given on the fact sheet. PROSPER measured productivity in piece-rate agricultural work over three months; whether the effect size transfers to other occupations, and whether it persists beyond three months, was not measured. The cost per pair in programme conditions could not be sourced to a programme document.

---

## Cataract

**What it is.** The lens of the eye goes cloudy, so less light gets through and vision dims and blurs. It builds up over years, usually with age. Taking the cloudy lens out and putting a plastic one in restores sight.

**Measured. 94 million** people have distance vision impairment or blindness from cataract, the largest single cause of distance vision impairment in the published breakdown and a modelled estimate. Cataract remains the leading cause of blindness globally; the fact sheet gives no overall blindness total, so its share cannot be computed from that source.

**One in two** people worldwide who need cataract surgery cannot get it. Effective cataract surgical coverage — surgery performed and a good visual result obtained — is **44 per cent**, female 43 and male 45 per cent. The disease is strongly age-related and most people with vision impairment and blindness are over 50. Burden is concentrated in low- and middle-income countries, where distance vision impairment prevalence is four times the high-income level. India performed about **8.3 million** cataract operations nationally in 2022–23. Case numbers are rising with ageing and coverage is improving, while the gap persists.

**Where it starts.** - **Age** — the dominant factor. - **Ultraviolet B exposure** — established for cortical cataract. - **Smoking** — dose-related, established for nuclear cataract. - **Diabetes** — accelerates onset. - **Systemic or inhaled corticosteroids** — cause posterior subcapsular cataract, dose- and duration-related. - **Ocular trauma, uveitis, prior vitrectomy, high myopia** — all established. - **Congenital cataract** — from intrauterine rubella, galactosaemia and genetic causes. Rubella-related congenital cataract is vaccine-preventable.

Genuinely not known: the molecular sequence that takes lens crystallins from soluble to aggregated is only partly described, and no intervention arrests it. Why identical exposures produce cataract at widely different ages is unexplained. No drug has ever been shown to clear or prevent human cataract.

**Cure status.** CURABLE. This is the clearest curable entry in the book. The diseased tissue is removed whole and replaced with a functioning artificial substitute, in one operation, usually under local anaesthesia, with vision restored within days and no maintenance treatment afterwards. The disease does not recur in the removed lens.

The outcomes at scale are measured. At the Aravind Eye Care System the complication rate was **1.5 per cent** and the endophthalmitis rate **0.02 per cent**, with the complication rate reported at about **half** the United Kingdom National Health Service rate. Mean operating time was about **6 minutes** at Aravind against **21 minutes** in the United States. Aravind performed **over 700,000 operations** and over 5.7 million outpatient visits in 2023, up from 29,928 operations in 1988 and 180,991 in 2007. Aravind surgeons perform **over 2,000 operations a year** against an Indian average of about 300, and one surgeon can perform **50 operations in a day**.

The limit on cure is access and surgical capacity, not biology. Two qualifications: posterior capsule opacification occurs in a minority and is cleared by laser capsulotomy; and eyes with co-existing glaucoma, macular degeneration or amblyopia do not recover full vision, because the cataract was not the only problem.

**Prevention.** - **Smoking cessation** — reduces nuclear cataract risk. **MODERATE**. - **Ultraviolet-blocking sunglasses and hats** — biologically grounded for cortical cataract; no randomised evidence of incidence reduction. **WEAK**. - **Rubella vaccination** — prevents congenital rubella cataract. **STRONG** for that cause. - **Glycaemic control in diabetes** — delays onset. **MODERATE**. - **Minimising systemic corticosteroid dose and duration. MODERATE**. - **Antioxidant vitamin supplements** — trials have not shown prevention. **CONTESTED**, effectively negative.

There is no strong primary prevention for age-related cataract. The public health lever is surgical volume.

**Treatment.** 1. **Small-incision cataract surgery with an intraocular lens.** Manual, sutureless, no phacoemulsification machine needed, and the workhorse of high-volume programmes. The lens is a device and not on the Essential Medicines List; it appears on the World Health Organization's priority medical devices lists. The technique is unpatented. Cost: **US$29.02** total direct and indirect cost per operation to Aravind in 2013, with the lens charged separately at **US$12.80 to 96.00**, giving an all-in **US$41 to 125** per case. Hospital surgical expenses have been reported as low as **US$10 per operation**, with a bilateral procedure in India at **US$41 to 125** against **US$2,410 to 5,243** in the United States. United States Medicare reimbursement for comparison: **US$1,766** to the ambulatory surgery centre plus **US$760** to the surgeon. 2. **Phacoemulsification with a foldable lens.** The high-income standard; faster visual recovery, needs a machine and consumables. Not listed. 3. **Topical antibiotic and corticosteroid drops after surgery.** Several are listed — azithromycin and aciclovir eye preparations, betamethasone. Off-patent. Cents to a few dollars per course. 4. **Intracameral antibiotic prophylaxis.** Reduces endophthalmitis.

There is no medical treatment for cataract. No drops, tablets or diet reverse it.

**Simple means.** High-volume cataract surgery is the standout case in the book of a cheap intervention removing a very large burden, and its economics are documented.

Aurolab, Aravind's manufacturing arm, cut the intraocular lens price from hundreds of US dollars to **below US$10**, with a current price of **US$3** per lens in 2023, against **US$4,000 to 6,000** quoted for lenses in the United States. Aurolab production rose from 35,000 lenses

in 1992–93 to nearly 600,000; about **60 per cent** of its lenses go to non-governmental organisations in India and other developing countries, and it exports to over 130 countries.

The model's components are organisational rather than technological. Task-shifting to mid-level ophthalmic personnel raised each ophthalmologist's productivity **more than fourfold**; cross-subsidy lets paying patients fund the **50 per cent** of patients treated free or heavily subsidised; the day runs at 65 patients per surgical session with 6-minute operations.

What the chain minimally requires: a sterile operating room, a trained surgeon, an operating microscope, a sterilisable instrument set, and an intraocular lens. That is not nothing. At US$41 to 125 all-in per restored eye at Aravind in India, 2013, it is close to the cheapest restoration of a major lost function available anywhere in medicine.

**Gaps.** The fact sheet gives no overall global blindness total, so cataract's share of blindness cannot be computed from it. The 94 million figure is a model estimate without a published interval on that page. The Aravind cost figures are from 2013, reported in 2014, and from 2023, and are not directly comparable with each other. Whether Aravind's outcomes transfer to settings without its volume, cross-subsidy and training pipeline is not established by these sources. A 2025 Aravind cost-trend paper covering 2012 to 2023 could not be retrieved and would supersede the 2013 figures.

---

## Glaucoma — primary open-angle

**What it is.** The optic nerve is progressively damaged, usually with raised pressure inside the eye. Sight is lost from the edges inwards, painlessly, and the person often does not notice until a great deal is gone. What is lost does not come back.

**Measured. 7.7 million** people have distance vision impairment or blindness from glaucoma, all types combined, a modelled estimate.

Pooled global glaucoma prevalence in people aged 40 to 80 is **3.54 per cent**, 95% credible interval 2.09 to 5.82. Numbers aged 40 to 80 with glaucoma were **64.3 million in 2013**, projected to **76.0 million in 2020** and **111.8 million in 2040** — a 74 per cent increase on 2013. Open-angle prevalence is highest in **Africa at 4.20 per cent**, 95% credible interval 2.08 to 7.35. Men are more likely than women to have open-angle glaucoma, odds ratio **1.36**, 95% credible interval 1.23 to 1.52. People of African ancestry are more likely than those of European ancestry to have it, adjusted odds ratio **2.80**, 95% credible interval 1.83 to 4.06. Prevalence rises steeply with age in all populations.

**Where it starts.** - **Raised intraocular pressure** — the only modifiable risk factor with randomised trial evidence. In the Early Manifest Glaucoma Trial each millimetre of mercury of pressure reduction was associated with reduced progression risk, and the treated group achieved a mean **25 per cent** pressure reduction. - **Age** — the strongest non-modifiable factor. - **African ancestry** — adjusted odds ratio 2.80 against European ancestry. - **Male sex** — odds ratio 1.36. - **Family history** — a first-degree relative raises risk several-fold. - **Thin central cornea, large cup-disc ratio, myopia, low ocular perfusion pressure, type 2 diabetes** — all established associations†.

Genuinely not known: why the optic nerve dies. Normal-tension glaucoma progresses at statistically normal pressures and ocular hypertension often never progresses, so pressure is neither necessary nor sufficient — and pressure is the only thing treatment addresses. No treatment targets the retinal ganglion cell directly, and neuroprotection trials have not produced a usable agent. The African-ancestry excess is not explained by any identified mechanism.

**Cure status.** CONTROLLABLE. Nothing restores lost visual field. Retinal ganglion cells and their axons do not regenerate in humans, and no treatment has ever recovered a glaucomatous field defect. What treatment does is slow or halt further loss.

The evidence for that control is the Early Manifest Glaucoma Trial: 255 patients aged 50 to 80 with early glaucoma, 129 treated immediately and 126 untreated controls. Mean pressure fell **25 per cent** in the treated group. At six years, **45 per cent** of treated patients had progressed against **62 per cent** of controls, and progression occurred significantly later in treated patients.

Treatment reduced six-year progression by 17 percentage points absolute, and **45 per cent of treated patients still progressed**. Control is partial even when it is achieved, and that is why the label cannot be raised.

**Prevention.** There is no demonstrated primary prevention for open-angle glaucoma. Nothing is known to stop the disease starting. What is demonstrated is prevention of blindness in people who already have it. - **Case detection by pressure measurement, optic disc assessment and visual fields, then pressure-lowering treatment.** Reduces six-year progression from 62 to 45 per cent. **MODERATE** — strong trial evidence for the treatment effect, weaker evidence that population screening programmes improve outcomes. - **Targeted screening of high-risk groups** — African ancestry, family history, age 40 and over. **MODERATE**. - **Population screening of unselected adults. CONTESTED**; not recommended by most national screening bodies on cost-effectiveness grounds. - **Exercise, diet and supplements. CONTESTED**; no trial evidence of incidence reduction.

**Treatment.** 1. **Prostaglandin analogues (latanoprost, travoprost, bimatoprost), topical.** First-line; reduce pressure about **25 to 33 per cent**, once daily†. Latanoprost is on the Essential Medicines List — the list document did not load and the searchable index displayed the ophthalmological section incompletely. Off-patent. Generic latanoprost runs roughly **US$2 to 10 per bottle** in generic markets, a bottle lasting about a month†. 2. **Beta-blockers (timolol 0.25 to 0.5 per cent), topical.** Reduce pressure about **20 to 25 per cent**†. Timolol is on the Essential Medicines List as an antiglaucoma agent. Off-patent. **Under a few US dollars per bottle** generic. Contraindicated in asthma and bradycardia. 3. **Selective laser trabeculoplasty.** The LiGHT trial found laser as first-line gave better disease stability and lower cost than drops over three and six years. One treatment, repeatable, no daily adherence needed. A procedure, not listed. 4. **Carbonic anhydrase inhibitors — topical dorzolamide, oral acetazolamide.** Acetazolamide is listed. Off-patent. Cents per tablet. 5. **Pilocarpine, a miotic.** Listed, with carbachol as therapeutic equivalent. Off-patent, cheap, now largely superseded for this indication. 6. **Trabeculectomy.** For failed medical control; effective, with bleb-related complications. Not listed. A surgical episode. 7. **Minimally invasive glaucoma surgery devices.** Expensive implants with modest additional pressure reduction.

**Simple means.** Weaker here than anywhere else in the chapter, and that needs saying.

What works with almost no supply chain is **generic timolol drops**, at well a few US dollars a bottle, lowering pressure about 20 to 25 per cent†. That is a genuine low-cost intervention and it is on the Essential Medicines List.

The rest of the chain is not simple. Glaucoma requires detection before symptoms, which requires tonometry, optic disc examination and ideally perimetry; and it requires lifelong adherence and monitoring, which requires a clinic the patient can reach for decades. A one-off encounter achieves nothing. This is the structural opposite of cataract, where a single episode of care ends the problem. Laser trabeculoplasty partly escapes the adherence problem — one session, repeatable, no drops — but needs a laser and an operator.

There is no simple means that substitutes for sustained clinical contact in glaucoma. The minimum chain is a tonometer, a trained examiner, a drug supply that does not run out, and a patient who returns.

**Gaps.** The 7.7 million figure covers all glaucoma types and cannot be split between open-angle and angle-closure from that source. The prevalence figures cover ages 40 to 80 only and are not whole-population counts. The global pooled open-angle prevalence was not on the abstract read, only the regional maximum. The 2020 and 2040 figures are projections. Normal-tension glaucoma's share varies greatly between populations and no figure was obtainable. Whether population screening is justified is genuinely disputed between expert bodies. Generic drug prices were not sourced to a price database.

---

## Glaucoma — primary angle-closure

**What it is.** The drainage angle of the eye is blocked by the iris, so pressure rises. It can creep up slowly or shut suddenly. A sudden attack is painful, with a red eye, blurred sight, haloes and vomiting, and it can blind an eye in days.

**Measured.** Included in the **7.7 million** glaucoma figure and not separable from it. Angle-closure prevalence is highest in **Asia at 1.09 per cent**, 95% credible interval 0.43 to 2.32, in people aged 40 to 80.

Angle-closure is a minority of glaucoma by case count and causes a disproportionate share of glaucoma blindness; it is reported to account for roughly half of glaucoma blindness worldwide despite being much less common than open-angle disease. Prevalence rises with age, with mean age of presentation above 50†. It is more common in women and concentrated in East and South Asia and in Inuit populations.

**Where it starts.** - **A shallow anterior chamber, short axial length, thick lens, hyperopia** — the direct structural cause. - **Asian and Inuit ancestry** — angle-closure prevalence 1.09 per cent in Asia, the highest regional figure. - **Age** — the lens thickens through life, progressively crowding the angle. - **Female sex**. - **Family history**. - **Pupil dilation** — mydriatic drops, anticholinergics, dim light and prone positioning can precipitate acute closure in a predisposed eye.

Genuinely not known: why only a minority of anatomically narrow angles ever close. Which narrow-angle eyes to treat prophylactically is not settled, and the cost-effectiveness of population angle screening is unresolved.

**Cure status.** Eyes treated by laser peripheral iridotomy before synechial closure and optic nerve damage: CURABLE. Eyes with extensive peripheral anterior synechiae: CONTROLLABLE. Optic nerve damage already sustained: RELIEF ONLY. The anatomical mechanism can be removed: **laser peripheral iridotomy** makes a hole in the iris, equalises pressure across it and abolishes the pupillary-block mechanism. In an eye treated before synechial closure and optic nerve damage, this removes the risk, which is closer to a cure than anything available in open-angle disease. Cataract surgery itself relieves angle crowding by removing the thick lens and in many eyes is definitive.

Against that: optic nerve damage already sustained is permanent and unrecoverable, as in open-angle disease, and eyes with extensive peripheral anterior synechiae remain pressure-unstable after iridotomy and need ongoing treatment. Early mechanical intervention is definitive only in the first stratum above.

**Prevention.** - **Laser peripheral iridotomy in eyes with occludable angles.** Prevents acute attacks. The Zhongshan Angle Closure Prevention trial found prophylactic iridotomy reduced incident angle-closure disease, while the absolute event rate in untreated fellow eyes was low, which weakened the case for population-wide prophylaxis. **MODERATE**, and genuinely contested at population level. - **Avoiding precipitating drugs in known narrow angles** — anticholinergics, mydriatics. **MODERATE**. - **Early cataract surgery in narrow-angle eyes.** The EAGLE trial reported better outcomes from clear-lens extraction than laser iridotomy. **MODERATE**. - **Opportunistic angle assessment at any eye examination in at-risk populations** — gonioscopy, or the van Herick estimate, which needs no equipment beyond a slit lamp or even a torch. **MODERATE**.

**Treatment.** For the acute attack, which is an emergency: 1. **Pilocarpine 2 to 4 per cent drops.** Constricts the pupil and pulls the iris from the angle. Listed as an antiglaucoma miotic, with carbachol as equivalent. Off-patent, cents to a few dollars. 2. **Oral or intravenous acetazolamide.** Listed. Off-patent, cents per tablet. 3. **Topical timolol, apraclonidine and a topical steroid.** Timolol listed. 4. **Oral or intravenous hyperosmotic agents, glycerol or mannitol**. 5. **Laser peripheral iridotomy.** Definitive once the eye is clear enough to treat. A procedure, not listed. Requires a laser.

For chronic disease:

6. **Lens extraction.** Increasingly first-line.
7. **Trabeculectomy** for synechially closed angles with uncontrolled pressure.

**Simple means.** Pilocarpine drops and acetazolamide tablets are the simple means here, and in an acute attack they are sight-saving. Both are off-patent, both are on the Essential Medicines List, both cost cents, and both can be given anywhere a tablet and a dropper bottle can be kept. In a setting with no laser, this combination buys the time needed to move a patient.

Gonioscopy, or the van Herick slit-lamp estimate, costs nothing beyond the examiner’s time and identifies the occludable angle before it closes.

What the chain minimally requires for the definitive step is a laser for iridotomy, or an operating theatre for lens extraction. There is no non-industrial substitute for making a hole in an iris. Surgical iridectomy is possible without a laser and needs a theatre.

**Gaps.** Angle-closure cannot be separated from open-angle disease in the 7.7 million figure. The claim that it causes about half of global glaucoma blindness is widely repeated and could not be sourced. Whether to perform prophylactic iridotomy on screen-detected occludable angles is genuinely disputed, and expert bodies read the Zhongshan result differently. Global case counts outside ages 40 to 80 are not available.

---

### Age-related macular degeneration — dry (non-neovascular)

**What it is.** The central part of the retina slowly degenerates, so the middle of vision fades and distorts while the edges stay. Reading and faces go first. The slow form has no restorative treatment.

**Measured.** Macular degeneration in both forms accounts for **8 million** people with distance vision impairment or blindness, a modelled estimate. The dry form is the large majority by case count, commonly reported as about 80 to 90 per cent of cases, with the wet form the minority but historically the greater cause of rapid severe loss.

A dedicated Global Burden of Disease analysis of macular degeneration with forecasts to 2050 exists and could not be retrieved. The disease is strongly age-related, uncommon before 55 and rising steeply after 75†, with higher reported prevalence in populations of European ancestry. Burden is rising with ageing populations.

**Where it starts.** - **Age** — dominant. - **Smoking** — the strongest modifiable factor; roughly doubles to triples risk, dose-related, and risk falls after cessation. - **Genetics** — complement factor H Y402H and ARMS2/HTRA1 variants carry large effect sizes, among the largest known for a common complex disease. - **European ancestry**. - **Family history**. - **Hypertension, obesity, low dietary carotenoid intake** — associated,

---

Genuinely not known: why drusen form, and why some eyes progress to geographic atrophy while others remain stable for decades. The complement pathway is clearly implicated by genetics, yet complement-inhibiting drugs have produced only modest slowing of atrophy growth and no visual benefit, so the link from genotype to treatable mechanism is incomplete. There is no way to predict which eye will progress.

**Cure status.** RELIEF ONLY. Nothing restores lost central vision, and until recently nothing slowed it. Complement inhibitors — pegcetacoplan, avacincaptad pegol — have been licensed in some jurisdictions for geographic atrophy on the basis of slowed lesion growth on imaging, without a demonstrated visual acuity benefit. Slowing a measured lesion is not restoration. Supplements slow progres-

What helps function is magnification, lighting, large print and eccentric-viewing training. These are rehabilitation and not treatment. The World Health Organization states that vision rehabilitation is very effective in improving functioning for people with irreversible vision loss.

**Prevention.** - **Smoking cessation.** The single most effective measure; smoking roughly doubles to triples risk. **STRONG** — consistent, dose-related, reversible on cessation. - **The AREDS2 supplement formulation** — vitamin C, vitamin E, zinc, copper, lutein, zeaxanthin — in people with *intermediate* disease or advanced disease in one eye. Reduced five-year progression to advanced disease by about **25**

**Treatment.** 1. **AREDS2 supplements**, for intermediate disease only; about a 25 per cent relative reduction in five-year progression†. Not on the Essential Medicines List. Off-patent as a vitamin and mineral combination. Roughly **US$10 to 30 per month** in retail markets†. 2. **Complement inhibitors for geographic atrophy — pegcetacoplan, avacincaptad pegol.** Slow lesion growth; no acuity benefit demonstrated;

**Simple means.** This is a condition where simple means do nearly all of the available good, because the industrial options do so little.

---

- **Smoking cessation.** No supply chain. The largest modifiable effect on incidence.
- **Good task lighting and a hand magnifier.** A magnifier costs a few US dollars and restores reading for many people with moderate central loss. No effect size was sourced here, and the World Health Organization states that rehabilitation is very effective in improving functioning for people

No simple means slows dry macular degeneration itself beyond stopping smoking and, in intermediate disease, a supplement. The chain for the disease-modifying drugs requires intravitreal injection in a sterile setting, monthly, indefinitely.

**Gaps.** The 8 million figure covers both forms and cannot be split from that source. The dedicated burden analysis with 2050 forecasts could not be retrieved, so no trend or projection figures are carried. The 80 to 90 per cent dry share is widely reported and unsourced here. The AREDS effect sizes come from reports that could not be read. Whether slowed geographic atrophy lesion growth will ever translate into

## Age-related macular degeneration — wet (neovascular)

**What it is.** New leaky blood vessels grow under the central retina, and fluid and blood lift and scar it. Central vision can be lost in weeks, much faster than in the dry form. Injections into the eye can stop it and sometimes recover some sight.

**Measured.** Included in the **8 million** macular degeneration figure. The wet form is the minority of cases and historically caused the majority of severe rapid central vision loss. Anti-VEGF intravitreal injection is one of the highest-volume procedures in medicine in high-income health systems. Age pattern and geography follow the dry form. Incidence is rising with ageing, while blindness from the wet form has fallen in countries with anti-VEGF access, with reported declines in attributable blindness registrations after its introduction.

**Where it starts.** The same risk set as the dry form, from which it usually develops: age, smoking at roughly two to three times risk, complement factor H and ARMS2/HTRA1 variants, European ancestry, family history†. The specific step is pathological choroidal neovascularisation driven by vascular endothelial growth factor, which is why blocking that factor works, and works quickly.

Genuinely not known: what triggers conversion from dry to wet in a given eye at a given time. No predictive test exists. Why some eyes become treatment-resistant, and why a proportion develop fibrosis and atrophy despite perfectly suppressed exudation, is not understood. The long-term consequence of years of VEGF suppression on the retina is not fully characterised, and the CATT five-year data showed substantial net decline despite treatment.

**Cure status.** CONTROLLABLE. Anti-VEGF injections stop the leakage, usually improve vision initially, and prevent the catastrophic rapid loss that was the natural history. They do not remove the disease: the eye needs repeat injections for years, and stopping usually allows recurrence.

The long-term picture is measured. CATT at five years: of 914 living participants, 647 (71 per cent) had acuity measured at a mean of 5.5 years. Mean visual acuity was **3 letters worse than baseline** and **11 letters worse than at two years**, with half of eyes at 20/40 or better. Treatment converts a disease that blinded rapidly into one that declines slowly under continued treatment. That is a major gain and it is not a cure.

**Prevention.** - **Smoking cessation. STRONG**. - **AREDS2 supplements in intermediate disease, or advanced disease in the fellow eye.** About a 25 per cent relative reduction in five-year progression to advanced disease. **MODERATE**. - **Amsler grid or other self-monitoring, with prompt presentation on new distortion.** Prevents irreversible loss by getting treatment started early, since outcomes depend heavily on baseline acuity. **MODERATE**. This prevents blindness rather than disease, and it costs a printed sheet. - **Treating the fellow eye's risk factors** once one eye is affected. **MODERATE**.

**Treatment.** This is the major documented cost case in the chapter. Both the efficacy comparison and the price gap are measured.

1. **Bevacizumab, intravitreal, repackaged.** In CATT — 1,208 participants, 44 centres — bevacizumab and ranibizumab given on the same schedule had **equivalent effects on visual acuity** at one year, and similar effects at two years. The proportion losing at least 15 letters and the proportion gaining at least 15 letters were the same across groups.

Safety in CATT: serious adverse events were **40 per cent** with bevacizumab against **32 per cent** with ranibizumab. Both figures belong in print, and so does the trial's own observation about them: the events were spread across many unrelated conditions, and **fewer doses were associated with a higher serious-adverse-event rate**, which is not a dose-response pattern. There was no difference in death or in arteriothrombotic events.

At five years, the group originally assigned to ranibizumab for two years had lost 4 **more** letters than the bevacizumab group between years two and five, p=0.008, with no other significant drug or regimen differences.

**Bevacizumab is the Essential Medicines List anti-VEGF agent**. Off-patent, with biosimilars available. **Cost: tens to hundreds of US dollars per dose**. 2. **Ranibizumab, intravitreal.** Licensed for the indication, with efficacy equivalent to bevacizumab in CATT. Not the listed anti-VEGF entry; bevacizumab is the listed item. Biosimilars now exist. **Cost:**

**thousands of US dollars per dose**. 3. **Aflibercept, intravitreal.** Comparable efficacy with potentially fewer injections; priced in the same range as ranibizumab. Not listed. Biosimilars entering. 4. **Monthly against as-needed dosing.** CATT found monthly slightly better than as-needed, by about half a line on the eye chart, for either drug. 5. **Photodynamic therapy and laser.** Largely superseded.

The price gap, as documented: bevacizumab at about **tens to hundreds of US dollars** per dose against ranibizumab at about **thousands of US dollars** per dose — a ratio of roughly **20- to 40-fold** for drugs that CATT found equivalent in visual outcome. The CATT investigators' conservative estimate of the differential was **US$26,800 per patient per year**, with potential United States Medicare savings of up to **US$3 billion per year**. Bevacizumab is the listed agent, and it is the one that is off-patent and cheap. That the expensive drugs retain large market share is a fact of the field and not a clinical finding.

**Simple means.** Limited, and the limit should be stated.

- **An Amsler grid on paper** for self-monitoring. It costs a printed sheet, and getting a patient treated weeks rather than months after conversion materially changes the outcome, because final acuity tracks baseline acuity.
- **Repackaged bevacizumab** is the nearest thing to a simple means in the treatment itself. A single vial intended for oncology can be split into many intravitreal doses, which is what brings the per-dose cost to tens to hundreds of US dollars or below. It requires a sterile compounding facility; the historical cluster endophthalmitis outbreaks from poorly controlled repackaging are why this cannot be done casually.
- **Low-vision rehabilitation, magnifiers and lighting** for established loss.

What the chain minimally requires: a sterile procedure room, a trained injector, an operating microscope or slit lamp, cold-chain drug storage, imaging for monitoring, and a patient who returns every 4 to 12 weeks for years. This is not a simple-means condition. The drug can be made cheap; the delivery cannot be made simple.

**Gaps.** Wet disease cannot be separated from dry in the 8 million figure. CATT's serious-adverse-event finding, 40 against 32 per cent, is a real result with a disputed interpretation, and the trial itself recorded that it did not follow a dose-response pattern; sources genuinely disagree on whether bevacizumab carries excess systemic risk, and both readings are printed. The cost figures are CATT-era United States prices, and biosimilar entry has changed ranibizumab and aflibercept prices since; current figures were not obtainable. Long-term outcomes beyond five years under modern treat-and-extend regimens are not established.

---

## Diabetic retinopathy

**What it is.** High blood sugar damages the small blood vessels of the retina. They leak, close off, and new fragile vessels grow that bleed and pull the retina away. It is silent until late, which is why screening matters.

**Measured. 3.9 million** people have distance vision impairment or blindness from diabetic retinopathy, a modelled estimate.

The denominator is **830 million** people with diabetes in 2022, up from 200 million in 1990, and **14 per cent** of adults aged 18 and over, up from 7 per cent in 1990 (World Health Organization fact sheet, *Diabetes*, 14 November 2024). Prevalence is rising faster in low- and middle-income countries. That is the all-ages figure. Other chapters of this book use the International Diabetes Federation figure of **589 million adults aged 20 to 79**† as their denominator, and the two give substantially different global figures; attributable burden computed on one is not comparable with attributable burden computed on the other. Both stand, unresolved.

The diabetes fact sheet gives no figure for how many people with diabetes have retinopathy. Duration of diabetes is the dominant determinant, so retinopathy prevalence rises with years since diagnosis rather than with age alone. The burden is rising, driven by the denominator, and diabetic retinopathy is a leading cause of vision loss in working-age adults in high-income countries. The World Health Organization states that for this condition early detection and timely treatment are crucial to avoid irreversible vision loss.

**Where it starts.** - **Duration of diabetes** — the strongest predictor. - **Glycaemic control.** The Diabetes Control and Complications Trial in type 1 diabetes found intensive control reduced retinopathy onset by about **76 per cent** and progression by about **54 per cent** against conventional control; the United Kingdom Prospective Diabetes Study in type 2 found intensive control reduced microvascular endpoints by about **25 per cent**†. These are among the largest effect sizes in chronic disease prevention. - **Blood pressure.** Tight control reduced retinopathy progression in that study. - **Dyslipidaemia.** Fenofibrate reduced progression in the FIELD and ACCORD-Eye trials. - **Pregnancy, puberty, renal disease, anaemia** — accelerate progression. - **Rapid tightening of long-standing poor control** can cause transient early worsening.

Genuinely not known: why some people with decades of poor control never develop sight-threatening retinopathy and others progress quickly with modest hyperglycaemia. Duration and glycated haemoglobin together explain only part of the variance. The relative contributions of neurodegeneration and vascular change, and which comes first, are disputed. There is no test that identifies the patient who will progress.

**Cure status.** CONTROLLABLE. Treatment prevents further loss and in macular oedema often recovers vision; it does not remove the retinopathy, and photoreceptors already lost do not return.

Panretinal photocoagulation is the clearest result: the Diabetic Retinopathy Study found laser reduced severe vision loss in proliferative retinopathy by about **50 per cent** or more†. That is prevention of blindness in an eye that already has advanced disease — control, not cure. Laser also destroys peripheral retina deliberately, costing peripheral and night vision to save central vision. Anti-VEGF for diabetic macular oedema improves acuity, often substantially, and requires repeated injection. The disease is driven by the underlying diabetes, which is itself CONTROLLABLE and not curable, so the retinopathy cannot be more than controlled.

**Prevention.** This is one of the strongest prevention stories in the chapter. - **Glycaemic control.** About **76 per cent** reduction in retinopathy onset and **54 per cent** in progression in type 1; about **25 per cent** reduction in microvascular endpoints in type 2†. **STRONG**. - **Blood pressure control. MODERATE**. - **Systematic retinopathy screening with treatment of what is found.** The intervention that converts a silent blinding disease into a managed one. The English diabetic eye screening programme is credited with diabetic retinopathy ceasing to be the leading cause of certifiable blindness in working-age adults in England, for the first time in at least five decades. **STRONG** for blindness prevention. Screening interval annually, or every two years in low-risk screen-negative people. - **Fenofibrate.** Reduced progression in FIELD and ACCORD-Eye. **MODERATE**. - **Smoking cessation. MODERATE**.

**Treatment.** 1. **Panretinal photocoagulation for proliferative retinopathy.** About a 50 per cent or greater reduction in severe vision loss†. A procedure, not listed, and the technique is unpatented. Cost: a laser plus an operator — and **one or a few sessions, then no maintenance**, which makes it far more robust than injections in low-resource settings. 2. **Anti-VEGF injection for diabetic macular oedema.** Superior to laser for central oedema. **Bevacizumab is on the Essential Medicines List**, off-patent, at about **tens to hundreds of US dollars per dose**, against ranibizumab at about **thousands of US dollars per dose**. The DRCR Protocol T comparison found aflibercept better at worse baseline acuity, with the three agents similar at better baseline acuity, and the associated cost-effectiveness analysis found bevacizumab the most cost-effective. 3. **Focal or grid macular laser.** Cheaper, one-off, now second-line for centre-involving oedema. 4. **Intravitreal corticosteroids — triamcinolone, dexamethasone implant.** For anti-VEGF non-responders; cause cataract and raise pressure. 5. **Vitrectomy** for vitreous haemorrhage and tractional detachment. 6. **Glycaemic, blood pressure and lipid control.** Metformin, insulin, ACE inhibitors, statins and amlodipine are all on the Essential Medicines List and all off-patent, at cents per day.

**Simple means.** - **Screening with a hand-held or smartphone-based fundus camera, images read remotely or by a trained non-specialist grader.** This is the key low-cost move, because it removes the need for an ophthalmologist at the point of screening. Diagnostic accuracy of smartphone-based and non-mydriatic camera screening is adequate for referral triage, and automated grading systems are licensed in several jurisdictions. - **Direct ophthalmoscopy through a dilated pupil by a trained health worker.** Needs an ophthalmoscope and tropicamide drops only, with lower sensitivity than photography. -

**Laser photocoagulation** is itself a simple means in an important sense: it requires capital equipment but **no consumables, no cold chain and no repeat visits for years** — one or a few sessions per eye. In a setting that cannot sustain monthly injections for a decade, laser is the intervention that actually works. - **Glycaemic control with off-patent metformin and insulin**, both listed, at low cost.

The cheap intervention here is finding the disease, and the cheap treatment is laser. Both are available without a pharmaceutical supply chain.

**Gaps.** No figure exists on the sources read for what proportion of the 830 million people with diabetes have retinopathy, or sight-threatening retinopathy — a notable absence given that the denominator is published. The 3.9 million figure covers vision impairment and blindness only, not retinopathy prevalence. The trial effect sizes could not be verified against their primary reports. Optimal screening intervals differ between national programmes. The real-world performance of automated grading outside validation datasets is not established.

---

## Trachoma

**What it is.** A blinding eye disease. Repeated infection with a bacterium, *Chlamydia trachomatis*, is spread by flies, fingers and shared cloths. Years of infection scar the inner eyelid until the lashes turn inwards and scrape the cornea. The scraping blinds, and that blindness is preventable at every stage before it.

ICD-11 codes trachoma in chapter 1, among the infectious diseases, because it is an infection. The full entry is there, under Trachoma, in the chapter on certain infectious or parasitic diseases.

A reader in the eye chapter is sent there for a reason that concerns the eye. The cure status differs by stage. The infection is curable, and so is the in-turned eyelid once it is corrected by surgery. The corneal opacity and blindness already caused are not reversible. One label cannot hide that difference. The entry in chapter 1 states it, with the measured burden, the SAFE strategy, the treatments and the simple means.

---

### Retinitis pigmentosa and inherited retinal dystrophies

**What it is.** A group of inherited conditions in which the retina’s light-sensing cells die off over years. Night vision and the edges of sight usually go first, narrowing to tunnel vision. Most forms have no treatment that stops them.

**Measured.** No global prevalence figure was retrievable, and inherited retinal dystrophies do not appear as a line in the published cause breakdown. Retinitis pigmentosa prevalence is commonly reported at about **1 in 4,000**, giving on the order of 1.5 to 2 million people worldwide†. Inherited retinal dystrophies are collectively the leading cause of blindness certification in working-age adults in Eng-

**Where it starts.**

- **Single-gene mutations.** Over 280 genes are implicated across inherited retinal dystrophies†. Inheritance is autosomal recessive, autosomal dominant, X-linked or mitochondrial depending on the gene.
- **Consanguinity** — raises the prevalence of recessive forms.

There are no established environmental or lifestyle risk factors for onset. This is a genetic disease in the strict sense.

Genuinely not known: why the same mutation produces very different severity and age of onset between family members. Modifier genes are suspected and largely unidentified. In a substantial minority of patients — commonly cited as around 30 to 40 per cent — no causative mutation is found even on full gene panel testing. Whether photoreceptor death can be slowed by any general measure is unresolved.

| |
|---|
| **Cure status.** RELIEF ONLY. For almost all patients nothing stops the degeneration and nothing restores lost vision. |

One narrow exception exists. **Voretigene neparvovec**, a gene therapy for biallelic RPE65 mutation-associated retinal dystrophy, improved functional vision on a multiluminance mobility test in its pivotal trial and is licensed. RPE65 disease is a very small fraction of all inherited retinal dystrophy, the benefit is improvement rather than normalisation, and durability beyond several years is not established. It was

---

Retinal prostheses produced crude light perception; one such product was withdrawn commercially, leaving implanted patients without support. RELIEF ONLY is the honest classification for the condition group, with one licensed gene therapy for one rare genotype.

**Prevention.** - **Genetic counselling and carrier testing** in affected families. This prevents transmission rather than disease in an affected person. **STRONG** for that purpose, where available and acceptable. - **Avoiding consanguineous marriage** reduces recessive disease incidence at population level. **MODERATE**, and a matter of social practice rather than clinical intervention. - **Vitamin A palmitate**

Nothing prevents the disease in a person carrying the mutation.

**Treatment.** 1. **Low-vision rehabilitation, orientation and mobility training, white cane, screen readers, magnification.** The mainstay for the great majority. Not medicines. The World Health Organization states that rehabilitation is very effective in improving functioning for people with irreversible vision loss. 2. **Voretigene neparvovec** for biallelic RPE65 disease. Not listed, on-patent, about **hundreds**

**Simple means.** Almost everything that helps these patients is low-technology, because the high-technology options barely exist.

- **A white cane and mobility training.** Transforms independent travel. Negligible cost. - **Task lighting, high-contrast marking of steps and door frames, magnification.** - **Screen readers and text-to-speech**, now standard and free on ordinary phones — a substantial functional gain at zero marginal cost. - **Braille literacy** where appropriate. - **Genetic counselling**, which needs trained counsellors but no laboratory where a family his-

There is no simple means that affects the disease. The minimum chain for the one licensed disease-modifying therapy is genetic sequencing, a subretinal surgical delivery service, and hundreds of thousands of US dollars — which places it outside the reach of almost every patient who has the condition.

**Gaps.** No global prevalence estimate was obtainable. The 1-in-4,000 figure is widely cited and unsourced here. The proportion of patients with no identified mutation varies by population and panel. Long-term durability of voretigene neparvovec is unknown. Whether the many gene therapies in trial will generalise beyond rare genotypes is unresolved. Sources disagree on whether vitamin A supplementation

## Retinal detachment

**What it is.** The retina peels away from the back of the eye. Floaters, flashes and then a dark curtain across the vision. It blinds the eye within days to weeks if the retina is not put back, and putting it back is a surgical emergency.

**Measured.** No global prevalence or incidence figure was retrievable, and retinal detachment is not a line in the published cause breakdown. Annual incidence of rhegmatogenous detachment is commonly reported at about **10 to 18 per 100,000** population per year†. There is a peak in the 50s to 70s, with a second younger peak in high myopes and after trauma†. Incidence tracks myopia prevalence and cataract surgery volume, both of which raise risk, so rising myopia in East Asia implies rising detachment incidence.

**Where it starts.** - **High myopia** — the major risk factor; risk rises steeply with axial length. This connects directly to the myopia entry: the detachment risk is a consequence of the long eye that spectacles correct optically and do not change. - **Posterior vitreous detachment** — the usual precipitant, tearing the retina as the vitreous separates. - **Prior cataract surgery** — raises risk several-fold, more so after capsule rupture. - **Ocular trauma**. - **Lattice degeneration, retinal breaks, family history, prior detachment in the fellow eye**. - **Age**.

Genuinely not known: why most posterior vitreous detachments cause no retinal tear and a few do. Which asymptomatic retinal breaks need prophylactic treatment is unsettled, and prophylactic laser to lattice degeneration has not been shown in randomised trials to prevent detachment.

**Cure status.** CURABLE. A detached retina is reattached in about **85 to 90 per cent** of cases with one operation, and in over **95 per cent** with more than one†. The anatomical problem is fixed permanently and the eye does not re-detach in most cases.

The qualification that must be stated: visual recovery depends on whether the macula had detached and for how long. A macula-on detachment repaired promptly usually keeps good vision. A macula-off detachment of some weeks leaves permanent central loss even after perfect anatomical reattachment. The disease is curable and the *timing* determines whether the sight is saved, which makes this a condition where access speed, not technology, decides the outcome.

**Prevention.** - **Prompt assessment of new floaters, flashes or a visual field shadow**, so that a retinal tear is found and treated with laser before it detaches. **MODERATE** for preventing detachment in symptomatic patients. It costs a dilated examination. - **Laser or cryotherapy to a symptomatic retinal tear.** Prevents progression to detachment. **STRONG** for that specific lesion. - **Prophylactic laser to asymptomatic lattice degeneration. CONTESTED**; not supported by randomised evidence. - **Myopia control in childhood.** Reduces adult axial length and should therefore reduce lifetime detachment risk, and this has never been demonstrated as an outcome. **WEAK** — mechanistically expected, not measured. - **Eye protection in hazardous work and sport.** Prevents traumatic detachment. **MODERATE**.

**Treatment.** 1. **Pars plana vitrectomy with gas or oil tamponade.** The dominant modern operation, with 85 to 90 per cent single-operation success†. A procedure, not listed. Requires a vitrectomy machine and consumables. 2. **Scleral buckle.** A silicone band sutured around the eye, with comparable success and particularly good results in younger phakic patients, and **no machine required** beyond an operating microscope and cryotherapy. Not listed. 3. **Pneumatic retinopexy.** A gas bubble injected in the clinic plus cryotherapy or laser, with head positioning. Lower single-operation success than vitrectomy and by far the lowest-resource option — a needle, a gas cylinder and positioning. 4. **Laser or cryotherapy retinopexy** for a tear without detachment. Cheap, one-off, definitive for that lesion.

**Simple means.** Partly simple, and worth distinguishing from the rest of the chapter.

- **Dilated fundus examination with an indirect ophthalmoscope** finds the tear. The equipment is a lens and a headset light; the cost is training.
- **Cryotherapy retinopexy** needs a cryoprobe and a gas cylinder, no laser.
- **Pneumatic retinopexy** is the closest thing to a simple-means repair: an intravitreal gas injection, retinopexy, and strict head positioning by the patient. It can be done without a vitrectomy suite.
- **Scleral buckling** needs no vitrectomy machine — sutures, a silicone band, a microscope, cryotherapy.

- **Public and primary-care knowledge that a curtain across the vision is an emergency today, not next month.** This costs a message, and it determines whether the macula is still attached when the patient arrives. Given that macula-off duration decides final vision, it is the highest-value zero-cost intervention in the entry.

What the chain minimally requires: an operating theatre, a microscope, a cryoprobe or laser, and a surgeon trained in retinal repair. There is no non-surgical means of reattaching a retina.

**Gaps.** No global incidence or prevalence figure was obtainable; the 10 to 18 per 100,000 range is widely cited and unverified. Reattachment success rates vary with case mix and were not sourced to a registry. Whether prophylactic treatment of asymptomatic lesions helps is genuinely disputed. The expected effect of the myopia epidemic on future detachment incidence has not been quantified in any source read.

---

## Amblyopia and strabismus

**What it is.** In strabismus the two eyes do not point the same way. In amblyopia one eye's vision never develops properly because the brain learned to ignore it in early childhood. Treated young it recovers; left past childhood it does not.

**Measured.** Neither appears as a line in the published cause breakdown and no global figure was retrievable. Amblyopia prevalence is commonly reported at about **1 to 4 per cent** of children, and strabismus at about **2 to 4 per cent**†.

Age is the critical determinant. Visual development is plastic until roughly age **7 to 8** and treatment response falls steeply after that†. Prevalence is similar across populations; *treated* prevalence is not, and where vision screening and spectacles are unavailable amblyopia is permanent. Amblyopia is a leading cause of monocular vision loss in adults worldwide.

**Where it starts.** - **Uncorrected refractive error, especially anisometropia** — unequal refraction between the eyes — and significant hyperopia. The commonest cause, linking directly to the hyperopia entry. - **Strabismus** — the deviating eye is suppressed. - **Visual deprivation** — congenital cataract, ptosis, corneal opacity. The most severe and most urgent form. - **Prematurity, low birth weight, maternal smoking, family history** — associated with strabismus.

Genuinely not known: why some children with significant anisometropia never become amblyopic. The cortical basis of suppression, and why plasticity closes when it does, are not fully described. Whether adult amblyopia can be reopened to treatment is unresolved; current evidence shows small gains at best.

**Cure status.** Treated within the plastic period: CURABLE. Treated after it closes: RELIEF ONLY.

This is the sharpest age dependency in the book. Within the plastic period, amblyopia is genuinely curable: spectacle correction alone resolves a substantial proportion of cases, and patching or atropine penalisation resolves much of the rest. The eye reaches normal or near-normal acuity and keeps it.

After the critical period closes, no intervention restores normal acuity in an adult amblyopic eye. Strabismus surgery in an adult can realign the eyes — a real functional and social gain, and sometimes it restores binocularity — and it does not restore the amblyopic eye's acuity. The determinant of outcome is therefore the age at which the child is found, which makes screening the whole intervention.

**Prevention.** - **Preschool vision screening around age 3 to 5, followed by spectacle correction and amblyopia treatment.** This is the intervention: it converts a permanent monocular disability into a treated condition. **MODERATE**; national screening bodies differ on the optimal age and method, which is why it is not graded STRONG uniformly. - **Treating congenital cataract and ptosis urgently in infancy.** Prevents deprivation amblyopia. **STRONG**. - **Correcting significant childhood hyperopia and anisometropia. STRONG**. - **Photoscreening devices usable by non-specialists** for detection at scale. **MODERATE**.

**Treatment.** 1. **Spectacle correction alone, given time** — refractive adaptation. This resolves a substantial share of amblyopia before any patching is added, and the Amblyopia

Treatment Studies established that spectacles alone should be tried first. A device, not listed. 2. **Patching the better eye.** The Amblyopia Treatment Studies found **2 hours** of daily patching as effective as 6 hours, and part-time as effective as full-time in moderate amblyopia. Cost: an adhesive patch, cents. 3. **Atropine 1 per cent penalisation of the better eye.** As effective as patching in moderate amblyopia, with better adherence in some children. **Atropine is on the Essential Medicines List** as an ophthalmological mydriatic. Off-patent. Cents to a few dollars per bottle, and one bottle lasts months. 4. **Strabismus surgery.** Realigns the eyes, may restore binocularity if performed early, and gives a substantial cosmetic and social benefit at any age. A procedure, not listed. 5. **Botulinum toxin** as an alternative to surgery in selected strabismus. 6. **Prism spectacles** for small deviations and diplopia.

**Simple means.** This is one of the strongest cheap-intervention entries in the book, and it is underused.

- **A vision chart and a trained screener.** Detecting amblyopia needs a letter or picture chart, an occluder and someone trained for an afternoon. Capital cost: a printed chart.
- **Spectacles** at roughly **a few US dollars per pair** in low-cost programmes — and spectacles alone cure a substantial fraction of amblyopia if given early enough.
- **An adhesive eye patch** costs cents, and 2 hours a day suffices in moderate amblyopia† — a finding that cut treatment burden by two-thirds at no cost.
- **Atropine drops**, listed, off-patent, cents per bottle, as an alternative to patching with equivalent effect in moderate amblyopia.
- **The cover test** for strabismus detection: an occluder and an examiner’s eye. Free.

A chart, a patch, a pair of spectacles and a bottle of atropine — a few US dollars in total — prevent a lifetime of monocular vision loss, and only if applied before about age seven. The binding constraint is not cost, it is finding the child in time. Strabismus surgery is the one component requiring a theatre.

**Gaps.** No global prevalence figure for either condition was obtainable, and neither appears in the published cause breakdown despite amblyopia being a leading cause of monocular vision loss. The 1 to 4 per cent prevalence figures are widely cited and unverified. The Amblyopia Treatment Studies effect sizes could not be verified against the primary reports. National screening bodies genuinely disagree on whether and when to screen preschool children, and have reached different conclusions from similar evidence. Whether adult amblyopia treatment can work is an open question with small positive trials and no established therapy.

---

## Dry eye disease

**What it is.** The tear film does not keep the eye surface wet enough, either from too little tear or from tears that evaporate too fast. The eyes sting, burn, feel gritty and sometimes water paradoxically. It is chronic and it fluctuates.

**Measured.** No global figure was retrievable. The World Health Organization names dry eye among conditions that do not usually cause vision impairment but are treatable, with treatment relieving symptoms and preventing progression to more severe disease.

Reported prevalence varies enormously with definition, commonly **5 to 50 per cent** of adults depending on whether symptoms, signs or both are required. That spread is the central measurement problem in the condition. Prevalence rises with age and is substantially higher in women, particularly after the menopause, with higher reported prevalence in Asian populations. The trend is reported as rising, attributed to screen use and ageing.

**Where it starts.** - **Age**. - **Female sex and post-menopausal status**. - **Meibomian gland dysfunction** — the commonest contributor; blocked lid oil glands let the tear film evaporate. - **Screen use and reduced blink rate**. - **Low ambient humidity, air conditioning, wind, air travel**. - **Drugs** — antihistamines, anticholinergics, antidepressants, isotretinoin, diuretics, beta-blockers. - **Autoimmune disease, especially Sjögren syndrome; graft-versus-host disease**. - **Contact lens wear; prior refractive or cataract surgery**. - **Vitamin A deficiency** — causes conjunctival and corneal drying; see that entry.

Genuinely not known: why symptoms and signs correlate so poorly. Many people with severe dryness on examination have no symptoms and the reverse also holds, which undermines

both diagnosis and trial endpoints. The relative primacy of inflammation against tear deficiency against lid disease is disputed. Why the condition fluctuates is unexplained.

**Cure status.** RELIEF ONLY. Treatment relieves symptoms and protects the surface; nothing restores a damaged lacrimal gland or reverses established meibomian gland dropout. Gland loss visible on meibography is permanent, and the condition is managed indefinitely. In vitamin A deficiency dry eye the underlying cause is itself curable by repletion, which is the exception.

**Prevention.** - **Avoiding or substituting causative drugs** where clinically possible. **MODERATE**. - **Blink awareness and regular breaks during screen work**, and lowering screens below eye level to reduce exposed ocular surface area. **WEAK**. - **Humidification, avoiding direct airflow at the face. MODERATE**. - **Lid hygiene to prevent meibomian gland dropout. WEAK** for prevention of incident disease. - **Omega-3 supplementation.** The DREAM trial found **no benefit** over placebo. **CONTESTED**, effectively negative. - **Vitamin A sufficiency. STRONG** for the deficiency form specifically.

**Treatment.** 1. **Artificial tears and ocular lubricants.** First-line; relieve symptoms with no disease modification, with preservative-free formulations for frequent use. Not confirmed as a core item in the Essential Medicines List ophthalmological section displayed. Off-patent. A few US dollars per bottle, with preservative-free unit doses considerably more. 2. **Warm compresses and lid massage** for meibomian gland dysfunction. Free; see *Simple means*. 3. **Topical ciclosporin 0.05 per cent.** Reduces inflammation, with a modest effect and slow onset. Ciclosporin is listed as a systemic immunosuppressant and not as the ophthalmic preparation. Off-patent as a molecule; the licensed ophthalmic emulsion is expensive. 4. **Topical lifitegrast.** A similar role, on-patent, expensive. 5. **Punctal plugs.** Block tear drainage, retaining the tears the eye makes. Cheap, reversible, effective in aqueous-deficient disease. 6. **A short course of topical corticosteroid** for flares; betamethasone and other steroids are listed. Off-patent, cents to a few dollars. Not for long-term use. 7. **Autologous serum eye drops and scleral lenses** for severe disease. 8. **Oral doxycycline or azithromycin** for meibomian gland dysfunction and rosacea-associated disease; both listed, both off-patent, cents per day.

**Simple means.** Unusually good, because the mainstays are physical rather than pharmaceutical.

- **Warm compresses and lid massage.** A clean cloth and warm water, twice daily. This is the primary treatment for meibomian gland dysfunction, which is the commonest cause. Zero supply chain. No measured effect size was sourced.
- **Lid margin cleaning** with a clean cloth or a dilute mild shampoo.
- **Humidity and airflow management** — moving away from a fan or vent, a bowl of water in a dry room.
- **Blink breaks during close work.**
- **Protective wrap-around spectacles or a moisture chamber** reduce evaporation; ordinary sunglasses give part of this effect.
- **Simple artificial tears** at a few dollars a bottle; in severe aqueous deficiency, punctal occlusion is a minor office procedure with a cheap plug.

For the common form, warm water and a cloth are first-line therapy. The industrial chain is needed only for the anti-inflammatory drugs, which deliver modest additional benefit.

**Gaps.** This is the condition in the chapter with the weakest measurement base. No global prevalence figure exists on the sources read, and published prevalence ranges from about 5 to about 50 per cent depending entirely on case definition† — the sources do not disagree about the data so much as measure different things. Symptoms and signs correlate poorly, which means trial endpoints are contested and effect sizes are hard to compare. Omega-3 evidence is genuinely split: earlier positive observational and small-trial data against the null DREAM result, and the null result is the stronger evidence. No effect size for warm compresses could be sourced. The Essential Medicines List status of ocular lubricants could not be confirmed.

## Conjunctivitis

**What it is.** The clear skin over the white of the eye becomes inflamed, so the eye is red, gritty and discharging. Most cases are viral or allergic and settle on their own. A few kinds are dangerous.

**Measured.** No global figure was retrievable; conjunctivitis is not a line in the published cause breakdown, and the World Health Organization names it among conditions that do not usually cause vision impairment. It is among the commonest reasons for primary-care and emergency eye presentation worldwide.

Neonatal conjunctivitis — ophthalmia neonatorum — from gonococcal or chlamydial infection is the form that blinds, and is the reason for universal neonatal ocular prophylaxis in many countries. Viral and bacterial forms concentrate in children and allergic forms follow atopy. Epidemic viral keratoconjunctivitis occurs in outbreaks, and adenoviral outbreaks are regularly reported in institutions.

**Where it starts.** - **Adenovirus** — the commonest infectious cause, highly contagious via hands and shared surfaces. - **Bacteria** — *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*. - ***Neisseria gonorrhoeae* and *Chlamydia trachomatis*** — in neonates from the maternal genital tract, and in adults by autoinoculation. Gonococcal conjunctivitis can perforate a cornea within days. - **Allergens** — seasonal and perennial allergic conjunctivitis. - **Contact lens wear, poor hand hygiene, crowding, shared towels**.

Genuinely not known: clinical signs do not reliably distinguish viral from bacterial conjunctivitis, which is the direct cause of large-scale unnecessary antibiotic use, and no cheap point-of-care test has entered routine use. Why some adenoviral infections cause prolonged subepithelial opacities and others resolve cleanly is unexplained.

**Cure status.** Viral: SELF-LIMITING — resolves in 1 to 3 weeks without treatment and no antiviral is indicated for adenovirus. Simple bacterial: SELF-LIMITING — the Cochrane review of topical antibiotics found most cases resolve without them, with antibiotics modestly speeding resolution. Gonococcal and chlamydial: CURABLE, and treatment is mandatory and urgent, because untreated gonococcal conjunctivitis perforates the cornea. Allergic: RELIEF ONLY — the atopic tendency persists.

The dominant cause is viral, so SELF-LIMITING is the single best answer for conjunctivitis as a whole, with the named exceptions treated as emergencies.

**Prevention.** - **Hand hygiene and not sharing towels or face cloths.** Interrupts the main transmission route. **STRONG** for outbreak control. No supply chain beyond soap and water. - **Neonatal ocular prophylaxis** with tetracycline 1 per cent or erythromycin 0.5 per cent eye ointment at birth. Prevents gonococcal ophthalmia neonatorum. **STRONG**. - **Antenatal screening and treatment of maternal gonorrhoea and chlamydia. STRONG**. - **Excluding infected children from school during the contagious phase. MODERATE/CONTESTED** — widely practised, limited evidence of benefit. - **Allergen avoidance** for allergic forms. **MODERATE**. - **Contact lens hygiene. MODERATE**.

**Treatment.** 1. **Nothing, plus hygiene advice and cool compresses**, for viral and most simple bacterial conjunctivitis. **The action is omission.** Cost: zero. This is the evidence-based first option and it is the one most often not taken. 2. **Topical antibiotics — chloramphenicol, tetracycline 1 per cent ointment, fusidic acid, azithromycin drops** — for bacterial conjunctivitis. They shorten illness modestly over placebo. **Azithromycin eye drops and tetracycline eye ointment are on the Essential Medicines List**. Off-patent, cents per tube. 3. **Systemic ceftriaxone plus azithromycin** for gonococcal conjunctivitis — urgent; both listed, both off-patent, low cost. 4. **Oral azithromycin or doxycycline** for adult chlamydial conjunctivitis — both listed, off-patent, under a dollar per course. 5. **Topical antihistamine or mast-cell stabiliser — olopatadine, sodium cromoglicate** — for allergic conjunctivitis. Sodium cromoglicate is off-patent and cheap. 6. **Topical corticosteroid.** Only under ophthalmic supervision, and contraindicated if herpes simplex keratitis is possible, where it can destroy the cornea.

**Simple means.** Nearly everything here is simple means.

- **Hand washing with soap**, and not sharing towels. The single most effective measure for the infectious forms.
- **Cool compresses and eye toilet with clean water** for symptomatic relief.

- **Not treating.** The action is omission. Withholding antibiotics in self-limiting disease is a zero-cost intervention with a real benefit — less cost, less resistance, the same outcome in most cases. It also saves money directly, since the antibiotic is not bought.
- **Tetracycline 1 per cent eye ointment at birth.** Cents per neonate, and it prevents gonococcal blindness. Listed, off-patent. This is one of the cheapest blindness-prevention interventions that exists.
- **Allergen avoidance and a cold compress** for allergic forms.

What the chain minimally requires: for the dangerous forms, an injectable cephalosporin and the clinical judgement to recognise them. For everything else, soap.

**Gaps.** No global incidence figure exists on the sources read for one of the commonest eye conditions in the world. The viral, bacterial and allergic proportions are not established and vary by setting and season. Clinical differentiation of viral from bacterial is unreliable and no deployable point-of-care test exists, so antibiotic prescribing rates far exceed bacterial prevalence. The Cochrane antibiotic effect sizes could not be verified. Whether school exclusion achieves anything is disputed.

---

### Keratitis and corneal opacity

**What it is.** Keratitis is inflammation or infection of the cornea, the clear window at the front of the eye. If it scars, the window goes cloudy and sight is permanently reduced. It can destroy an eye in days.

**Measured.** Corneal opacity is named as a cause of blindness and no count is given on the World Health Organization fact sheet; no global figure was retrievable. India's national survey in 2023 found about **880,000** people with avoidable blindness from corneal opacities.

Onchocerciasis contributes. Global Burden of Disease estimated **1.15 million** people with vision loss from onchocerciasis and **14.6 million** with onchocercal skin disease, on 2017 estimates (World Health Organization fact sheet, *Onchocerciasis*, 4 December 2025). **252.3 million** people required preventive treatment in 2024, and **171.6 million** were reached across **26** reporting countries. **More than 99 per**

---

Trachoma contributes about **1.9 million** people with blindness or visual impairment; the end stage of trachoma is corneal opacity.

Microbial keratitis affects all ages, and agricultural trauma concentrates in working-age men in low-income settings. Fungal keratitis is far more common in tropical agricultural regions, while in high-income countries contact-lens-related bacterial keratitis dominates.

**Where it starts.** - **Corneal trauma, especially agricultural injury with vegetable matter** — the dominant cause in low-income rural settings, and the entry point for fungal keratitis. - **Contact lens wear**, especially overnight wear and poor hygiene — the dominant cause in high-income settings; *Pseudomonas* and *Acanthamoeba*. - **Herpes simplex virus** — recurrent, and a leading infectious cause of corneal blindness in high-

Genuinely not known: why some corneal ulcers scar centrally and densely while similar ulcers heal clear. Why herpes simplex reactivates when it does. The optimal role of adjunctive corticosteroid in bacterial keratitis is unsettled — the Steroids for Corneal Ulcers Trial found no overall benefit with a possible benefit in subgroups with worse baseline vision.

**Cure status.** The infection: CURABLE. The resulting opacity: RELIEF ONLY.

The split is the whole story. Active microbial keratitis is curable — appropriate intensive topical antimicrobials eradicate most bacterial and many fungal infections. The scar they leave is not reversible by any medical means. Established corneal opacity is restored only by **corneal transplantation**, which is genuinely restorative — penetrating and endothelial keratoplasty can return normal vision — and de-

Cure the infection early and there is no opacity. Arrive late and the available answer is a transplant that most of the affected world cannot reach.

**Prevention.** Prevention is overwhelmingly more effective than treatment here. - **Eye protection in agriculture and industry. MODERATE**, and essentially free. - **Prompt topical antibiotic prophylaxis after corneal abrasion.** Village-level programmes in Nepal, Bhutan and Myanmar reported large reductions in ulcer incidence after training village health workers to treat corneal abrasions with topical antibi-

**Treatment.** 1. **Intensive topical antibiotics for bacterial keratitis** — fluoroquinolone monotherapy or fortified cefazolin with gentamicin or tobramycin, hourly initially. Ciprofloxacin and gentamicin eye preparations are listed, with amikacin as therapeutic equivalent to gentamicin. Off-patent, a few dollars per course. 2. **Topical natamycin 5 per cent for fungal keratitis.** The Mycotic Ulcer Treatment Trial found natamycin

**Simple means.** Strong, and the village-level pro-phy-laxis find-ing is the key one.

- **Eye protection** in farm work: goggles, or even spectacles. Negligible cost. - **Topical antibiotic ointment applied by a trained village health worker to any corneal abrasion.** Reported to reduce corneal ulcer incidence substantially in Nepalese, Bhutanese and Burmese programmes; the effect sizes could not be verified. The inputs are a tube of tetracycline or chloramphenicol ointment, a torch and a half-day of

What the chain minimally requires for an established opacity: an eye bank and a corneal surgeon. There is no simple means that clears a scarred cornea.

**Gaps.** No global figure for corneal opacity or microbial keratitis exists on any source read, despite its being a major blindness cause — the fact sheet names it without a count. Only the India 2023 national survey figure was obtainable. The village abrasion-prophylaxis effect sizes, which matter a great deal for policy, could not be verified. The bacterial and fungal split differs completely between regions and no global

## Vitamin A deficiency blindness (xerophthalmia, keratomalacia)

**What it is.** Without enough vitamin A the eye cannot make the pigment it needs to see in dim light, and the surface of the eye dries out. Night blindness comes first, then the cornea softens and can melt away within days. It mostly happens to young children and it is entirely preventable.

**Measured.** The World Health Organization vitamin A deficiency fact sheet did not load, and the figures below are carried as widely reported and are not verified.

Children affected are commonly reported as about **190 million** preschool children with low serum retinol†. Children going blind annually from vitamin A deficiency are commonly reported as **250,000 to 500,000**, of whom about half die within 12 months of losing their sight†. That figure originates in older estimates and is widely repeated; its current accuracy is uncertain. A 2023 systematic review and modelling analysis of prevalence in low- and middle-income countries exists and could not be retrieved.

The World Health Organization names nutrition-related diseases among preventable causes of vision loss without giving a figure. The affected groups are preschool children and pregnant women, concentrated in sub-Saharan Africa and South Asia, and the trend is falling with supplementation coverage and food fortification.

**Where it starts.** - **Dietary vitamin A inadequacy** — the necessary cause: low intake of liver, dairy and eggs, and of provitamin A carotenoids from dark green leaves, orange sweet potato, mango, papaya and carrot. - **Measles** — depletes vitamin A acutely and precipitates keratomalacia in a marginally deficient child. The measles–vitamin A–corneal melt sequence is the classic route to childhood corneal blindness. The World Health Organization directs two doses of vitamin A to every suspected measles case under five, with a third dose 4 to 6 weeks later if there are eye complications. - **Diarrhoeal disease and intestinal parasites** — fat malabsorption and loss. Diarrhoeal disease kills **443,832** children under five and **50,851** children aged 5 to 9 each year, with nearly **1.7 billion** childhood episodes annually and no data year stated on the page (World Health Organization fact sheet, *Diarrhoeal disease*, 7 March 2024). - **Protein-energy malnutrition** — impairs retinol transport. - **Lack of breastfeeding**. - **Pregnancy and lactation** raise requirement.

Genuinely not known: why individual susceptibility to corneal involvement varies at similar serum retinol levels. Serum retinol is a poor marker of liver stores, which makes population assessment imprecise. The DEVTA trial in India found no significant mortality benefit from vitamin A supplementation, contradicting earlier trials, and that disagreement has never been fully resolved.

**Cure status.** The deficiency: CURABLE. Established corneal destruction: RELIEF ONLY.

Night blindness and conjunctival xerosis reverse within **days** of high-dose vitamin A — one of the fastest and cheapest cures in medicine. Bitot's spots and corneal xerosis also resolve. But keratomalacia that has melted the cornea leaves permanent opacity or a destroyed eye, and vitamin A cannot undo it. The window between reversible and irreversible is measured in days, which is why this condition is classified by stage and why supplementation programmes rather than treatment are the answer.

**Prevention.** This is among the best-evidenced and cheapest preventive interventions in all of medicine, and its central effect size is disputed. - **High-dose vitamin A supplementation twice yearly for children 6 to 59 months.** The Cochrane review of supplementation in children aged 6 months to 5 years found a reduction in all-cause mortality of about **24 per cent**, and reductions in measles incidence, diarrhoea and night blindness — the Cochrane page did not load. **STRONG**, with the important caveat that the large DEVTA trial found no mortality benefit, so the pooled estimate is disputed. Both readings are printed. - **Measles vaccination.** Removes the main acute precipitant. **STRONG**; the vaccine costs a few US dollars per child. - **Food fortification** — vegetable oil, sugar, flour with vitamin A. **STRONG**. - **Biofortification** — orange-flesh sweet potato, biofortified rice. **MODERATE**. - **Breastfeeding promotion. STRONG**. - **Home gardening and dietary diversification** with dark green leaves and orange fruit. **MODERATE**. - **Vitamin A with measles treatment.** The World Health Organization directs two doses to every child with suspected measles under five, which reduces mortality and corneal complications. **STRONG**.

**Treatment.** 1. **High-dose oral vitamin A (retinyl palmitate), 200,000 IU on days 1, 2 and 14**, age-adjusted, with 100,000 IU for infants 6 to 11 months. Reverses night blindness and conjunctival and corneal xerosis within days. **Retinol is on the Essential Medicines List** — the list document did not load. Off-patent. **Approximately under one US dollar per capsule**, making a full course a few cents. 2. **Topical antibiotic and cycloplegic** to the affected cornea to prevent secondary bacterial infection of a melting cornea. 3. **Treatment of concurrent measles, diarrhoea and malnutrition.** 4. **Corneal grafting** for a healed scar. Rarely available in the affected settings, with poor outcomes in these eyes.

**Simple means.** This is arguably the single highest-return simple intervention in the book: a capsule costing about two to five US cents, given twice a year, prevents childhood blindness and reduces child mortality.

- **Twice-yearly high-dose vitamin A capsules** delivered by community health workers or on campaign days. No cold chain, no needle, no clinical skill beyond dosing by age. Cochrane gives about a 24 per cent all-cause mortality reduction†, with the DEVTA null result as the counter-evidence.
- **Dark green leafy vegetables, orange sweet potato, mango and papaya** grown in a household garden. No supply chain at all. Provitamin A carotenoid bioavailability from leaves is lower than from animal sources, so quantity and added fat matter.
- **A small amount of oil or fat with the meal** to permit absorption — a free dietary change with a real effect on bioavailability.
- **Breastfeeding.** Free, and breast milk is a vitamin A source for the infant.
- **Measles vaccination** — a listed vaccine at a few US dollars per child.
- **Two doses of vitamin A to every child with measles** — the World Health Organization protocol, at cents.

Nothing else in this book prevents blindness at a lower unit cost.

**Gaps.** This entry has the weakest sourcing in the chapter, because the World Health Organization vitamin A deficiency fact sheet, the Cochrane review and the 2023 modelling analysis all failed to load. Every prevalence figure above is unverified. Sources genuinely disagree on the mortality effect: the pooled Cochrane estimate of about a 24 per cent reduction against DEVTA, in about a million children, finding no significant mortality benefit. That disagreement is unresolved and material to policy, and both are printed. The 250,000 to 500,000 children blinded annually derives from older estimates and may substantially overstate the current burden; no current figure was obtainable. Serum retinol is an imprecise measure of status, so prevalence estimates carry large uncertainty.

---

## Retinopathy of prematurity

**What it is.** In babies born very early the retinal blood vessels have not finished growing. After birth they can grow abnormally, scar and pull the retina off. It is a disease produced by survival — babies who would once have died now live, and some are blinded.

**Measured.** No count is given on the World Health Organization fact sheet and no global figure was retrievable. Retinopathy of prematurity is a leading cause of childhood blindness worldwide, and is reported to cause blindness or severe visual impairment in roughly **20,000 to 30,000** infants per year†.

By definition it is confined to preterm infants, with risk rising steeply as gestational age and birth weight fall. Preterm birth is the context: **13.4 million** babies were born preterm in 2020, about 1 in 10 of all births, and preterm birth complications killed about **900,000** children in 2019 (World Health Organization fact sheet, *Preterm birth*, 10 May 2023).

The geography is the distinguishing feature. Blindness from retinopathy of prematurity is concentrated in **middle-income** countries — a “third epidemic” — where neonatal intensive care now lets very preterm infants survive and oxygen monitoring and screening have not caught up. In high-income countries with tight oxygen control and universal screening it is rare; in the poorest countries very preterm infants still do not survive. The trend is rising in middle-income countries as neonatal survival improves.

**Where it starts.** - **Low gestational age and low birth weight** — the primary determinants.
- **Supplemental oxygen, especially unmonitored or fluctuating high concentrations** —

the classic modifiable cause; uncontrolled oxygen produced the first epidemic in the 1940s and 1950s†. - **Sepsis, blood transfusion, poor postnatal weight gain, hyperglycaemia, intraventricular haemorrhage**. - **Absence of screening** — not a cause of the disease but the cause of the blindness, since treatable disease goes undetected.

Genuinely not known: the optimal oxygen saturation target, which is genuinely unresolved and where the evidence is in tension. Lower saturation targets reduce retinopathy, and the SUPPORT, BOOST-II and COT trials together suggested lower targets increase mortality. This is a direct trade-off between death and blindness and no target satisfies both. Why some infants with identical exposures progress to stage 5 is unexplained. The role of insulin-like growth factor 1 and the balance of the two phases of the disease are incompletely described.

**Cure status.** Caught in the treatment window: CURABLE. After detachment: RELIEF ONLY.

Treated at threshold disease, ablation or anti-VEGF causes regression and the great majority of eyes retain useful vision; the CRYO-ROP and ETROP trials established that treatment substantially reduces unfavourable outcomes. That is a cure of the sight-threatening process. Once the retina has detached, at stage 4 to 5, surgery rarely restores useful vision and stage 5 outcomes are very poor†.

The treatment window is narrow — a matter of days to a couple of weeks — which makes this a condition where the entire outcome turns on screening logistics rather than therapeutic power. A baby not examined at the right week is blinded by an omission.

**Prevention.** - **Controlled, monitored supplemental oxygen with pulse oximetry, defined saturation targets and alarm limits.** The core preventive measure, and it ended the first epidemic. **STRONG** for reducing retinopathy — and the target itself is **CONTESTED**, because of the mortality trade-off above. - **Universal screening of all infants meeting gestational age and birth weight criteria, at the correct postnatal timing.** Does not prevent the disease; prevents the blindness. **STRONG** for that outcome. - **Antenatal corticosteroids, delayed cord clamping, breast milk feeding, sepsis prevention, avoiding unnecessary transfusion, optimising postnatal weight gain. MODERATE**. - **Preventing preterm birth** — the true primary prevention, and the least tractable. - **Avoiding unnecessary oxygen in more mature preterm infants. STRONG**, and effectively free. The action is omission.

**Treatment.** 1. **Laser photocoagulation of the avascular retina.** The long-standing standard. A procedure, not listed, and the technique is unpatented. Cost: a capital laser plus an operator, with **no consumables and no repeat dosing**, and it is definitive. It destroys peripheral retina by design and induces myopia. 2. **Intravitreal anti-VEGF (bevacizumab, ranibizumab).** The BEAT-ROP trial found bevacizumab superior to laser for zone I disease. It avoids peripheral retinal destruction and requires prolonged follow-up for late reactivation, and systemic VEGF suppression in a developing infant raises unresolved concerns about neurodevelopment. **Bevacizumab is on the Essential Medicines List**, off-patent, at about **tens of US dollars to 100 per dose** against ranibizumab at about **thousands of US dollars per dose**. For this indication the dose is a fraction of the adult dose, so the per-infant drug cost from a shared vial is very small. 3. **Cryotherapy** — the original CRYO-ROP intervention, still usable where no laser exists. 4. **Vitrectomy, or lens-sparing vitrectomy**, for stage 4 to 5. Poor outcomes.

**Simple means.** Mixed, and the division is instructive.

- **A pulse oximeter with a correctly set alarm range.** This is the key cheap item: a pulse oximeter costs tens of US dollars and, used with defined saturation targets, prevents the oxygen-driven disease. The first epidemic ended when oxygen was controlled, before any treatment existed.
- **Written oxygen protocols and trained nursing staff.** Costs training, not equipment, and in middle-income neonatal units this is the documented gap.
- **Screening by indirect ophthalmoscopy with a 20 D or 28 D lens and a speculum**, by a trained examiner at the bedside. No imaging equipment required.
- **Telemedicine screening using a retinal camera**, images graded remotely, where no ophthalmologist is available.
- **Breast milk feeding.** Free, and associated with lower risk.
- **Bevacizumab from a shared vial** brings the drug cost per treated infant to a few US dollars.

What the chain minimally requires: a functioning neonatal unit with oxygen blending and monitoring, a trained examiner visiting on schedule, and a laser or an injection. This condition cannot be addressed at all without a neonatal intensive care service. It is the one condition in the chapter that exists only where a hospital exists.

**Gaps.** No verified global figure for incidence or for blindness was obtainable; the fact sheet gives no count. The 20,000 to 30,000 annual figure is widely cited and unverified. The optimal oxygen saturation target is a genuine, unresolved conflict between retinopathy risk and mortality risk, with three trials pointing one way and the eye outcomes the other; both are printed. Long-term neurodevelopmental safety of intravitreal anti-VEGF in preterm infants is not established and is actively disputed. Screening criteria calibrated in high-income populations miss larger, more mature babies who develop the disease in middle-income settings, so imported guidelines under-detect.

---

## Optic neuritis

**What it is.** The optic nerve becomes inflamed. Vision in one eye dims or greys over hours to days, colours wash out, and moving the eye hurts. Most people recover much of their sight, and it is often the first sign of a wider disease.

**Measured.** No global figure was retrievable; optic neuritis is not a line in the published cause breakdown. Annual incidence is commonly reported at about **1 to 5 per 100,000**†. It is typically a disease of ages 20 to 45 and more common in women†, with incidence rising with latitude, mirroring multiple sclerosis.

Conversion to multiple sclerosis is the clinically decisive measure. The Optic Neuritis Treatment Trial followed patients 15 years and reported a cumulative probability of multiple sclerosis of about **50 per cent** overall, about **25 per cent** with a normal baseline brain magnetic resonance image and about **72 per cent** with one or more lesions†. These figures are the clinical backbone of the condition and could not be verified against the primary report.

**Where it starts.** - **Multiple sclerosis** — the commonest associated condition; optic neuritis is a frequent first demyelinating event. - **Myelin oligodendrocyte glycoprotein antibody disease and aquaporin-4-antibody neuromyelitis optica spectrum disorder** — distinct antibody-mediated causes with different prognosis and different treatment, and distinguishing them changes management completely. - **Female sex, age 20 to 45, higher latitude, low vitamin D, Epstein-Barr virus exposure, smoking, HLA-DRB1*15:01 **— the multiple sclerosis risk-factor set†. -** Infections and post-infectious inflammation **— syphilis, Lyme disease, tuberculosis, viral. -** Ethambutol, amiodarone and methanol** cause optic neuropathy rather than true neuritis, present similarly, and are reversible only if stopped early.

Genuinely not known: what triggers the attack at the moment it occurs. Why some patients recover to 6/6 and others are left with permanent loss despite similar presentation. Whether early disease-modifying therapy after a first episode changes long-term disability is still debated. Neuromyelitis optica and myelin oligodendrocyte glycoprotein antibody disease were only recently separated from multiple sclerosis, so older incidence and prognosis data conflate distinct diseases.

**Cure status.** The episode: SELF-LIMITING. The underlying disease: CONTROLLABLE.

The individual attack resolves largely on its own. The Optic Neuritis Treatment Trial established that intravenous methylprednisolone **speeds recovery and does not change visual outcome** at six months or beyond, and that **oral prednisone alone at the dose studied was associated with an increased risk of recurrence**. That is an unusually clear negative result and it defines the treatment of the episode: steroids are given for speed, not for outcome.

Most patients recover good acuity, though many retain measurable deficits in contrast sensitivity, colour vision and the visual field, and the nerve thins permanently. The underlying disease is CONTROLLABLE and not curable. Neuromyelitis optica attacks in particular can leave severe permanent loss, which is why distinguishing it matters.

**Prevention.** - **No primary prevention of a first episode is established.** - **Disease-modifying therapy in diagnosed multiple sclerosis.** Reduces relapse rate, including further optic neuritis. **STRONG** for relapse reduction. - **Immunosuppression in neuromyeli-**

**tis optica** — rituximab, eculizumab, satralizumab, azathioprine. Prevents attacks, and this matters more than in multiple sclerosis because the attacks are more destructive. **STRONG** for attack prevention. - **Avoiding oral prednisone monotherapy after an episode**, which was associated with increased recurrence. **MODERATE**, and the action is omission. - **Smoking cessation and vitamin D sufficiency. WEAK**, and **CONTESTED** for vitamin D. - **Stopping ethambutol promptly on any visual symptom**, and dose-limiting by weight and renal function. Prevents irreversible toxic optic neuropathy. **STRONG** for that cause.

**Treatment.** 1. **Intravenous methylprednisolone 1 g daily for three days**, with or without an oral taper. Speeds recovery and does not improve final outcome. Methylprednisolone and dexamethasone are listed. Off-patent, low tens of US dollars per course. 2. **High-dose oral methylprednisolone** — a bioequivalent alternative to the intravenous route, cheaper and deliverable without infusion. 3. **Plasma exchange** for severe steroid-refractory attacks, especially in neuromyelitis optica. 4. **Aquaporin-4 and myelin oligodendrocyte glycoprotein antibody testing.** Changes diagnosis and treatment; not a treatment but the decisive step. 5. **Disease-modifying therapy for multiple sclerosis** — interferon beta, glatiramer, and the oral and monoclonal agents. Costs range from low hundreds to tens of thousands of US dollars per patient-year. 6. **Rituximab or azathioprine for neuromyelitis optica.** Azathioprine is listed, off-patent and cheap; rituximab is listed as a selected medicine in the complementary list, and biosimilars have reduced its cost. 7. **No treatment.** A defensible option for a typical isolated episode, given that steroids do not change the outcome. The action is omission.

**Simple means.** Limited for the disease, and two things are genuinely simple and matter greatly.

- **Clinical diagnosis without imaging.** Unilateral subacute vision loss with pain on eye movement, a relative afferent pupillary defect found with a torch, red desaturation tested with any red object, and reduced acuity on a printed chart. A torch, a chart and a red cap identify the condition. No scanner required.
- **Recognising and stopping a causative drug**, above all **ethambutol** in tuberculosis treatment. This costs nothing, requires only that someone asks about vision at each visit, and prevents permanent bilateral blindness. Given the scale of tuberculosis treatment — **10.7 million** new cases in 2024 (World Health Organization fact sheet, *Tuberculosis*, 24 March 2026) — this is the highest-value simple intervention in the entry.
- **High-dose oral steroid instead of intravenous** — equivalent, far cheaper, no infusion service.
- **Not giving low-dose oral prednisone alone**, which was linked to increased recurrence. The action is omission, and it is a free improvement.
- **Explanation**, since most episodes recover substantially.

What the chain minimally requires for proper management: antibody testing and magnetic resonance imaging to separate multiple sclerosis, neuromyelitis optica and myelin oligodendrocyte glycoprotein antibody disease, because their treatments differ and untreated neuromyelitis optica blinds. That is a laboratory and a scanner.

**Gaps.** No global incidence figure was obtainable. The widely quoted 1 to 5 per 100,000 and the 15-year conversion figures could not be verified against primary sources. Incidence and prognosis data published before the separation of neuromyelitis optica and myelin oligodendrocyte glycoprotein antibody disease conflate three diseases and should not be read as applying to any one of them. Whether very early disease-modifying therapy after a first episode changes long-term disability remains disputed. The proportion of optic neuritis attributable to each of the three diseases varies by population and is not globally established.

| # ICD-11 Chapter 10 — Diseases of the ear or mastoid process |
| ## Global totals for hearing |

**Over 1.5 billion** people live with some degree of hearing loss. Of these, **430 million** have moderate or higher loss in the better ear and need rehabilitation — over 5 per cent of the world population, including **34 million children** (World Health Organization fact sheet, *Deafness and hearing loss*, 3 March 2026; World report on hearing, 3 March 2021). **95.1 million** children aged 5 to 19 live with

Disabling hearing loss is defined as greater than **35 dB** in the better ear.

Projected to 2050: **nearly 2.5 billion** people with some degree of hearing loss, or 1 in 4. The fact sheet attaches **more than 700 million** to two different metrics on the same page — its key facts say that many will require hearing rehabilitation, and its body says that many will have disabling hearing loss, which it equates to 1 in 10 people. That is an internal contradiction in the source and both

Nearly **80 per cent** of people with disabling hearing loss live in low- and middle-income countries, and **over 25 per cent** of people older than 60 are affected. Rehabilitation need by region, in millions: Western Pacific 136.5; South-East Asia 109.4; Americas 62.8; Europe 57.3; Africa 39.7; Eastern Mediterranean 22.1.

Global Burden of Disease 2023 places age-related and other hearing loss at **53.1 million** years lived with disability, 95% uncertainty interval 37.5 to 71.6, the **fifth leading cause** of years lived with disability, which is 5.4 per cent of the all-cause total. Because hearing loss is non-fatal it contributes no years of life lost, so its disability-adjusted life years equal its years lived with disability at **53.1 mil-**

---

The avoidable share. In children, nearly **60 per cent** of hearing loss is due to avoidable causes. The World Health Organization states that the common adult causes — loud sound and ototoxic medicines — are preventable and gives no percentage. **Over 1 billion** young adults are at risk of permanent avoidable hearing loss from unsafe listening.

The correctable share. Only **17 per cent** of those who could benefit from a hearing aid use one, an **83 per cent** gap, ranging 77 to 83 per cent across regions and **74 to 90 per cent** across income levels. The hearing fact sheet does not report hearing aid need against use.

---

The economics are on the **fact sheet**, not on the report page. The World report on hearing's own item page carries no headline figures at all, and its launch release carries only the return on investment. The fact sheet (3 March 2026) carries all three figures the chapter needs: the annual global cost of unaddressed hearing loss is **almost US$1 trillion**; the additional investment needed to scale

The workforce constraint. **78 per cent** of low-income countries have fewer than one ear, nose and throat specialist per million population, and **93 per cent** have fewer than one audiologist per million. **50 per cent** have one or more teachers for the deaf per million, and **17 per cent** have one or more speech therapists per million. Any workable screening or rehabilitation in those settings must be

## Age-related hearing loss (presbycusis)

**What it is.** The hair cells of the inner ear die off with age and do not grow back. High notes go first, then speech becomes hard to follow, especially in noise. It is the commonest cause of hearing loss in the world.

**Measured. Over 25 per cent** of people older than 60 are affected by disabling hearing loss. Presbycusis sits inside the **430 million** people who need rehabilitation, of over 1.5 billion with some degree of hearing loss.

Global Burden of Disease 2023: **53.1 million** years lived with disability, 95% uncertainty interval 37.5 to 71.6, the fifth leading cause, and **53.1 million** disability-adjusted life years, fourteenth†.

Projection: **over 700 million** people needing rehabilitation by 2050 on the fact sheet's key facts, with the same number attached to disabling hearing loss in its body; the World report on hearing's disabling-loss series ends at **711 million in 2050**. Nearly **80 per cent** of people with disabling hearing loss live in low- and middle-income countries. Only **17 per cent** of those who could benefit from a hearing aid use one, an 83 per cent gap, 74 to 90 per cent across income levels. The annual cost of unaddressed hearing loss is almost **US$1 trillion**.

**Where it starts.** - **Age** — the defining factor. Cochlear hair cells, spiral ganglion neurons and the stria vascularis all degenerate cumulatively and irreversibly. - **Cumulative lifetime noise exposure** — adds to, and is largely indistinguishable from, pure ageing at the individual level. The World Health Organization names loud sound exposure among the common adult causes and states that it is preventable. - **Ototoxic medicines** — named among the common preventable adult causes. See that entry. - **Smoking** — named among adult causes. - **Chronic diseases**, including diabetes and cardiovascular disease — named. - **Genetic susceptibility** — delayed-onset or progressive genetic hearing loss across the life span, named. - **Male sex; occupational history**.

Genuinely not known: how much of "age-related" loss is intrinsic ageing and how much is accumulated noise and ototoxic injury. The two cannot be separated in an individual, and populations with low lifetime noise exposure show less loss, which suggests the intrinsic component may be smaller than assumed. Why hair cells do not regenerate in mammals when they do in birds and fish is understood descriptively and not therapeutically. Whether hearing loss causes dementia or shares a cause with it is unresolved and important; see *Prevention*.

**Cure status.** RELIEF ONLY. Nothing restores hearing lost to presbycusis. Mammalian cochlear hair cells do not regenerate, no drug regrows them, and no surgery replaces them.

What exists is substitution. Hearing aids amplify what remains, and cochlear implants bypass dead hair cells by stimulating the auditory nerve directly. Both are genuinely effective prostheses — a cochlear implant can restore open-set speech understanding in a profoundly deaf adult — and neither repairs the ear. Both require the device to be worn and powered, and function stops when the device is removed. This is the symmetrical counterpart to glaucoma: the damage is permanent and the deviation remains, and the label is RELIEF ONLY rather than CONTROLLABLE because there is no disease process being held in check. The loss simply accumulates.

**Prevention.** Presbycusis itself cannot be prevented, and a substantial part of what is called presbycusis is accumulated preventable injury. - **Lifetime noise exposure limits** — occupational limits and hearing conservation programmes, which the World Health Organization names among its prevention measures. **STRONG** for the noise-attributable component; see the noise-induced hearing loss entry for the dose-response data. - **Safe listening in recreational settings. Over 1 billion** young adults are at risk from unsafe listening. **STRONG** mechanistically; the World Health Organization–International Telecommunication Union safe listening standard is the instrument. - **Rational use of ototoxic medicines** — a named World Health Organization prevention measure. **STRONG**. - **Smoking cessation, diabetes and blood pressure control. MODERATE**. - **Hearing aids to prevent cognitive decline.** This is where the evidence is genuinely contested and must be reported as such. The ACHIEVE trial found **no significant effect** of hearing intervention on three-year cognitive decline in the full randomised population, and a substantial effect in the pre-specified higher-risk subgroup. The Lancet Commission on dementia prevention lists hearing loss as a major modifiable risk factor. **CONTESTED**: the observational association is strong, the randomised

evidence for the full population is null, and the subgroup effect is real and not confirmatory. Both readings are printed. - **Nothing prevents the intrinsic ageing component.**

**Treatment.** 1. **Hearing aids.** The mainstay. They improve hearing-specific quality of life and speech understanding in noise. A device, not on the Essential Medicines List; hearing aids appear on the World Health Organization's priority assistive products list. The access gap: only **17 per cent** of those who would benefit use one, a gap of 74 to 90 per cent across income levels. Device cost ranges from around **US$100 or less** for basic and over-the-counter devices to **US$2,000 to 6,000 per pair** for fitted high-end devices in high-income private markets — the World report on hearing gives the access gap and no price figures. 2. **Cochlear implants.** For severe to profound loss where aids fail. They restore open-set speech perception in most postlingually deafened adults. The World report on hearing describes them as effective and cost-effective and gives **no** access, coverage or cost figures. Reported total cost including surgery and rehabilitation is approximately **US$30,000 to 100,000 per recipient** in high-income systems, with the device a large share. The access gap is severe and the primary source does not quantify it. 3. **Assistive listening devices, personal amplifiers, loop systems, captioning.** The World Health Organization names hearing assistive technology including alerting devices and captioning, and lists bone conduction and middle ear implants among hearing technologies. 4. **Communication training, speech and language therapy, counselling and support, auditory rehabilitation, lip-reading training.** Named as rehabilitation components. 5. **No pharmacological treatment exists.**

**Simple means.** Better than the access figures suggest, and this is where the 83 per cent gap could be attacked.

- **Communication tactics, which cost nothing.** Facing the person; speaking at normal volume but more slowly and clearly; not shouting; reducing background noise; turning off the television; one speaker at a time; good lighting on the speaker's face so lips can be read. These measurably improve comprehension and they are free.
- **Low-cost and over-the-counter hearing aids and personal sound amplifiers** at around **hundreds of US dollars or less**. The 74 to 90 per cent access gap is substantially a price and service-delivery gap rather than a technology gap.
- **Community-based hearing screening with a whispered-voice test or a free smartphone audiometry application**, usable by a non-specialist. In low-income countries 78 per cent have fewer than one ear, nose and throat specialist per million and 93 per cent fewer than one audiologist per million, so any workable screening must be deliverable without them.
- **Hearing loops and captioning** in public buildings.
- **Noise reduction in the home and workplace.** Moving away from a noise source costs nothing.

The economics of doing this at scale are measured, and the three headline figures are on the fact sheet. Scaling ear and hearing care to 90 per cent coverage requires an additional **less than US$1.40 per person per year** and returns **nearly US$16 per US$1** over ten years, against an annual global cost of unaddressed hearing loss of **almost US$1 trillion** (World Health Organization fact sheet, *Deafness and hearing loss*, 3 March 2026). The World report on hearing gives the per-capita figure as **US$1.33** and the averted burden as nearly **130 million** disability-adjusted life years, benefiting **1.4 billion** people.

What the chain minimally requires: a hearing aid is a microphone, an amplifier, a receiver and a battery. It is not a simple object and it is a cheap one at scale, and the binding constraint named by the primary source is service delivery and workforce, not manufacture.

**Gaps.** The World Health Organization figures do not separate presbycusis from other causes within the 430 million, so no condition-specific prevalence exists. The World report on hearing gives the hearing aid access gap and **no device price figures and no cochlear implant access or cost figures at all**; the cost and access numbers above are unverified. The fact sheet attaches "more than 700 million" to two different metrics on the same page, and both readings are printed. Whether treating hearing loss prevents dementia is genuinely unresolved: ACHIEVE was null overall with a positive high-risk subgroup, against strong observational data, and both are printed. The split between intrinsic ageing and accumulated noise is not quantified anywhere read.

## Noise-induced hearing loss

**What it is.** Loud sound kills the hair cells of the inner ear. It can happen slowly over years of noisy work, or suddenly from one blast. The damage is permanent, and it is almost entirely preventable.

**Measured. Over 1 billion** young adults are at risk of permanent, avoidable hearing loss from unsafe listening practices. The World Health Organization names loud noise and work-related ototoxic chemicals among causes acting across the life span, and states that the common adult causes including loud sound exposure are preventable.

Noise-induced loss is counted within the **430 million** needing rehabilitation and the over 1.5 billion with some hearing loss; no separate global count was retrievable. Occupational noise is among the leading occupational disease burdens worldwide, and occupational noise-induced hearing loss is one of the most commonly compensated occupational diseases in countries with compensation schemes.

It begins in working life and in adolescence with recreational exposure, and the notch at 4 kHz is the characteristic early sign†. It concentrates in unregulated industry, mining, construction, agriculture and military service, with recreational exposure global. Occupational exposure is falling in regulated economies while recreational exposure from personal audio devices and entertainment venues is rising, which is the basis of the one-billion-at-risk figure.

**Where it starts.** - **Sound energy dose — intensity combined with duration.** The dose-response is the established basis of all noise regulation: permissible exposure halves for each 3 dB increase in level under the equal-energy principle, so 85 dB(A) for 8 hours, 88 dB(A) for 4 hours, 91 dB(A) for 2 hours, and so on. The commonly applied occupational limit is **85 dB(A) averaged over 8 hours**, and the World Health Organization's recommended recreational limit is **80 dB(A) for 40 hours per week** for adults and **75 dB(A)** for children, under the World Health Organization–International Telecommunication Union safe listening standard — the standard document was not retrievable. - **Impulse and blast noise** — gunfire, explosions, fireworks. A single exposure above about 140 dB peak can cause immediate permanent loss†. - **Personal audio devices at high volume for long periods, and entertainment venues** — the basis of the over-one-billion-at-risk figure. - **Co-exposure to ototoxic chemicals** — solvents including toluene and styrene, and heavy metals, acting synergistically with noise. The World Health Organization names work-related ototoxic chemicals explicitly. - **Co-exposure to aminoglycosides and cisplatin** — synergistic with noise. - **Individual susceptibility** — wide and largely unexplained.

Genuinely not known: why susceptibility varies so widely at identical measured dose. "Tough" and "tender" ears are a real observation without a usable predictive test. Whether the equal-energy principle holds at the extremes of very short, very intense exposure is disputed. Whether temporary threshold shift reliably predicts eventual permanent shift is unresolved. No pharmacological otoprotectant is established in humans.

**Cure status.** RELIEF ONLY. Hair cells lost to noise do not return. There is no treatment that restores noise-induced hearing loss and no licensed otoprotective drug.

One qualification: temporary threshold shift after a single loud exposure recovers over hours to days, and that recovery is genuine. It is not a treatment effect, and repeated temporary shifts produce permanent loss. Sudden severe acoustic trauma is sometimes treated with systemic corticosteroids by analogy with sudden sensorineural hearing loss, on weak evidence. Management is substitution with hearing aids, as for presbycusis.

The significance of this condition is not its treatability — it has none — but that it is the most preventable cause of permanent hearing loss in the chapter.

**Prevention.** The strongest prevention evidence in this part of the chapter. - **Engineering noise control at source** — quieter machinery, enclosure, damping, isolation. The top of the hierarchy of controls, and the only approach that does not depend on individual behaviour. **STRONG**. - **Administrative controls** — limiting exposure time, job rotation, distance from the source. This follows directly from the dose-response: halving exposure time offsets a 3 dB increase in level. **STRONG**. - **Occupational exposure limits, commonly 85 dB(A) over 8 hours**, with mandatory hearing conservation programmes above an action level. **STRONG**.

- **Hearing protection — earplugs and earmuffs.** Laboratory attenuation of roughly **15 to 30 dB** depending on type and fit, and **real-world attenuation is substantially lower than the labelled rating** because of fit and wear-time failures, which is why protection ranks below engineering control. **STRONG** when worn correctly and consistently, **MODERATE** as actually delivered. - **Audiometric surveillance** — detects early shift so exposure can be changed before disabling loss. **MODERATE**. - **Safe listening standards for personal audio devices and venues**, with volume limiting, dose tracking and parental controls; the recommended limits are 80 dB(A) over 40 hours weekly for adults and 75 dB(A) for children†. **MODERATE** — effective where implemented, and adoption is the constraint. The World Health Organization names safe listening strategies among its prevention measures. - **Controlling solvent and heavy-metal co-exposure. MODERATE**. - **Avoiding fireworks and gunfire without protection. STRONG**.

**Treatment.** There is no treatment that restores the loss. What follows is substitution and salvage. 1. **Hearing aids.** As for presbycusis. A device, not listed. Access gap **83 per cent**, 74 to 90 per cent across income levels. **hundreds of US dollars** to **thousands of US dollars per pair**. 2. **Cochlear implants** for profound loss. Not listed. About **US$30,000 to 100,000** per recipient in high-income systems†; the World report on hearing gives no cost or access figure. 3. **Systemic corticosteroids for acute acoustic trauma** — weak evidence, used by analogy. Prednisolone and dexamethasone are listed, off-patent, cents per day. 4. **Tinnitus management**, since tinnitus very commonly accompanies the loss. See that entry. 5. **Removal from further exposure** — the only intervention that changes the trajectory.

**Simple means.** Unusually strong, and essentially free.

- **Distance.** Sound intensity falls with distance from the source, and stepping back halves exposure quickly. No cost.
- **Time.** Under the equal-energy dose-response, halving exposure duration offsets a 3 dB increase in level. Shortening exposure costs nothing and is quantitatively protective.
- **Turning the volume down.** The over-one-billion-at-risk figure is produced by voluntary exposure. The 80 dB(A) over 40 hours weekly budget for adults, and 75 dB(A) for children, is achieved by a volume setting†.
- **Earplugs.** Foam plugs cost **cents per pair** and attenuate roughly 15 to 30 dB when correctly inserted†. This is the clearest cents-for-permanent-disability trade in the chapter.
- **Fingers in the ears, or hands over the ears**, for unexpected impulse noise. Free, and effective for the seconds it is applied.
- **The arm’s-length rule.** If a raised voice is needed to be understood at arm’s length, the level is likely above the action level. This requires no meter.
- **Free smartphone sound-level meter applications** to identify hazardous environments, and **smartphone audiometry** for screening where 93 per cent of low-income countries have fewer than one audiologist per million people.

A cents-per-pair earplug, consistently worn, prevents a permanent disability that no money can subsequently repair. There is no other condition in this book with a better ratio.

**Gaps.** No separate global prevalence or disability-adjusted life year figure for noise-induced hearing loss was obtainable; it is not disaggregated in the World Health Organization or Global Burden of Disease figures read. The safe listening standard document could not be retrieved, so the 80 and 75 dB(A) limits and the 85 dB(A) occupational limit are unverified here. Real-world against laboratory attenuation of hearing protection differs substantially and no measured field figure was obtainable. Individual susceptibility variation is unexplained and unpredictable. Whether temporary threshold shift predicts permanent loss is disputed. No otoprotectant has been established, despite decades of candidates.

---

### Otitis media — acute

**What it is.** Infection of the middle ear, behind the eardrum. The ear hurts, hearing dulls and there is often fever. In young children it is one of the commonest reasons for a doctor visit and an antibiotic prescription. Most cases clear up by themselves.

**Measured.** Around **200 million** people have preventable or treatable chronic ear infections; that figure is for chronic disease and belongs to the next entry. Global Burden of Disease 2023 records **700 deaths** from otitis media in 2023. No global prevalence or incidence figure for the acute condition was located on the World Health Organization sources read.

---

Acute otitis media is among the commonest childhood infections worldwide and the commonest reason for antibiotic prescription in children in high-income countries. Incidence peaks between **6 and 24 months** and falls after age 5 as the Eustachian tube lengthens and angles†. It is universal, while complications and progression to chronic suppurative disease concentrate in low-income settings,

**Where it starts.** - **Eustachian tube dysfunction** — the anatomical basis. The infant tube is short, horizontal and floppy, which is why incidence peaks under 2†. - **A preceding viral upper respiratory infection** — the usual trigger. - **Bacteria** — *Streptococcus pneumoniae*, non-typeable *Haemophilus influenzae*, *Moraxella catarrhalis*. - **Childcare attendance, crowding, siblings**. - **Tobacco smoke exposure**. - **Bottle feeding,**

Genuinely not known: why a minority of children have recurrent disease and progress to chronic suppurative otitis media while most have one or two uneventful episodes. Host factors are suspected and not identified. Which child benefits from antibiotics cannot be determined at the bedside, which is the root of the overprescription problem. Whether grommets improve long-term language outcomes is genuinely disputed.

**Cure status.** SELF-LIMITING. Most episodes resolve without treatment. The Cochrane review of antibiotics for acute otitis media in children found **no difference in pain at 24 hours**, a modest benefit at two to three days, and an estimated **number needed to treat of about 20** for one child to have less pain, against a clear increase in diarrhoea, vomiting and rash — the Cochrane Library did not load. Spon-

---

Antibiotics do cure the bacterial infection where it matters — young infants, bilateral disease, perforation with discharge, systemic illness — and they prevent the complications that make this condition dangerous: mastoiditis, intracranial spread, progression to chronic suppurative disease. So the condition is SELF-LIMITING, with antibiotics for the children who need them. SELF-LIMITING is the label the evidence

**Prevention.** **Pneumococcal conjugate vaccination.** Reduces episodes caused by vaccine serotypes, with a modest reduction in all-cause acute otitis media and replacement by non-vaccine serotypes partly offsetting the gain. **MODERATE**. A listed vaccine. The World Health Organization names immunization as a prevention measure. - **Influenza vaccination.** Reduces episodes. **MODERATE**. - **Breastfeeding.** Con-

———

**Treatment.** 1. **Analgesia — paracetamol or ibuprofen.** The highest-value treatment, because pain is the symptom that matters and antibiotics do not relieve it at 24 hours†. Both are on the Essential Medicines List. Off-patent, cents per dose. 2. **Delayed or no antibiotic prescribing, with safety-net advice**, for children over 2 with mild unilateral disease. **The action is omission.** The Cochrane number

**Simple means.** - **Paracetamol or ibuprofen, and watchful waiting.** This is the evidence-based standard for most children, costs cents, and outperforms antibiotics for the symptom that actually troubles the child. - **Not prescribing an antibiotic.** The action is omission, and it is a zero-cost intervention with measurable benefit: fewer adverse effects, less resistance, the same outcome

What the chain minimally requires: an analgesic, an otoscope, a trained examiner, and access to amoxicillin for the minority who need it. All of that is cheap and on the Essential Medicines List. This is one of the least supply-chain-dependent conditions in the book.

**Gaps.** No global incidence figure for acute otitis media exists on the sources read, despite its being one of the commonest childhood illnesses. The 700 deaths recorded by Global Burden of Disease almost certainly understate deaths from complications in settings without care. The Cochrane effect sizes for antibiotics, and the roughly 80 per cent spontaneous resolution figure, could not be verified. Whether grommets improve long-

## Otitis media — chronic suppurative

**What it is.** A hole in the eardrum with a middle ear that keeps discharging pus, for months or years. It deafens the ear, it smells, and it is the commonest preventable cause of childhood hearing loss in poor countries. Occasionally it kills by spreading into the skull.

**Measured.** Around **200 million** people have preventable or treatable chronic ear infections — the key figure for this entry. Global Burden of Disease 2023 records **700 deaths** from otitis media in 2023.

The World Health Organization names chronic suppurative otitis media and chronic non-suppurative otitis media among the childhood and adolescent causes of hearing loss, and states that nearly **60 per cent** of childhood hearing loss is due to **avoidable** causes. **95.1 million** children aged 5 to 19 live with hearing loss, and chronic suppurative otitis media is a major contributor in low-income settings. The World report on hearing's 2030 target includes a **20 per cent relative reduction** in chronic ear disease and unaddressed hearing loss in children aged 5 to 9.

It begins in early childhood, often after poorly resolved acute otitis media, and persists for years. It is strongly concentrated in low-income settings, crowded households and certain indigenous populations — Australian Aboriginal, Inuit, Greenlandic and Pacific Island communities report some of the highest prevalences recorded worldwide. The trend is falling where acute otitis media is treated and living conditions improve.

**Where it starts.** - **Unresolved or recurrent acute otitis media with persistent perforation** — the direct route. - **Crowding and large household size**. - **Poor access to care for the acute episode** — the central determinant of why this is a poverty disease. - **Lack of breastfeeding; tobacco smoke exposure; poor nutrition**. - **Water contamination of the middle ear through the perforation.** Swimming and bathing in contaminated water perpetuate discharge, and *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the dominant organisms. - **Cleft palate, Down syndrome, immunodeficiency**. - **Indigenous ancestry in specific populations**.

Genuinely not known: why perforations heal in most children and persist in some. Why certain indigenous populations carry such extreme prevalence — whether this is Eustachian tube anatomy, bacterial carriage load, crowding or access — is not resolved. The optimal duration of topical antibiotic treatment is not established. Whether ototopical aminoglycosides cause clinically significant hearing loss through a perforated drum is a long-running dispute that affects what can safely be used in the field.

**Cure status.** CURABLE. Both components can be cured, and that deserves to be stated clearly.

The discharge: topical antibiotics, particularly topical quinolones, with aural toilet, dry the ear in the large majority of cases, and topical antibiotics are more effective than systemic for resolving discharge.

The perforation: tympanoplasty or myringoplasty closes the drum with reported success rates of roughly **80 to 90 per cent**, and closing it both stops recurrent infection and recovers the conductive component of the hearing loss.

The qualifications: a sensorineural component acquired over years of infection does not recover; cholesteatoma requires mastoid surgery and can recur, needing lifelong surveillance; and in practice most of the 200 million affected people have access to neither drops nor surgery, so the disease persists for reasons of access rather than biology. This is one of the clearer curable entries in this part of the chapter, in sharp contrast with presbycusis and noise-induced loss, where nothing is recoverable.

**Prevention.** - **Prompt and adequate treatment of acute otitis media**, so perforations do not become chronic. **MODERATE**. The World Health Organization names identification and management of common ear conditions among prevention measures. - **Keeping water out of a perforated ear** — no swimming or diving, and preventing bath and shower water entering. Stops the reinfection cycle. **MODERATE**, and free. - **Breastfeeding. MODERATE**, free. - **Pneumococcal and influenza vaccination. MODERATE**. The World Health Organization names immunization. - **Reducing crowding and tobacco smoke exposure. MODERATE**. - **School-based ear screening with otoscopy**, which finds the discharging ears that families have stopped regarding as abnormal. **MODERATE**. The 2030 target of a

20 per cent relative reduction in chronic ear disease in children aged 5 to 9 presumes such detection. - **Nutrition improvement. WEAK**.

**Treatment.** 1. **Aural toilet — dry mopping or suction — plus topical antibiotic drops, ciprofloxacin or ofloxacin.** The most effective standing treatment. Topical quinolones outperform systemic antibiotics, and outperform topical aminoglycosides for safety, since quinolones are not ototoxic. Ciprofloxacin ear drops are on the Essential Medicines List — the list document did not load. Off-patent. **A few US dollars per bottle** generic. 2. **Topical aminoglycoside drops — gentamicin, neomycin.** Effective and much cheaper, and potentially ototoxic through a perforation. Widely used where quinolones are unavailable, and the risk-benefit is genuinely disputed. Gentamicin is listed. Off-patent, cents to a dollar. 3. **Topical antiseptics — acetic acid (dilute vinegar), boric acid, povidone-iodine.** Cheap alternatives with some evidence of benefit. See *Simple means* — this matters enormously for cost. 4. **Systemic antibiotics** for acute exacerbation, mastoiditis or intracranial complication. Amoxicillin-clavulanate, ciprofloxacin and ceftriaxone are all listed, all off-patent, all low cost. 5. **Tympanoplasty or myringoplasty.** Closes the perforation, about 80 to 90 per cent success, and recovers the conductive loss†. A procedure, not listed. A surgical episode. 6. **Mastoidectomy** for cholesteatoma or complications. 7. **A hearing aid** for residual loss. A device, not listed; access gap 83 per cent.

**Simple means.** This is one of the best simple-means entries in the book: the core treatment is a cloth, a wick and a cheap liquid.

- **Dry mopping (aural toilet).** A twist of clean cotton wool or a tissue wick, rolled to a point and used to absorb discharge from the canal, repeated until the wick comes out dry, several times daily. It requires no suction apparatus, no power and no clinician, and mothers can be taught it in minutes. Removing the pus is what allows any topical agent to reach the middle ear, and dry mopping alone improves many ears; the effect size could not be verified.
- **Dilute acetic acid (vinegar) or boric acid drops.** Acidifying the ear canal suppresses *Pseudomonas*. Household vinegar diluted with clean water costs effectively nothing and has evidence of benefit.
- **Keeping the ear dry** — no swimming, and a plug of cotton wool and petroleum jelly for bathing. Free, and it breaks the reinfection cycle.
- **Topical ciprofloxacin drops** at roughly **a few US dollars per bottle** where available — listed and off-patent.
- **An otoscope and a trained health worker or teacher** for school screening. 78 per cent of low-income countries have fewer than one ear, nose and throat specialist per million people, so detection must be task-shifted or it will not happen.
- **Teaching the family** that a chronically discharging ear is a treatable disease and not a normal state of childhood. Free, and in high-prevalence communities the perforated, discharging ear is often not recognised as abnormal at all.

The measured economics of acting at scale: scaling ear and hearing care needs an additional **less than US$1.40 per person per year**, with a return of **nearly US$16 per US$1** over ten years (World Health Organization fact sheet, *Deafness and hearing loss*, 3 March 2026), averting nearly **130 million** disability-adjusted life years.

What the chain minimally requires for the definitive repair: an operating microscope and a trained ear surgeon for tympanoplasty. Drying the ear and stopping the discharge — which is what preserves the hearing — needs cotton wool and vinegar.

**Gaps.** The 200 million figure covers chronic ear infections generally and is not disaggregated into chronic suppurative otitis media, chronic otitis media with effusion and cholesteatoma. No condition-specific global prevalence, and no figure for how much of the 95.1 million children with hearing loss is attributable to it, exists on the sources read. The 700 deaths figure is likely an undercount of complication deaths in settings without care. The safety of ototopical aminoglycosides through a perforation is a genuine long-running dispute, and it determines what can be used where quinolones are unaffordable; both positions exist in the literature. Effect sizes for dry mopping and for acetic acid could not be verified. Tympanoplasty success rates vary widely with case selection and surgeon volume.

## Otitis externa

**What it is.** Infection or inflammation of the ear canal, the tube from the outside to the eardrum. The ear itches, then hurts, often badly, and it may swell shut and discharge. Swimmers and people who poke their ears get it most.

**Measured.** No global prevalence or incidence figure was retrievable; otitis externa is not quantified on the World Health Organization sources read. Lifetime incidence is commonly reported at about **10 per cent**, and it is among the commonest reasons for ear, nose and throat presentation in primary care.

All ages are affected. Acute diffuse otitis externa peaks in children and young adults, and necrotising otitis externa occurs in older people with diabetes or immunosuppression. It is more common in humid and tropical climates and in swimming populations.

**Necrotising otitis externa** is the dangerous form: osteomyelitis of the skull base, with substantial mortality if untreated, occurring almost exclusively in diabetic or immunocompromised people, usually caused by *Pseudomonas aeruginosa*.

**Where it starts.** - **Water retention in the canal** — swimming, humidity, bathing; it macerates the skin and raises canal pH. - **Trauma to the canal skin** — cotton buds, fingernails, hairpins, hearing aid moulds, earphones. The combination of removing protective wax and abrading the skin is the classic cause. - **Removal of cerumen.** Wax is protective, acidic and water-repellent; over-cleaning causes the disease. - **Bacteria** — *Pseudomonas aeruginosa* and *Staphylococcus aureus* dominate, with fungal otitis externa from *Aspergillus* and *Candida* following prolonged antibiotic drops. - **Eczema, psoriasis or seborrhoeic dermatitis of the canal** — dermatitis of the canal predisposes to and perpetuates otitis externa. - **Diabetes and immunosuppression** — for the necrotising form. - **Hearing aid and earphone use** — occlusion and trauma.

Genuinely not known: why some people have a single episode and others become chronically affected. The relative contributions of infection against primary dermatitis in chronic cases is often undecidable in practice, which means treatment is frequently empirical. Optimal treatment duration is not established, and the threshold for suspecting necrotising disease in a diabetic patient with a painful ear is a clinical judgement without a validated rule.

**Cure status.** Acute otitis externa: CURABLE. Chronic and recurrent otitis externa: CONTROLLABLE. Necrotising otitis externa: CURABLE. Acute otitis externa resolves with topical treatment in the great majority, typically within **7 to 10 days**†, and the canal returns to normal. Topical treatment achieves clinical cure in around **65 to 80 per cent** at one week, against lower rates with placebo†.

Chronic and recurrent otitis externa, particularly where underlying dermatitis is the driver, behaves as a controllable condition requiring repeated or maintenance treatment. Necrotising otitis externa is curable and requires prolonged systemic antipseudomonal therapy, often for 6 to 12 weeks, with glycaemic control and sometimes surgery, and mortality is appreciable. The label is therefore split by form.

**Prevention.** - **Keep the ear canal dry.** Tilting the head to drain after swimming or bathing, drying the outer ear with a towel, and using a hair dryer on a cool low setting at a distance. **MODERATE**, and free. - **Do not put anything in the ear canal — above all, stop using cotton buds.** The single most effective preventive instruction, and the action is omission. It costs nothing. **MODERATE**. - **Leave the wax alone.** Cerumen is protective and its removal is a cause of the disease. **MODERATE**, and again the action is omission. - **Acidifying drops after swimming** — dilute acetic acid, or alcohol-acetic acid preparations — in people with recurrent episodes. **MODERATE**. - **Earplugs or a swim cap for recurrent swimmers' ear. WEAK**. - **Treating underlying eczema or seborrhoeic dermatitis of the canal. MODERATE**. - **Glycaemic control in diabetes**, to prevent the necrotising form. **MODERATE**. - **Cleaning and drying hearing aid moulds. MODERATE**.

**Treatment.** 1. **Aural toilet to clear debris, then topical antibiotic with or without corticosteroid.** Topical treatment is the standard and outperforms systemic antibiotics for uncomplicated disease. Topical quinolone drops — ciprofloxacin, ofloxacin — with ciprofloxacin ear preparations on the Essential Medicines List; off-patent; roughly **a few US dollars per bottle**. 2. **Topical aminoglycoside or polymyxin with corticosteroid.** Cheaper; avoid if the drum is perforated because of ototoxicity risk. Gentamicin listed, off-patent, cents

to a dollar. 3. **Topical corticosteroid alone** where the process is primarily dermatitis — effective, and it avoids antibiotic use. Betamethasone and hydrocortisone are listed, off-patent, cents per tube. 4. **Topical acetic acid or aluminium acetate.** Antiseptic and astringent; cheap and effective in mild disease. 5. **An ear wick** where the canal is too swollen for drops to enter — a compressed sponge or ribbon gauze that carries the drops in and expands the canal. Cheap and decisive. 6. **Analgesia — paracetamol or ibuprofen.** Both listed, off-patent, cents. Pain can be severe and is often undertreated. 7. **Topical antifungal (clotrimazole)** for otomycosis. Clotrimazole listed, off-patent, cheap. 8. **Systemic antipseudomonal therapy — ciprofloxacin, ceftazidime — for 6 to 12 weeks** in necrotising otitis externa†. Both listed, off-patent. 9. **Oral antibiotics for uncomplicated otitis externa are not indicated.** Topical therapy is superior, and systemic therapy adds adverse effects without benefit. **The action is omission.**

**Simple means.** Almost entirely a simple-means condition.

- **Nothing smaller than an elbow in the ear.** Stopping cotton bud use prevents a large share of cases. Free, and the action is omission.
- **Drying the ear after water exposure** — head tilt, towel, cool hair dryer at a distance. Free.
- **Dilute acetic acid — household vinegar diluted with clean water.** Acidifies the canal and suppresses *Pseudomonas*, usable both as treatment for mild disease and as prophylaxis after swimming. Cost effectively zero.
- **Aural toilet with a cotton wick**, as for chronic suppurative disease: rolled cotton wool to absorb debris so that any drop can reach the skin.
- **A wick of ribbon gauze or compressed sponge** to open an occluded canal. Cents.
- **Paracetamol for pain.** Listed, cents.
- **Leaving wax in place.** Free, and preventive.
- **An otoscope and a torch** for diagnosis.

What the chain minimally requires: for uncomplicated disease, essentially nothing beyond clean water, vinegar, cotton wool and an analgesic. For necrotising otitis externa, a 6 to 12 week course of systemic antipseudomonal antibiotic, imaging and inpatient care — a genuine hospital requirement, and the one form where simple means are inadequate.

**Gaps.** No global prevalence or incidence figure exists on the sources read; the roughly 10 per cent lifetime incidence figure is widely cited and unverified. Cure rates with topical therapy, about 65 to 80 per cent at one week, could not be verified. The relative contribution of primary dermatitis against infection in chronic cases is not established, and in practice the two are treated together. Optimal treatment duration is unsettled. Necrotising otitis externa incidence and mortality figures were not obtainable. Whether acidifying prophylaxis prevents recurrence has limited trial support.

---

## Cerumen impaction

**What it is.** Ear wax builds up and blocks the canal, so hearing dulls and the ear feels full. It is not a disease of dirtiness — wax is normal and protective, and impaction usually happens because of anatomy, hearing aids or attempts at cleaning. Removing it restores hearing immediately.

**Measured.** The World Health Organization names **cerumen impaction** among the causes of hearing loss acting across the life span and **gives no count**. No global prevalence figure was retrievable.

Prevalence is commonly reported at about **5 per cent** of healthy adults, far higher in older people — around **20 to 35 per cent** of nursing-home residents — and in children, in people with learning disability and in hearing aid users. The pattern is bimodal, with children and older adults most affected.

Its significance within this part of the chapter is specific: this is the only cause of hearing loss on the World Health Organization’s list that is completely and immediately reversible at trivial cost. That makes its contribution to the 430 million rehabilitation-need figure worth isolating, and it is not isolated in any source read.

**Where it starts.** - **Cotton bud use and self-cleaning**, which pushes wax inward and compacts it. The leading modifiable cause. - **Hearing aid and earphone wear**, which occludes the canal and obstructs natural migration. The loop is worth naming: hearing aids cause impaction, and impaction reduces hearing aid benefit. - **Narrow, tortuous or hairy ear canals; exostoses**. - **Age** — wax becomes drier and keratin migration slows. - **Dry, hard wax type** — genetically determined; the *ABCC11* genotype determines wet against dry earwax, and dry wax is more common in East Asian populations. - **Learning disability and inability to report symptoms**, where impaction goes unnoticed. - **Dermatitis or keratosis of the canal.**

Genuinely not known: why some canals self-clear perfectly and others impact repeatedly. Whether routine prophylactic wax removal in hearing aid users or older people improves outcomes has not been established by trial. Whether softening drops before irrigation reduce complications is supported by modest evidence only.

**Cure status.** CURABLE, unambiguously. Removing the wax restores hearing to the person's baseline immediately, in a single encounter, with no maintenance treatment and no residual deficit. The underlying tendency may recur, so the impaction can return — and each episode is fully and permanently resolved by removal, and a later impaction is a new episode rather than the persistence of the old one.

Alongside cataract, this is one of the few entries in the whole book where a single cheap intervention completely removes a functional deficit and then ends. It is also the cheapest of them. The distinction from refractive error is worth holding: a pair of spectacles is a prosthesis worn indefinitely, and wax removal is a procedure that ends.

**Prevention.** - **Do not use cotton buds or insert anything into the canal.** The primary preventive instruction, and the action is omission. **MODERATE**, and free. - **Regular ear checks in hearing aid users, older people in residential care, and people with learning disability**, which finds silent impaction that is being mistaken for sensorineural deterioration or cognitive decline. **MODERATE**. - **Periodic softening drops — olive oil, or water-based drops — in people who impact repeatedly. WEAK**. - **Cleaning hearing aid moulds and ear-tips. MODERATE**. - **Avoiding ear candling**, which is ineffective and causes burns and occlusion. **STRONG** evidence of harm and no benefit. The action is omission.

**Treatment.** 1. **Cerumenolytic (softening) drops** — olive oil, almond oil, water, sodium bicarbonate solution, docusate, or carbamide peroxide. Cochrane found any drops better than no treatment, with **no clear difference between agents, including plain water and saline**. Not individually listed as cerumenolytics. Off-patent. **Near zero** for olive oil, water or bicarbonate. 2. **Irrigation (syringing) with an electronic irrigator or bulb syringe**, using body-temperature water, after softening. Effective and widely task-shiftable. Risks are perforation, otitis externa and vertigo, and it is contraindicated with a known perforation, previous ear surgery or a single hearing ear. 3. **Manual removal under direct vision** — curette, hook or microsuction. The safest method, especially with a perforation, and it requires a light source, instruments and training. 4. **Microsuction** — the specialist standard; needs a microscope and a suction unit. 5. **No treatment** where the wax is not occluding and not symptomatic. Wax does not require removal merely for being present. **The action is omission.**

**Simple means.** This is the cheapest curative intervention in the book.

- **Olive oil, plain water, or sodium bicarbonate solution as softening drops.** Cochrane found no clear superiority of proprietary agents over **water or saline**. Cost: effectively zero. A few drops twice daily for several days often clears the impaction without any procedure at all, and it removes the proprietary product from the chain entirely.
- **Bulb syringe irrigation with clean body-temperature water.** A rubber bulb costs a few cents to a dollar and is reusable. It is task-shiftable to a community health worker after brief training. Water that is too cold or too hot causes vertigo, which is the main avoidable error.
- **A torch or otoscope and a curette.** Direct removal under vision.
- **The instruction to stop using cotton buds.** Free, and preventive.

- **Opportunistic ear examination in anyone complaining of hearing loss, before any audiology referral** — because in low-income countries 93 per cent have fewer than one audiologist per million people, and a blocked canal mistaken for sensorineural loss wastes the scarcest resource there is.

A bottle of cooking oil and a rubber bulb restore hearing in a condition the World Health Organization lists among the causes of global hearing loss. There is no cheaper restoration of a lost sense anywhere in medicine.

**Gaps.** The World Health Organization names cerumen impaction as a cause of hearing loss and gives no count, so its share of the 430 million rehabilitation-need figure is unknown — a significant gap, because this component is trivially reversible and the rest largely is not. All prevalence figures above are unverified. Cochrane's finding that water performs as well as proprietary cerumenolytics could not be verified. Whether routine prophylactic removal in high-risk groups helps is untested. Complication rates of irrigation against microsuction are not well quantified, and practice differs sharply between countries on whether irrigation should be used at all.

---

### Tinnitus

**What it is.** Hearing a sound — ringing, hissing, buzzing — that has no outside source. It usually comes with hearing loss. For most people it is an occasional nuisance; for a minority it is disabling and dominates their life.

———

**Measured.** No global figure was retrievable. Tinnitus is **not quantified** on the World Health Organization hearing fact sheet or in the World report on hearing executive summary read. Prevalence is commonly reported at about **10 to 15 per cent** of adults experiencing chronic tinnitus, with roughly **1 to 2 per cent** describing it as severely bothersome or disabling†. It rises with age, tracking hearing loss, and is

**Where it starts.** - **Hearing loss of any cause** — the dominant association: presbycusis, noise-induced loss, otosclerosis, sudden sensorineural loss. - **Noise exposure** — acute acoustic trauma frequently produces immediate tinnitus. - **Ototoxic drugs** — aspirin in high dose, aminoglycosides, loop diuretics, cisplatin, quinine. Salicylate tinnitus is reversible; aminoglycoside and cisplatin tinnitus is usu-

Genuinely not known: what generates the sound. The leading account is maladaptive central gain increase after reduced peripheral input, and it is not established, and no measurement identifies the generator in a given patient. Why distress correlates so poorly with psychoacoustic loudness is the central puzzle, and it is the reason treatment targets distress rather than the sound. Why some

**Cure status.** RELIEF ONLY. No treatment reliably abolishes tinnitus. No drug has been shown to eliminate it, no device removes it, and no surgery cures it.

The exceptions are the cases with a curable cause: cerumen impaction, otitis media with effusion, a perforation, and salicylate toxicity. Remove the cause and the tinnitus goes. These are a small minority and they are the reason every patient deserves an ear examination.

What is genuinely effective is reducing the distress and disability. Cognitive behavioural therapy has the best evidence of any intervention, improving tinnitus-related quality of life and distress without changing the sound itself. That is relief, and it is real relief, and the percept remains. Many people habituate over months to years.

**Prevention.** Prevention is almost entirely prevention of the hearing loss and noise injury that cause it. - **Noise exposure limits and hearing protection.** The primary preventive measure, given that over 1 billion young adults are at risk from unsafe listening. **STRONG** mechanistically; see the noise-induced hearing loss entry for the dose-response. - **Ototoxic drug stewardship** — avoiding unnecessary amino-

**Treatment.** 1. **Cognitive behavioural therapy, including internet-delivered therapy.** The best-evidenced intervention; it improves tinnitus-related quality of life and reduces distress, with no effect on perceived loudness. Not a medicine. Cost: a therapist's time, which internet-delivered programmes reduce substantially. 2. **Hearing aids where there is hearing loss.** Amplification reduces the contrast between the tinnitus

**Simple means.** Better than the absence of a cure suggests, and almost all of it is free.

- **Ear examination and wax removal.** A torch, a curette or a bulb syringe. Removes the curable minority. Cost: near zero; see the cerumen entry.
- **Sound enrichment with whatever is available** — an open window, a fan, a radio at low volume, running water. The principle is that tinnitus is most intrusive in silence. Cost: zero.
- **Explanation at first presentation:** that the

What the chain minimally requires: nothing, for the core management. Tinnitus is the condition in this chapter where the gap between what is sold and what works is widest, and where free measures constitute most of the real benefit.

**Gaps.** No global prevalence or burden figure exists on any source read — the hearing fact sheet and the World report on hearing do not quantify tinnitus at all, despite its burden. All prevalence figures above are unverified. There is no objective measure of tinnitus, so all trial endpoints rest on self-report questionnaires, which limits comparability between studies. The poor correlation between loudness and

## Ménière disease

**What it is.** Attacks of violent spinning vertigo lasting hours, with hearing loss, ringing and a feeling of fullness in one ear. Between attacks the person may be well, and the hearing in that ear declines step by step over years.

**Measured.** No global figure was retrievable; vestibular disorders are not quantified on the World Health Organization hearing sources read. Prevalence is commonly reported at about **20 to 200 per 100,000**, and the tenfold range reflects inconsistent diagnostic criteria†. Onset is typically between **40 and 60**†, and it is more common in women†. It is reported more frequently in populations of European ancestry, though ascertainment likely explains part of that.

The natural history matters for the label. Attacks typically remit over years while the hearing loss becomes permanent and progressive, often ending in a burnt-out ear with stable moderate to severe loss and few attacks. Bilateral involvement develops in a substantial minority over decades.

**Where it starts.** - **Endolymphatic hydrops** — raised pressure and volume of inner ear endolymph is the pathological finding, demonstrated histologically and now on delayed gadolinium imaging. Hydrops is also found in people without Ménière disease and the causal link is not settled. - **Family history** — reported in a minority, suggesting a genetic contribution. - **Autoimmune and allergic associations**. - **Migraine** — strongly comorbid, and vestibular migraine is the principal differential diagnosis and is frequently misdiagnosed as Ménière disease. - **Prior viral labyrinthitis, head trauma, syphilis**. - **High salt intake** — the basis of the standard dietary advice, though the evidence that it triggers attacks is weak.

Genuinely not known: the cause. Whether endolymphatic hydrops is the cause, a consequence or an epiphenomenon is unresolved after more than a century. Why attacks occur when they do — the triggers patients report, salt, stress, caffeine, weather, are not confirmed by controlled study. Whether Ménière disease is one condition or several with a shared presentation is genuinely open. There is no diagnostic test; diagnosis is by criteria applied to a history, which is why prevalence estimates vary tenfold.

**Cure status.** Vertigo attacks: CONTROLLABLE. Hearing loss: RELIEF ONLY. Nothing cures Ménière disease and nothing restores the hearing it has taken.

The attacks can be suppressed. Intratympanic gentamicin ablates vestibular function in the affected ear and controls vertigo in a high proportion, and surgical labyrinthectomy or vestibular neurectomy controls it almost completely — and these work by destroying the balance organ, which is a trade rather than a cure, and they carry hearing loss risk with gentamicin or require an already-deaf ear for labyrinthectomy.

Betahistine, the most widely prescribed drug for the condition in many countries, was found **ineffective against placebo** in the BEMED randomised trial — an important negative result given its prescribing volume. The sensorineural hearing loss is permanent and progressive.

**Prevention.** - **Nothing prevents the disease.** No primary prevention is established. - **Low-salt diet and diuretics to reduce attack frequency.** Long-standing standard advice with weak supporting evidence; Cochrane assessments of diuretics find insufficient evidence. **WEAK/CONTESTED**. It is free and harmless, which is why it persists. - **Avoiding caffeine, alcohol and tobacco; stress management; adequate sleep. WEAK**. - **Treating comorbid migraine.** Where vestibular migraine coexists or is the actual diagnosis, migraine prophylaxis can greatly reduce attacks. **MODERATE** for that group, and it matters because misdiagnosis is common. - **Hearing protection in the affected ear. WEAK**, and sensible. - **Preventing injury during attacks.** An attack causes sudden falls, and lying down immediately prevents fracture. **MODERATE** for injury prevention, and free.

**Treatment.** For the acute attack: 1. **Vestibular sedatives — prochlorperazine, promethazine, cinnarizine, or an antihistamine** for the hours of the attack, plus antiemetics and lying still. Promethazine and prochlorperazine are listed, off-patent, cents per dose. Not for long-term use, because they impede central compensation.

For attack prevention:

2. **Low-salt diet and a thiazide diuretic.** Weak evidence. Hydrochlorothiazide listed, off-patent, cents per day.

3. **Betahistine. Ineffective against placebo in BEMED**. Not on the Essential Medicines List. Off-patent. Widely prescribed despite the trial result. **Not prescribing it is the evidence-based action, and it is a direct saving.**
4. **Intratympanic corticosteroid (dexamethasone).** Reduces attacks with no hearing loss risk, and is the preferred second-line step. Dexamethasone listed, off-patent, cents per dose — the drug is trivially cheap and the delivery is an office procedure. The United Nations Children's Fund indicative price for dexamethasone 4 mg tablets, read October 2026, was **US$24.00 per 100**, about **US$0.24 per tablet**.
5. **Intratympanic gentamicin.** Chemical ablation of vestibular function; a high vertigo control rate with a real risk of further hearing loss. Gentamicin listed, off-patent, cents.
6. **A positive pressure device.** Not shown effective.
7. **Endolymphatic sac surgery.** Efficacy disputed; sham-controlled studies have questioned it.
8. **Labyrinthectomy or vestibular neurectomy.** Definitive vertigo control; the former destroys hearing and is reserved for already-deaf ears.
9. **Vestibular rehabilitation** between attacks, and a **hearing aid** for the loss.
10. **Migraine prophylaxis** where vestibular migraine is likely — propranolol, amitriptyline, both listed, both off-patent, cents per day.

**Simple means.** - **Lying still in a dark quiet room during an attack**, and not trying to move until it passes. Free, and it is what most patients do because it is what works. - **Lying down at the first warning symptom** — the aural fullness or tinnitus change that often precedes the vertigo — to prevent falls and fractures. Free, and the highest-value simple instruction in the entry. - **Low-salt diet.** Free. Weak evidence, no harm. - **Avoiding caffeine and alcohol** if the patient identifies them as triggers. Free. - **A home diary of attacks**, which distinguishes Ménière disease from vestibular migraine better than any test available in a low-resource setting — and migraine *is* treatable with cheap listed drugs. A notebook. - **Prochlorperazine or promethazine** for the attack: listed, off-patent, cents. - **Not paying for betahistine**, which BEMED found no better than placebo. **The action is omission**, and it is a direct saving in a drug prescribed at high volume. - **Vestibular rehabilitation exercises**, taught once and performed at home, for the between-attack imbalance. Free after instruction. - **A hearing aid** for the loss; the access gap is 83 per cent.

What the chain minimally requires: the intratympanic and surgical options need an ear, nose and throat service and a microscope. Nothing simple alters the disease course, and the free measures cover the attack management, the fall prevention and the differential diagnosis.

**Gaps.** No global prevalence or burden figure exists on the sources read, and vestibular disorders generally are absent from the World Health Organization's hearing figures. The tenfold prevalence range reflects genuinely inconsistent diagnostic criteria rather than differing populations. The cause is unknown and the role of endolymphatic hydrops is disputed. Betahistine is widely prescribed and BEMED found it ineffective; prescribing practice and trial evidence directly disagree, and both facts are recorded. Diuretic evidence is insufficient by Cochrane assessment while the practice is near-universal. Endolymphatic sac surgery efficacy is disputed with sham-controlled data against it. The frequency of misdiagnosis against vestibular migraine is unquantified and believed substantial.

---

## Benign paroxysmal positional vertigo

**What it is.** Crystals that belong in one part of the inner ear fall into a balance canal. Turning over in bed or looking up then sets off a short, violent spinning that lasts under a minute. A head-turning manoeuvre in the clinic usually fixes it on the spot.

**Measured.** No global figure was retrievable; vestibular disorders are not quantified on the World Health Organization hearing sources read. This is the **commonest cause of vertigo**, accounting for a large share of all vertigo presentations, with lifetime prevalence commonly reported at about **2.4 per cent** and one-year prevalence about **1.6 per cent**†.

Incidence rises markedly with age, and it is a major and frequently missed contributor to falls in older people. Falls carry **53.1 million** years lived with disability in Global Burden of Disease 2023, 95% uncertainty interval 38.4 to 72.2, the fourth leading cause. It is about

twice as common in women, and recurrence runs roughly **15 to 50 per cent** within a few years†.

This is among the highest-value diagnoses in the chapter, because it is extremely common, frequently misattributed to cerebrovascular disease or to “dizziness in the elderly”, and corrected in minutes at no cost.

**Where it starts.** - **Displacement of otoconia** — calcium carbonate crystals — from the utricle into a semicircular canal, most often the posterior canal. This is the mechanism and it is well established. - **Age** — otoconial degeneration. - **Head trauma** — a common identifiable precipitant, and it causes bilateral or multi-canal disease more often. - **Prolonged bed rest or supine positioning**, including after surgery or dental work. - **Vestibular neuritis, Ménière disease, prior inner ear disease**. - **Osteoporosis and low vitamin D** — associated with incidence and recurrence, and vitamin D and calcium supplementation reduced recurrence in at least one trial. - **Female sex; migraine**.

Genuinely not known: why otoconia detach when they do, and why in one canal and not another. Why recurrence rates vary so widely. Most cases are idiopathic, with no precipitant identified. Why some patients have persistent subjective unsteadiness after the positional vertigo has been cured is unexplained.

**Cure status.** CURABLE, and it is the fastest cure in this book. A particle-repositioning manoeuvre — the **Epley** manoeuvre for posterior canal disease — resolves the condition in a single session in a large majority, with reported success of roughly **80 per cent** after one manoeuvre and above **90 per cent** after repeat manoeuvres†. Cochrane supports the Epley manoeuvre as effective against sham.

The condition also remits spontaneously over weeks to months in many people, so it is partly self-limiting, and there is no reason to wait when a minute of treatment ends it. Recurrence happens in a substantial minority, and each recurrence is again curable by the same manoeuvre. The cure is complete, immediate, free and repeatable.

**Prevention.** - **Nothing reliably prevents a first episode.** - **Vitamin D and calcium supplementation in people with low vitamin D and recurrent disease.** Reduced recurrence in trial data. **MODERATE** for that group. Both are cheap and listed. - **Head protection and avoiding head trauma. MODERATE** for traumatic disease. - **Avoiding prolonged supine immobility where possible. WEAK**. - **Teaching patients the self-manoeuvre so recurrences are treated at home without a consultation.** Prevents disability and falls rather than the condition. **MODERATE**, and free. - **Treating this condition as part of falls prevention in older people**, which removes a correctable fall cause. **MODERATE**.

**Treatment.** 1. **The Epley (canalith repositioning) manoeuvre** for posterior canal disease. About 80 per cent resolution after one manoeuvre, above 90 per cent with repetition†. Not a medicine. **Cost: zero.** It takes about two minutes and needs only a couch. 2. **The Semont manoeuvre** — an alternative with comparable efficacy. 3. **The barbecue roll, or Lempert, manoeuvre** for horizontal canal disease. 4. **Brandt-Daroff exercises** — performed by the patient at home; less effective per session than Epley and requiring no clinician. Free. 5. **Vestibular rehabilitation** for residual unsteadiness after successful repositioning. 6. **Vestibular sedatives are not recommended.** Prochlorperazine, cinnarizine and antihistamines do not treat this condition, they impede central compensation, and they cause falls and sedation in older people. They are nonetheless very widely prescribed for it. **The action is omission**, and stating it matters: the standard drug treatment for “dizziness” is actively harmful in the commonest cause of dizziness. 7. **Posterior canal occlusion surgery** for intractable disease; very rarely needed.

**Simple means.** This is the purest simple-means entry in the book: the diagnosis and the cure are both performed with a pair of hands and a flat surface.

- **The Dix-Hallpike test** for diagnosis. The examiner lowers the patient’s head back and to one side and watches the eyes for a few seconds of rotatory nystagmus. Equipment: a couch. Cost: zero.
- **The Epley manoeuvre** for cure. Four head positions, about 30 seconds each, with about 80 per cent cured in one session†. Equipment: a couch. **Cost: zero.**
- **Brandt-Daroff exercises** taught to the patient for home use, for recurrences. Cost: zero.

- **Teaching the manoeuvre to primary care staff, nurses and community health workers.** Highly task-shiftable; it requires manual skill, not equipment or drugs. In low-income countries 78 per cent have fewer than one ear, nose and throat specialist per million people, so this capability must sit outside specialist services to be useful at all.
- **Not prescribing vestibular sedatives.** The action is omission: a zero-cost improvement that removes a fall risk and a sedation risk in exactly the age group most harmed by both, and it saves the cost of the drug.
- **Vitamin D and calcium** where deficient and recurrent — listed, off-patent, cents per day.

A very common, frightening, fall-causing condition is cured in two minutes with no equipment, no drug and no supply chain whatever. The binding constraint is purely whether the clinician knows the manoeuvre.

**Gaps.** No global prevalence or burden figure exists on the sources read; vestibular disorders are entirely absent from the World Health Organization's hearing figures. All prevalence and success-rate figures in this entry are unverified, including the 2.4 per cent lifetime prevalence and the 80 per cent single-manoeuvre success. Recurrence rate estimates range from about 15 to 50 per cent and sources disagree. The vitamin D recurrence-prevention finding rests on limited trial data. How often this condition is missed in primary care, and how much of the dizziness and falls burden in older people it accounts for, is not quantified in any source read, though it is widely held to be substantial. Vestibular suppressant prescribing for it remains common despite evidence against it.

---

## Vestibular neuritis and labyrinthitis

**What it is.** The balance nerve of one ear becomes inflamed, usually after a viral illness. Sudden severe spinning, vomiting and inability to stand, lasting days. The brain then relearns balance over weeks, and moving about speeds that up rather than slowing it.

**Measured.** No global figure was retrievable and the condition is not quantified on the World Health Organization hearing sources read. Annual incidence is commonly reported at about **3.5 to 15 per 100,000**†, peaking in middle age, ages 30 to 60†.

Most people recover functionally within weeks to months through central compensation, and caloric testing often shows **permanent unilateral vestibular hypofunction** — the nerve does not fully recover even when the person does. A minority develop persistent dizziness, and benign paroxysmal positional vertigo follows in a proportion of cases. Labyrinthitis — the same process involving the cochlea as well — adds hearing loss and tinnitus, and that hearing loss is often permanent.

**Where it starts.** - **Presumed viral or post-viral inflammation of the vestibular nerve**, with reactivation of latent herpes simplex virus type 1 in the vestibular ganglion as the leading hypothesis†. - **A preceding upper respiratory tract infection** — reported in a substantial proportion. - **The superior vestibular nerve division** is affected far more often than the inferior, attributed to its longer bony canal. - **Vascular occlusion of the labyrinthine artery** — an alternative mechanism in some cases, particularly with hearing loss. - **Bacterial labyrinthitis** — from otitis media or meningitis; a different and more dangerous entity with high rates of permanent deafness.

Genuinely not known: whether it is viral at all. The herpes simplex reactivation hypothesis rests largely on post-mortem and indirect evidence and has never been confirmed in life, which is precisely why antiviral treatment has no established role. Why only one nerve division is usually affected. Why some patients fail to compensate centrally and develop persistent postural-perceptual dizziness while most recover — this is the clinically important unknown and no predictor exists.

The critical diagnostic unknown is the one that matters at the bedside: a cerebellar or brainstem stroke can present identically. The head-impulse, nystagmus, test-of-skew examination distinguishes them with reported sensitivity exceeding early magnetic resonance imaging in expert hands, and it requires skill, and misdiagnosis in both directions is common.

**Cure status.** SELF-LIMITING. The acute attack resolves without treatment, and functional recovery occurs through central compensation over weeks, which is a reorganisation of the brain rather than healing of the nerve. Most people return to normal function.

The qualification: the peripheral vestibular deficit is often permanent on testing, and in labyrinthitis the hearing loss is often permanent. The illness is self-limiting while the damage may not be.

Corticosteroids improve caloric recovery of vestibular function and have **not been shown to improve the outcome patients care about** — long-term symptoms and function; Cochrane found insufficient evidence of clinical benefit. Antivirals are not effective. The one intervention that demonstrably improves the course is vestibular rehabilitation exercise, which is free.

**Prevention.** - **Nothing prevents vestibular neuritis.** No primary prevention is established. - **Prompt treatment of otitis media and meningitis**, which prevents bacterial labyrinthitis and the deafness it causes. **STRONG** for that specific route. This connects to the otitis media entries. - **Measles, mumps, rubella, *Haemophilus influenzae* type b and pneumococcal vaccination**, which prevent the infections that cause labyrinthitis and infective deafness. **STRONG**. The World Health Organization names immunization among its prevention measures, and global coverage of the measles first dose was **84 per cent** in 2025, with both doses at **77 per cent**. - **Early mobilisation and vestibular exercises during the acute illness**, which prevents prolonged disability rather than the disease. **STRONG**, and free. - **Avoiding prolonged vestibular sedative use**, which prevents delayed compensation. **MODERATE**, and the action is omission.

**Treatment.** 1. **Vestibular rehabilitation exercises, begun as early as tolerated.** The best-evidenced treatment; it accelerates central compensation and reduces persistent symptoms. Not a medicine. **Cost: zero** after instruction. 2. **A short-course vestibular sedative for the first 24 to 72 hours only** — prochlorperazine, promethazine or an antihistamine, for the vomiting and the severity of the acute attack. Prochlorperazine and promethazine are listed, off-patent, cents per dose. **It must be stopped early**, because prolonging it delays compensation and worsens the eventual outcome. 3. **Antiemetics and rehydration.** Oral rehydration salts are listed at cents; the United Nations Children's Fund indicative price for low-osmolarity sachets, read October 2026, was **US$4.80 per carton of 100**, about **US$0.048 per sachet**. Intravenous fluid where vomiting prevents oral intake. 4. **Corticosteroids (methylprednisolone, prednisolone).** They improve measured vestibular function recovery; clinical benefit is not established and Cochrane found insufficient evidence. Listed, off-patent, cents per day. Widely prescribed on weak evidence. 5. **Antivirals are not effective**, alone or with steroids. A clear negative, and **the action is omission.** 6. **Antibiotics** only for bacterial labyrinthitis secondary to otitis media or meningitis, where they are urgent and hearing-saving. Amoxicillin and ceftriaxone are listed, off-patent, low cost. 7. **Treating subsequent benign paroxysmal positional vertigo** with the Epley manoeuvre, since it commonly follows. Free. 8. **A hearing aid** for permanent loss after labyrinthitis. Access gap 83 per cent.

**Simple means.** Nearly all of the effective management is free.

- **Vestibular rehabilitation exercises** — gaze stabilisation, head movements, balance and gait tasks, performed at home several times daily. This is the best-evidenced treatment for the condition and it costs nothing but a demonstration.
- **Getting up and moving as soon as tolerated**, rather than resting in a darkened room for a week. Movement is the treatment; immobility prolongs the illness.
- **Stopping the sedative after two to three days.** Free, the action is omission, and it improves the outcome.
- **Oral rehydration salts** — listed, cents, and they address the main acute danger in a vomiting patient.
- **The head-impulse, nystagmus, test-of-skew bedside examination** — the examiner's hands and eyes, no equipment, to separate this from a cerebellar stroke. This is the highest-stakes free procedure in the entry, because the two conditions look the same and one of them kills.
- **Prochlorperazine** for the acute vomiting: listed, off-patent, cents.

- **Explanation** that this is a self-limiting illness with a recovery measured in weeks, which prevents the anxiety-driven avoidance that produces persistent postural-perceptual dizziness.

What the chain minimally requires: nothing, for the standard management. Imaging is required only to exclude stroke where the bedside examination is equivocal or unavailable — and that is a scanner.

**Gaps.** No global incidence or burden figure exists on the sources read; vestibular disorders are absent from the World Health Organization hearing figures entirely. The 3.5 to 15 per 100,000 incidence range is unverified. The viral aetiology is unconfirmed, which is why antiviral trials were negative. Corticosteroid evidence is genuinely split: steroids improve laboratory measures of vestibular recovery while Cochrane finds insufficient evidence of clinical benefit, and prescribing practice follows the laboratory finding rather than the clinical one; both positions are recorded. Rates of misdiagnosis against posterior circulation stroke are substantial and not reliably quantified. No predictor exists for who will fail to compensate.

---

### Congenital and early-onset hearing loss

**What it is.** Hearing loss present at birth or appearing in the first years. A child who cannot hear cannot learn spoken language in the normal window, so the consequence is not only deafness but delayed language, schooling and livelihood. Found early, that consequence is largely avoidable.

**Measured.** **34 million children** are among the 430 million people needing rehabilitation for disabling hearing loss, and **95.1 million** children aged 5 to 19 live with hearing loss. **Nearly 60 per cent of childhood hearing loss is due to avoidable causes** — the central figure for this entry.

The World Health Organization names the causes by period. Prenatal: genetic factors; intrauterine infections such as rubella and cytomegalovirus. Perinatal: birth asphyxia, hyperbilirubinaemia, low birth weight, other perinatal morbidities. Childhood and adolescence: chronic suppurative otitis media, chronic non-suppurative otitis media, meningitis and other infections. Across the life span: cerumen impaction, trauma, loud

Congenital hearing loss incidence is commonly reported at about **1 to 3 per 1,000** live births in high-income settings, higher where infection and perinatal morbidity are common. The World report on hearing's 2030 targets include a **20 per cent relative increase** in effective coverage of newborn hearing screening, and a 20 per cent relative reduction in chronic ear disease and unaddressed hearing loss in

The workforce constraint is severe. **50 per cent** of low-income countries have one or more teachers for the deaf per million population, and **17 per cent** have one or more speech therapists per million.

**Where it starts.** - **Genetic causes** — roughly half of congenital hearing loss in high-income settings; *GJB2* (connexin 26) is the commonest single gene, and most genetic deafness is nonsyndromic and autosomal recessive. The World Health Organization names genetic factors prenatally and delayed-onset genetic loss across the life span. - **Congenital cytomegalovirus** — the commonest nongenetic cause of congenital sen-

Genuinely not known: in a substantial share of children no cause is identified even after genetic and imaging investigation. Why congenital cytomegalovirus causes hearing loss in some infected infants and not others, and why it progresses when it does, is unexplained. The optimal age for cochlear implantation is agreed to be as early as possible, and the precise lower bound and the long-

**Cure status.** The hearing: RELIEF ONLY. The language consequence: CURABLE. This split is the whole substance of the entry. The hearing loss itself is not curable. Sensorineural loss from genetic causes, cytomegalovirus, kernicterus or meningitis is permanent, and no drug or surgery restores cochlear function.

But the consequence that matters — absent spoken language — is largely preventable, and that depends entirely on timing. A child fitted with hearing aids or implanted within the first year, with family support and therapy, can develop age-appropriate spoken language; a child identified at age four usually cannot catch up fully. Cochlear implants restore functional hearing well enough for spoken

Conductive loss from otitis media *is* curable — see those entries — and it is a substantial share of childhood hearing loss in low-income settings. So: RELIEF ONLY for the sensory deficit, with the strong qualification that early intervention converts a lifelong disability of language and livelihood into a managed hearing difference.

**Prevention.** This is where the "nearly 60 per cent avoidable" figure does the most work, and the measures are mostly cheap public health.

- **Rubella vaccination of girls and women of childbearing age.** Eliminates congenital rubella syndrome deafness. **STRONG**. The World Health Organization names immunization.
- ***Haemophilus influenzae* type b, pneumococcal and meningococcal vaccination**, which prevents meningitis deaf-

**Treatment.** 1. **Hearing aids, fitted as early as possible.** The first-line intervention for most degrees of loss. A device, not listed. Access gap **83 per cent** overall, 74 to 90 per cent across income levels. **hundreds of US dollars** to **thousands of US dollars per pair**. 2. **Cochlear implantation** for severe to profound loss, as early as feasible. It restores enough hearing for spoken language in

**Simple means.** Substantial, and concentrated in prevention and in language rather than in devices.

- **Vaccination — rubella, *Haemophilus influenzae* type b, pneumococcal, meningococcal, measles, mumps.** Cents to a few dollars per dose, listed vaccines, and they remove a large part of the “nearly 60 per cent avoidable” fraction†.
- **Phototherapy for neonatal jaundice, and basic newborn resuscitation.** Prevents kernicterus and asphyxia deafness at very low cost. - **Sign language.** This is the genuinely

---

The economics at scale: an additional **less than US$1.40 per person per year** scales ear and hearing care, with a return of **nearly US$16 per US$1** over ten years, averting nearly **130 million** disability-adjusted life years.

What the chain minimally requires: for a profoundly deaf child who is to acquire *spoken* language, a cochlear implant, a surgical service and years of therapy — unavailable to most of the world's deaf children. For that child to acquire *language*, sign language, which needs nobody's permission and no supply chain at all.

**Gaps.** The World Health Organization gives 34 million children with disabling hearing loss and 95.1 million children aged 5 to 19 with hearing loss, and **no breakdown by cause**, so the split between genetic, infective, perinatal and conductive causes is unknown globally, and the “nearly 60 per cent avoidable” figure cannot be decomposed. Congenital hearing loss incidence figures are

## Ototoxicity

**What it is.** Some medicines poison the inner ear. The commonest are certain antibiotics used for tuberculosis and severe infection, and a chemotherapy drug used for many cancers. The hearing loss they cause is usually permanent, and it is nearly always avoidable.

**Measured.** The World Health Organization names **ototoxic medicines** and **work-related ototoxic chemicals** among the causes of hearing loss acting across the life span, and states that the common adult causes including ototoxic medicines are preventable. The World report on hearing recommends surveillance of ototoxicity and gives **no numeric figures at all**. No global count of ototoxic hearing loss was retrievable. This is a notable gap: the World Health Organization identifies it as a preventable cause and quantifies none of it.

Reported incidence by agent, all unverified: - **Cisplatin** — hearing loss in a high proportion of treated patients, commonly reported above **60 per cent** in children receiving cumulative doses, dose-cumulative and usually permanent. - **Aminoglycosides (gentamicin, amikacin, streptomycin, kanamycin)** — cochleotoxicity commonly reported in roughly **10 to 25 per cent** of courses, with vestibulotoxicity in addition; gentamicin is predominantly vestibulotoxic and amikacin predominantly cochleotoxic. - **Multidrug-resistant tuberculosis regimens** containing injectable aminoglycosides historically caused hearing loss in a very large share of treated patients, reported above 50 per cent in some cohorts, which is a principal reason the World Health Organization moved to all-oral regimens. In 2024, **34,000** patients started the six-month all-oral regimens, against 5,653 in 2023 and 1,744 in 2022 (World Health Organization fact sheet, *Tuberculosis*, 24 March 2026). - **Loop diuretics (furosemide)** — usually reversible, and they potentiate aminoglycoside toxicity. - **High-dose salicylates and quinine** — usually reversible. - **Mitochondrial *m.1555A>G* variant carriers** — profound hearing loss after even a single standard aminoglycoside dose.

All ages are affected. Neonates and young children on aminoglycosides, and children on cisplatin, are the highest-stakes groups, because the loss arrives before language and schooling. The burden falls where aminoglycosides and multidrug-resistant tuberculosis treatment are most used and audiometric monitoring is least available — the inverse of what is needed.

**Where it starts.** - **Cumulative dose and peak serum concentration** of the agent — the primary determinant for both aminoglycosides and cisplatin. - **Duration of therapy**. - **Renal impairment** — reduces clearance and raises exposure. - **Age** — the very young and the old. - **Concurrent noise exposure** — synergistic with both aminoglycosides and cisplatin. The World Health Organization names loud noise and ototoxic medicines as co-occurring life-span causes. - **Concurrent loop diuretics** — potentiate aminoglycoside toxicity. - **Mitochondrial DNA variants, especially *m.1555A>G* and *m.1494C>T*** — maternally inherited hypersusceptibility, in which a single standard dose can cause profound permanent loss. Point-of-care genotyping before administration is feasible and has been implemented in some neonatal services. - **Prior hearing loss**.

Genuinely not known: why susceptibility varies so widely outside the known mitochondrial variants. Whether any otoprotectant works reliably in humans — sodium thiosulfate reduced cisplatin hearing loss in children in the SIOPEL 6 and COG ACCL0431 trials, with a concern about reduced tumour control in disseminated disease in one of them, which is an unresolved trade-off. The optimal monitoring schedule and the threshold for changing therapy are not established. Extended high-frequency audiometry detects loss earlier than standard audiometry, and whether acting on it improves outcomes has not been demonstrated.

**Cure status.** Aminoglycoside and cisplatin damage: RELIEF ONLY. Salicylate, quinine and loop diuretic effect: SELF-LIMITING.

The split is by agent and it is clinically decisive. Aminoglycoside and cisplatin damage destroys outer hair cells, typically beginning at the highest frequencies, and it is permanent. No treatment restores it, and it can progress after the drug is stopped. Salicylate, quinine and loop diuretic effects are usually reversible on discontinuation — genuinely self-limiting.

For the permanent forms, management is substitution: hearing aids, or cochlear implants for profound loss. No otoprotectant is established except the partial and contested cisplatin case above. Because nothing reverses it, this condition is defined by its prevention, which is why it belongs with noise-induced hearing loss as the most preventable entry in this part of the chapter.

**Prevention.** Ototoxic drug stewardship. The World Health Organization names rational use of medicines to prevent ototoxic hearing loss among its prevention measures, and the World report on hearing recommends ototoxicity surveillance. - **Avoiding aminoglycosides where an equally effective alternative exists**, and using the shortest effective course. **STRONG**; the action is omission and it costs nothing, being a prescribing decision. - **All-oral multidrug-resistant tuberculosis regimens replacing injectable aminoglycosides.** The World Health Organization's shift away from injectables removed a large share of iatrogenic deafness from tuberculosis programmes, and 34,000 patients started the six-month all-oral regimens in 2024. **STRONG**. This is the single largest documented ototoxicity prevention measure of recent years. - **Once-daily rather than divided aminoglycoside dosing, with therapeutic drug monitoring, weight-based dosing and renal adjustment. MODERATE**. - **Baseline and serial audiometry during treatment, including extended high-frequency audiometry**, so therapy can be changed before speech frequencies are lost. **MODERATE** — detection is reliable, and evidence that acting on it improves the final outcome is weaker. - **Screening for *m.1555A>G* before aminoglycoside exposure** where feasible, which prevents catastrophic single-dose deafness in carriers; rapid point-of-care testing has been deployed in neonatal units. **MODERATE** for that group. - **Avoiding concurrent noise exposure and concurrent loop diuretics. MODERATE**. - **Sodium thiosulfate with cisplatin in children** — reduces hearing loss; **CONTESTED** because of the tumour-control concern in disseminated disease. - **Avoiding ototopical aminoglycosides through a perforated eardrum** where a quinolone is available. **MODERATE**, and disputed; see the chronic suppurative otitis media entry. - **Asking about hearing and tinnitus at every treatment visit.** Free, and the realistic detection method where no audiometry exists.

**Treatment.** There is no treatment that reverses aminoglycoside or cisplatin ototoxicity. What follows is substitution, salvage and the single protective agent. 1. **Stopping or substituting the offending drug** — the only action that changes the course. Free, and it reverses salicylate, quinine and diuretic effects completely. **The action is omission.** 2. **Sodium thiosulfate** as cisplatin otoprotection in children. Not on the Essential Medicines List. Off-patent as a molecule — it is an old, cheap compound — and cost is low. The barrier is the tumour-control question, not price. 3. **Hearing aids.** Access gap **83 per cent**, 74 to 90 per cent across income levels. A device, not listed. **hundreds of US dollars** to **thousands of US dollars per pair**. 4. **Cochlear implantation** for profound loss. Not listed. About **US$30,000 to 100,000** per recipient in high-income systems†; the World report on hearing gives no figure. 5. **Vestibular rehabilitation** for aminoglycoside vestibulotoxicity, which causes persistent imbalance and oscillopsia rather than deafness — gentamicin is predominantly vestibulotoxic and this disability is frequently missed. Free after instruction. 6. **Tinnitus management.** See that entry. 7. **No otoprotectant is established for aminoglycosides.**

**Simple means.** This entry's simple means are almost entirely acts of restraint and record-keeping, and they are free.

- **Not prescribing the drug.** Using a non-ototoxic alternative where one exists is the whole intervention. **The action is omission**, it costs nothing, and the World Health Organization's rational-use recommendation is precisely this.
- **Weight-based once-daily dosing, renal adjustment, shortest course.** A calculation and a prescribing habit. Free.
- **Asking whether hearing has changed or ringing has started, at every visit**, and recording the answer. Free, deliverable by any health worker, and in programmes without audiometry it is the only early-warning system available.
- **A maternal family history question before aminoglycosides.** Deafness after injections in maternal relatives suggests a mitochondrial variant and should change the drug. Free, and it prevents the most catastrophic form.
- **Free or low-cost smartphone audiometry** for serial monitoring where 93 per cent of low-income countries have fewer than one audiologist per million people. This is the practical substitute for a sound booth.
- **A written card given to the patient**, recording that they have had an ototoxic drug and their last hearing status, so that cumulative exposure across episodes of care is visible. It costs a card.
- **Avoiding noise during and after treatment.** Free, and it reduces synergistic damage.

- **Using a topical quinolone rather than aminoglycoside ear drops** where the drum is perforated — a few dollars a bottle.

What the chain minimally requires: nothing for prevention beyond prescribing discipline and a question. Audiometric surveillance requires equipment, and smartphone audiometry has lowered that threshold substantially.

**Gaps.** This is the largest quantitative gap in this part of the chapter. The World Health Organization identifies ototoxic medicines as a preventable cause of hearing loss across the life span and the World report on hearing recommends surveillance, and **neither gives a single number** — no global count, no disability-adjusted life year figure, no incidence. Every incidence figure above is unverified and the ranges are wide: aminoglycoside cochleotoxicity reported from about 10 to 25 per cent; cisplatin loss in children reported above 60 per cent; historic injectable tuberculosis regimens above 50 per cent. Sources disagree on sodium thiosulfate: SIOPEL 6 and COG ACCL0431 both showed hearing protection and differed on tumour-control safety in disseminated disease, and that disagreement is unresolved and material. Optimal monitoring schedules and the threshold for changing therapy are not established. Whether acting on extended high-frequency changes improves final speech-frequency outcomes has not been demonstrated. The prevalence of mitochondrial susceptibility variants varies by population and is not globally characterised.

---

# ICD-11 Chapter 14 — Diseases of the skin

## A note on this part's provenance

Condition-level global prevalence counts for the skin chapter were not retrievable. Global Burden of Disease 2023 gives dermatitis as a group — atopic, contact and seborrhoeic — **15.2 million** years lived with disability, 95% uncertainty interval 8.9 to 24.2, the **eighteenth leading cause** of years lived with disability. Global Burden of Disease 2021 analyses exist for immune-related, allergic-related and fungal skin

Three entries are the exception and are well sourced from World Health Organization pages read off the page this week: scabies, bacterial skin infection in its scabies-related part, and burns. Those figures were read off the page, and each names the page and its printed date. Hidradenitis suppurativa and bullous pemphigoid, written after this note, almost wholly carry daggers, and the key trials of the bullous pem-

## Atopic dermatitis (eczema)

**What it is.** A long-running itchy skin inflammation. The skin barrier leaks water and lets irritants and allergens in, so the skin is dry, red and intensely itchy, and scratching makes it worse. It usually starts in infancy and often improves with age.

**Measured.** Global Burden of Disease 2023 gives dermatitis as a group — atopic, contact and seborrhoeic — **15.2 million** years lived with disability, 95% uncertainty interval 8.9 to 24.2, the eighteenth leading cause. Atopic dermatitis is the largest component of that group.

Prevalence is commonly reported at about **15 to 20 per cent of children** and **2 to 10 per cent of adults**, with wide international variation†. Onset is before age 5 in the large majority; a substantial share remit by adolescence, and a minority persist or begin in adulthood. International surveys found large variation, with rising prevalence in low- and middle-income countries undergoing urbanisation. Prevalence rose substantially in high-income countries through the late twentieth century and has plateaued in several, and is still rising in many low- and middle-income countries.

**Where it starts.** - **Filaggrin loss-of-function mutations** — the strongest single genetic risk factor, carried by a substantial minority of European patients, producing a defective skin barrier. The effect size is large relative to most complex-disease variants. - **Family history of atopy** — the strongest clinical predictor. - **Skin barrier dysfunction with raised transepidermal water loss**, present before eczema appears. - ***Staphylococcus aureus* colonisation** — near-universal in affected skin, and it drives flares. - **Urban living, hard water, low humidity, soap and detergent exposure**. - **Food allergy** — strongly comorbid. The direction of causation now favours eczema preceding and enabling food sensitisation through the broken barrier, rather than food causing the eczema. That reversal matters clinically: dietary elimination is not an eczema treatment.

Genuinely not known: whether the primary defect is the barrier or the immune response. The outside-in against inside-out question is unresolved, and it determines whether barrier repair should be able to prevent the disease. The failure of the emollient prevention trials below is direct evidence against the simplest barrier-first account. Why most children outgrow it and some do not. Why prevalence rose so fast in a few decades, which rules out genetic change and implicates environment without identifying the factor.

**Cure status.** CONTROLLABLE. No treatment removes atopic dermatitis. Disease can be brought to clear or near-clear skin and held there — topical therapy for most, systemic therapy for the severe minority, with dupilumab and JAK inhibitors achieving high rates of clearance — and stopping treatment generally allows relapse, and the atopic tendency persists. A substantial share of childhood cases remit spontaneously with age, which is genuine resolution rather than treatment effect.

**Prevention.**

Emollient use in infancy to prevent eczema is the clearest case in this book of a plausible, cheap intervention that failed when properly tested, and the results must be read together.

- **BEEP (Barrier Enhancement for Eczema Prevention).** 1,394 term infants at high risk, randomised to 693 receiving daily emollient plus skincare advice against 701 receiving skincare advice alone, with emollient applied daily through the first year. Result: **no difference** between groups in the number of children who developed eczema at age 2, nor in how early it appeared, nor in how severe it was. A 2024 review records the conclusion as “daily emollient application during the first year of life does not prevent atopic dermatitis”, with eczema diagnosis comparable in both groups at 3, 4 and 5 years.

Harms: infants in the daily emollient group were at **slightly increased risk of skin infections** and had a **slightly higher rate of food allergy**. **The exact event rates, relative risks and confidence intervals could not be retrieved** — the journal full text and the trial report both failed to load — so the harms are carried directionally and the exact rates could not be confirmed.

Cost-effectiveness: first-year emollient treatment was found **not cost-effective**.

- **PreventADALL.** Factorial, multicentre, cluster-randomised. The 2024 review reports **2,379** neonates in its text and **2,397** in its own Table 1; the review is internally inconsistent and both figures are printed. 597 were in the emollient group and 583 in the

combined intervention group. The intervention was a skin emollient — oil bath additives plus facial cream — and/or early complementary feeding. Result: **skin emollients did not reduce development of atopic dermatitis by age 12 months**. Full protocol adherence in the skin intervention group was only **32 per cent**, which is a real limitation on interpretation.

- **STOP-AD.** 321 infants, 161 intervention and 160 control. Daily emollient **until 2 months of age only** reduced incidence in the first year in high-risk infants; the review gives no incidence figures, relative risk or confidence interval. Children with the filaggrin mutation may benefit more than those without.
- **The pooled estimate.** A meta-analysis reports **RR 0.75, 95% CI 0.62 to 1.11** in high-risk populations. **The confidence interval includes 1**, so this does not demonstrate benefit. The 2024 review that prints that interval describes a "significant benefit", which its own printed interval contradicts. Both the description and the interval are recorded here, and the interval is the evidence. Another review found six of nine studies supported early emollient use and three did not, and a third concluded that emollients may be ineffective in healthy infants and may increase food allergy and skin infection risk.

**Grade for emollient prevention: CONTESTED.** The two largest and best-powered trials were both negative; a small short-duration trial was positive; the pooled estimate's confidence interval crosses one; and there is a signal of harm in skin infection and food allergy. The honest reading is that daily infant emollient does not prevent eczema and may cause harm. Whether a very short early course in filaggrin-mutation carriers helps is open.

Other preventive measures: - **Exclusive breastfeeding. CONTESTED** for eczema prevention specifically. - **Early introduction of allergenic foods.** Prevents *food allergy* and not eczema. **STRONG** for food allergy, **not** for eczema. - **Probiotics in pregnancy and infancy. CONTESTED**, with inconsistent trials. - **Avoiding soap and detergents; using water softeners.** A trial of water softeners for treatment was negative. **WEAK**. - **Avoiding tobacco smoke. MODERATE**.

Nothing is established to prevent atopic dermatitis.

**Treatment.** 1. **Emollients, applied liberally and frequently.** The foundation of *treatment*, in contrast to prevention, where they fail. They reduce dryness, itch and flare frequency, and reduce the topical steroid requirement. Emollients are not a specific Essential Medicines List entry; petroleum jelly and zinc and calamine preparations are listed, with calamine confirmed. Off-patent. **Petroleum jelly and paraffin-based emollients cost a few US dollars per large tub**, and proprietary creams cost many times more for no demonstrated advantage. 2. **Topical corticosteroids**, potency matched to site and severity, used in short bursts or as twice-weekly maintenance to previously affected sites. The most effective and most cost-effective anti-inflammatory. **Betamethasone and hydrocortisone are on the Essential Medicines List**. Off-patent. **Cents to a few dollars per tube.** 3. **Topical calcineurin inhibitors — tacrolimus, pimecrolimus.** Steroid-sparing, particularly for face and eyelids. Not listed. Off-patent. Considerably more expensive than steroids. 4. **Treating *Staphylococcus aureus* infection** — flucloxacillin or another appropriate oral antibiotic for infected eczema; listed, off-patent, under a dollar a course. Dilute bleach baths: evidence weak. 5. **Wet wrap therapy** for severe flares — emollient and steroid under damp bandaging. Cheap, effective, and it needs no new drug. 6. **A sedating antihistamine at night** for sleep disruption; **non-sedating antihistamines do not help eczema itch**. Chlorphenamine is listed, off-patent, cents. 7. **Narrowband ultraviolet B phototherapy**. 8. **Systemic immunosuppression — ciclosporin, methotrexate, azathioprine, mycophenolate.** Ciclosporin, methotrexate and azathioprine are listed, off-patent, and cost cents to a few dollars per day. 9. **Dupilumab and the JAK inhibitors — upadacitinib, abrocitinib, baricitinib.** High efficacy in severe disease. **Not on the Essential Medicines List**. On-patent. **Tens of thousands of US dollars per patient-year** in high-income markets. The cost gap between step 2 and step 9 is roughly four orders of magnitude. 10. **Dietary elimination is not indicated** without proven food allergy; it risks nutritional harm and does not treat the eczema. **The action is omission.**

**Simple means.** Strong, and the cheap options do most of the work.

- **Petroleum jelly or plain paraffin ointment** as the emollient. A few dollars per large tub, no refrigeration, indefinite shelf life, and no demonstrated inferiority to proprietary creams for treatment.
- **Topical hydrocortisone or betamethasone**, listed, off-patent, **cents per tube** — the single most effective cheap intervention in the entry.
- **Soap substitution:** washing with an emollient instead of soap, short lukewarm baths, patting dry. Free, and it removes a major irritant exposure.
- **Wet wraps** using ordinary cotton bandages, clean cotton clothing or tubular gauze over emollient. Cheap and effective for severe flares.
- **Cotton clothing, short nails, scratch mitts for infants, keeping the room cool at night.** Free, and they interrupt the itch-scratch cycle.
- **Identifying and removing irritants** — detergents, fragrance, wool, overheating. Free.
- **Not buying the expensive options that do not work:** proprietary emollients at many times the cost of petroleum jelly, non-sedating antihistamines, and dietary elimination without proven allergy. All three are omissions and all three are savings.

What the chain minimally requires: a tub of paraffin and a tube of hydrocortisone. For the severe minority, phototherapy or systemic drugs — and for the refractory few, biologics at tens of thousands per year.

**Gaps.** No verified global prevalence figure; Global Burden of Disease 2023 gives only the combined dermatitis total and the 2021 allergic-skin analysis was unreachable. All prevalence figures above are unverified. **The BEEP and PreventADALL exact event rates, relative risks and confidence intervals could not be retrieved** — the journal full texts and the trial report all failed — so only the directional results and the pooled relative risk of 0.75, 95% CI 0.62 to 1.11, are carried, and the event rates could not be confirmed. PreventADALL's own sample size is reported inconsistently, 2,379 against 2,397, within one review. Sources genuinely disagree on emollient prevention: the two large trials are negative, STOPAD is positive, and the 2024 review describes a "significant benefit" that its own printed confidence interval contradicts; all positions are recorded above. Whether barrier dysfunction or immune dysregulation is primary is unresolved. Long-term safety of JAK inhibitors in eczema is not established.

---

## Psoriasis

**What it is.** Skin cells multiply far too fast, piling up as thick red plaques with silvery scale, typically on elbows, knees and scalp. It is an immune disease, not an infection, and it comes with joint disease and heart risk in a substantial minority.

**Measured.** The World Health Organization psoriasis fact sheet did not load and no global figure was retrievable. Global prevalence is commonly reported at about **60 million** people, and roughly **2 to 3 per cent** of the population in high-income countries, with substantial geographic variation. A Global Burden of Disease 2021 immune-related skin disease analysis exists and was unreachable.

Onset is bimodal, with peaks in the late teens to early thirties and again in the fifties to sixties. Prevalence is reported higher at higher latitudes and in populations of European ancestry, and low in parts of East Asia and in indigenous populations of the Americas and West Africa.

The major measured burden beyond the skin is comorbidity: **psoriatic arthritis** in roughly **20 to 30 per cent** of patients, and elevated cardiovascular, metabolic syndrome, depression and inflammatory bowel disease risk.

**Where it starts.** - **Genetic predisposition.** *HLA-C*06:02* is the strongest association, together with *IL23R*, *IL12B* and *TNFAIP3* among more than 60 identified loci†. Family history is present in roughly a third. - **IL-23 and Th17 axis activation** — the established effector pathway, and the reason IL-17 and IL-23 blockade works so well. This is one of the few conditions in this book where genetics led to a mechanism and the mechanism led to highly effective drugs. - **Streptococcal pharyngitis** — precipitates guttate psoriasis. - **Smoking** — dose-related, and strongly associated with palmoplantar pustulosis. - **Obesity** — associated with incidence and with severity, and weight loss improves disease. - **Alcohol**. - **Drugs:**

**beta-blockers, lithium, antimalarials, and corticosteroid withdrawal**. - **Skin trauma (the Köbner phenomenon); stress; HIV infection**.

Genuinely not known: the antigen, if any, that drives the immune response. Why lesions occur at the sites they do and why they are so symmetrical. Why the disease waxes and wanes. Whether treating skin inflammation reduces the excess cardiovascular risk — an important open question with observational support and no definitive trial. Why some patients develop psoriatic arthritis and most do not, and no predictive test exists.

**Cure status.** CONTROLLABLE. No treatment removes psoriasis, and the degree of control now achievable is as high as anywhere in this book: IL-17 and IL-23 inhibitors achieve a 90 per cent reduction in disease severity in a majority of treated patients, and complete clearance in a substantial share.

Clearance is not cure. Withdrawal is followed by relapse in most patients, the genetic predisposition remains, and treatment is indefinite. Control can now be near-total for those who can access the drugs, and the access gap is the binding constraint, since originator biologics cost tens of thousands of US dollars per patient-year.

**Prevention.** - **No primary prevention is established.** Nothing prevents psoriasis. - **Smoking cessation** — reduces incidence and severity. **MODERATE**. - **Weight loss in overweight patients** — improves severity and treatment response. **MODERATE**. - **Treating streptococcal throat infection** — may prevent guttate flares. **WEAK**. - **Avoiding precipitating drugs** where alternatives exist, notably beta-blockers and lithium. **MODERATE**, and the action is omission. - **Avoiding abrupt systemic corticosteroid withdrawal**, which can precipitate generalised pustular psoriasis. **MODERATE**, and important: systemic steroids should generally not be used for psoriasis at all. - **Alcohol reduction. WEAK**. - **Managing cardiovascular risk factors.** Prevents the comorbidity that causes the excess mortality rather than the skin disease. **STRONG** for cardiovascular outcomes.

**Treatment.** 1. **Topical corticosteroids**, alone or with a vitamin D analogue. First-line for mild to moderate disease. **Betamethasone is on the Essential Medicines List**. Off-patent. **Cents to a few dollars per tube.** 2. **Topical vitamin D analogues — calcipotriol.** Listed, with calcitriol as therapeutic equivalent. Off-patent. Low tens of US dollars per tube generic. The combination of calcipotriol and betamethasone is more effective than either alone. 3. **Coal tar, dithranol, salicylic acid.** Old, cheap, effective and messy, and largely displaced in high-income practice by convenience rather than by efficacy. Off-patent, very low cost. 4. **Narrowband ultraviolet B phototherapy** — effective for extensive plaque and guttate disease. Not a medicine. Capital equipment, low running cost. See *Simple means* for the sunlight alternative. 5. **Methotrexate**, oral weekly. The standard cheap systemic agent. **Listed**. Off-patent. **A few US dollars per month**. It requires blood monitoring and is teratogenic. 6. **Ciclosporin** — rapid acting, for short courses. **Listed.** Off-patent, low cost. Nephrotoxic with prolonged use. 7. **Acitretin** — an oral retinoid, teratogenic for years after stopping. Off-patent. 8. **Apremilast**, oral. 9. **Biologics: TNF inhibitors (adalimumab, etanercept, infliximab), IL-17 inhibitors (secukinumab, ixekizumab), IL-23 inhibitors (guselkumab, risankizumab), IL-12/23 (ustekinumab).** The most effective treatments, with a 90 per cent severity reduction in a majority on the IL-17 and IL-23 agents†. **Adalimumab is on the Essential Medicines List as a selected medicine**, in the complementary list, with psoriasis among its indications and including quality-assured biosimilars; **infliximab is listed only as a therapeutic equivalent to adalimumab** and not as a selected medicine in its own right. Adalimumab, etanercept and infliximab have biosimilars; the IL-17 and IL-23 agents are on-patent. Originator biologics cost **tens of thousands of US dollars per patient-year**, and **biosimilar adalimumab has fallen to a small fraction of the originator price** in competitive markets. That price collapse is the most important access development in this entry. 10. **Systemic corticosteroids — avoid.** Risk of rebound and pustular flare on withdrawal. **The action is omission.**

**Simple means.** Better than might be expected, because sunlight and tar are genuinely effective.

- **Sunlight.** Natural ultraviolet exposure improves psoriasis in most patients, and this is the oldest and cheapest effective treatment there is. Free. The limits are latitude, season, burn risk and skin cancer risk with cumulative exposure.
- **Climatotherapy** — the documented effectiveness of sun-and-saltwater regimens.

- **Topical hydrocortisone or betamethasone** — listed, off-patent, cents per tube.
- **Coal tar preparations and salicylic acid ointment** — very cheap, off-patent, effective, and still among the better value treatments despite being displaced by convenience.
- **Emollients and scale removal** — petroleum jelly, a few dollars a tub, softens plaque and reduces scale and cracking.
- **Salt water bathing and sunlight together**, where available. Free.
- **Methotrexate** for severe disease: listed, off-patent, **a few dollars a month**. This is the key point for access — effective systemic treatment for severe psoriasis costs a few dollars monthly, not tens of thousands yearly. It needs blood monitoring, which is the real constraint.
- **Smoking cessation and weight loss.** Free, and they improve disease and comorbidity together.

What the chain minimally requires: for most patients, a cheap steroid, an emollient and sunlight. For severe disease, methotrexate plus a laboratory for monitoring. Only the refractory minority need biologics.

**Gaps.** No verified global prevalence figure — the World Health Organization fact sheet did not load and the Global Burden of Disease 2021 immune-skin analysis was unreachable. The commonly cited 60 million and 2 to 3 per cent figures are unverified. Psoriatic arthritis prevalence estimates range widely and depend on case definition. Whether treating skin inflammation reduces cardiovascular events is unresolved and is the most consequential open question in the field. Biologic prices vary by an order of magnitude between originator and biosimilar and between markets, and no current price source was obtainable. Comparative long-term safety of the newer biologics is not established. No predictor exists for who develops psoriatic arthritis.

---

## Acne vulgaris

**What it is.** Blocked, inflamed oil glands in the skin, mostly on the face, chest and back. Blackheads, spots and cysts. It affects most adolescents to some degree and can leave permanent scars and lasting psychological harm.

**Measured.** No global figure was retrievable. Acne is commonly reported to affect roughly **85 per cent of people aged 12 to 24** at some point, with clinically significant acne in a smaller share, and it is consistently among the most prevalent skin diseases in Global Burden of Disease analyses.

Onset is around puberty, with a peak in mid to late adolescence and resolution in the early twenties for most; **adult female acne**, persisting or beginning after 25, is common†. It is universal, with reported severity differences likely reflecting diagnosis and treatment access.

Acne causes little physical disability and substantial **psychological morbidity** — depression, anxiety, social withdrawal and suicidal ideation are measurably increased, and this is the principal reason it carries real burden. Scarring is permanent in a significant minority, which is what makes early treatment a disfigurement-prevention measure.

**Where it starts.** Four established mechanisms act together: androgen-driven sebum production, which is why it starts at puberty; follicular hyperkeratinisation, the blocked pore; *Cutibacterium acnes* colonisation of the blocked follicle, which is not an infection in the ordinary sense because the organism is a normal commensal; and inflammation, present early, including in clinically uninvolved skin.

Risk factors: - **Genetics and family history** — substantial heritability. - **Androgen excess** — polycystic ovary syndrome, congenital adrenal hyperplasia. Acne with hirsutism and irregular periods should prompt endocrine assessment. - **High glycaemic load diet and dairy** — associated in observational and some trial data. The evidence is real and modest, and far weaker than popular belief holds. - **Drugs: corticosteroids, anabolic steroids, lithium, isoniazid, some progestogens, EGFR inhibitors**. - **Mechanical occlusion and friction** — helmets, straps, masks.

Genuinely not known: why severity varies so widely at the same hormonal stage. Why some people scar heavily and others not at all, with no predictor. The role of diet is genuinely unsettled — the association is consistent, the effect size is small, and dietary trials are hard

to blind. Whether *Cutibacterium acnes* strain type matters. Chocolate and greasy food, the two things most often blamed, have no established causal role.

**Cure status.** Standard topical and oral therapies: CONTROLLABLE — they control acne while they are used and it returns when they stop. A single adequate course of isotretinoin: CURABLE in roughly 70 to 80 per cent, the complement of relapse in roughly 20 to 30 per cent†.

Isotretinoin is the exception and deserves naming as such. A single adequate course over several months produces prolonged or permanent remission in a majority of patients, with relapse rates commonly reported around **20 to 30 per cent** needing a second course†. That is durable remission after a finite treatment, which is unusual in this book. Against that: isotretinoin is severely teratogenic, requiring pregnancy prevention programmes, and carries mucocutaneous, hepatic and lipid effects, with a contested association with depression.

Acne also remits spontaneously in most people by the mid-twenties, so a large part of the natural history is self-limiting. The label is split between isotretinoin and the other treatments, and the usual spontaneous resolution with age is noted.

**Scarring, once established, is not curable** by any of these treatments and is only partially improved by resurfacing procedures. That is why treating before scars form matters.

**Prevention.** - **Early effective treatment to prevent scarring.** The real preventive goal; acne itself is not preventable. **STRONG** for scar prevention. - **Avoiding causative drugs** where possible. **MODERATE**. - **Low glycaemic load diet. CONTESTED**; some trial support, small effect. - **Reducing dairy intake. CONTESTED**, observational. - **Not scrubbing, not picking, avoiding comedogenic and occlusive cosmetics. WEAK** , free, and the action is omission. - **Avoiding mechanical occlusion** where practical. **WEAK**. - **Nothing prevents acne.** It is a normal consequence of pubertal androgens in predisposed people.

**Treatment.** 1. **Benzoyl peroxide, topical.** Antibacterial and comedolytic, available over the counter, and it **does not generate antibiotic resistance**, which is why it is the backbone of modern regimens and why it should be combined with any topical antibiotic. **Benzoyl peroxide is on the Essential Medicines List**. Off-patent. **A few US dollars per tube, and often less.** 2. **Topical retinoids — tretinoin, adapalene.** They target the blocked follicle; first-line and essential for comedonal acne, and adapalene is available without prescription in several countries. Essential Medicines List status not confirmed in the sections displayed. Off-patent, low cost generic. 3. **A fixed combination of topical retinoid plus benzoyl peroxide, or clindamycin plus benzoyl peroxide.** More effective than monotherapy. 4. **Topical antibiotics (clindamycin, erythromycin) — never as monotherapy**, because of resistance. Listed as systemic agents; topical status not confirmed. Off-patent, cheap. 5. **Oral tetracyclines — doxycycline, lymecycline, minocycline** — for moderate to severe inflammatory acne, for a limited course of around three months with a topical retinoid and benzoyl peroxide. **Doxycycline is listed**, off-patent, and costs **cents per day**. Not in pregnancy or under 12. 6. **Combined oral contraceptives and anti-androgens (spironolactone, cyproterone acetate)** — effective in women. Combined oral contraceptives and spironolactone are listed, off-patent, cents per day; spironolactone is listed under diuretics and heart failure, not for this indication. 7. **Oral isotretinoin** — the most effective treatment, with durable remission in a majority. **Not** on the Essential Medicines List. Off-patent. **Low tens of US dollars per month generic**, though monitoring and pregnancy prevention programme requirements add substantially. 8. **Intralesional corticosteroid** for individual nodules. 9. **Scar treatment** — resurfacing, microneedling, subcision, fillers. Partial improvement only, not restorative. Expensive and rarely available.

**Simple means.** Good, and the single best-value agent is cheap and listed.

- **Benzoyl peroxide.** A few dollars a tube, listed, off-patent, available without a prescription in most places, effective as monotherapy for mild acne, and resistance-proof. This is the highest-value simple intervention in the entry.
- **Washing gently twice daily with a mild cleanser, and not scrubbing.** Free. Scrubbing and harsh antiseptics make acne worse, so part of the free advice is stopping harmful practices.
- **Not picking or squeezing** — directly reduces scarring. Free, and the action is omission.
- **Avoiding occlusive and oil-based cosmetics and hair products.** Free.

- **Doxycycline** for inflammatory acne: listed, off-patent, cents per day.
- **Sun protection**, since several acne treatments cause photosensitivity and post-inflammatory pigmentation is worsened by sun — particularly important in darker skin, where pigmentation is often the patient's main concern.
- **Explanation** that acne is not caused by poor hygiene, chocolate or greasy food. Free, and it removes blame and futile restriction.
- **Early treatment**, since the scars are what is permanent. The cost of a tube of benzoyl peroxide against a lifetime of facial scarring is the relevant comparison.

What the chain minimally requires: a tube of benzoyl peroxide. For severe nodular acne, isotretinoin plus laboratory monitoring and pregnancy prevention — a genuine clinical service requirement.

**Gaps.** No verified global prevalence or burden figure; condition-level Global Burden of Disease skin data were unobtainable. The widely cited 85 per cent of 12 to 24 year olds figure is unverified. Diet evidence is genuinely contested: a consistent observational association with high glycaemic load and dairy, small trial effects, and strong popular overstatement; all positions are recorded. Isotretinoin relapse rates vary with cumulative dose and are disputed. The association between isotretinoin and depression is contested, with large cohort studies not supporting a causal link while case reports and regulatory warnings persist; both exist. No predictor of scarring exists. Psychological burden is widely documented and not quantified in any source read.

---

### Contact dermatitis (irritant and allergic)

**What it is.** Skin inflammation caused by something touching it — either a direct chemical injury, which is irritant contact dermatitis, or an immune reaction to a specific substance, which is allergic contact dermatitis. Remove the cause and it clears; keep contact and it does not.

**Measured.** Counted within the dermatitis group at **15.2 million** years lived with disability, 95% uncertainty interval 8.9 to 24.2, the eighteenth leading cause. Contact dermatitis is not separately quantified in any source read.

It is consistently reported as the commonest occupational skin disease and among the commonest occupational diseases overall, accounting for a large share of occupational disease claims in countries with reporting systems. Irritant disease is roughly **80 per cent** of occupational contact dermatitis, with allergic disease the remainder.

Occupational cases predominate in working age, with hand eczema in healthcare, cleaning, catering, hairdressing, construction and agriculture. A substantial share of affected workers change or lose their job, which is the measured economic burden. Nickel allergy prevalence fell in Europe after regulation of nickel release in consumer items — a documented regulatory effect.

**Where it starts.** Irritant: cumulative exposure to water (wet work), soaps and detergents, solvents, oils, acids and alkalis, friction, and low humidity. Wet work — prolonged or repeated hand wetting and glove occlusion — is the dominant occupational cause. There is no immune memory; it is dose-dependent injury.

Allergic delayed hypersensitivity to a specific allergen. The commonest, from patch-test series:

- **Nickel** — the most frequent positive patch test worldwide; jewellery, fasteners, coins, mobile devices.
- **Fragrance mix and balsam of Peru.**
- **Preservatives: methylisothiazolinone**, which caused a documented European epidemic after its introduction into leave-on cosmetics, **formaldehyde releasers,**

Risk factors: atopic dermatitis raises irritant contact dermatitis risk substantially; female sex, reflecting exposure; and existing barrier damage, which enables sensitisation.

Genuinely not known: why only some exposed people become sensitised to a given allergen. Why some sensitised people react at tiny exposures and others need large ones. Whether irritant damage is a necessary precursor to sensitisation in most cases. Why a minority have persistent post-occupational dermatitis that continues for years after all exposure stops — this is the clinically important unknown, and it undermines the as-

| |
|---|
| **Cure status.** CURABLE. Both forms resolve completely when the causative exposure is removed and the skin is allowed to heal, with no residual deficit and no treatment needed thereafter. That makes this one of the clearest curable entries in this part of the chapter. |

---

Two qualifications. **Allergic sensitisation is lifelong**: the dermatitis is cured, the allergy is not, and re-exposure reproduces it, which is why identification of the allergen is the treatment. **Persistent post-occupational dermatitis** occurs in a minority, continuing after exposure ceases, and in those patients the condition behaves as controllable.

Where the exposure cannot be removed, because it is the person's livelihood, the cure is theoretically available and practically not, which is the core difficulty of occupational skin disease.

**Prevention.** This is the strongest prevention entry in this part of the chapter and much of it is regulatory.
- **Substitution of the allergen or irritant at source** — the top of the hierarchy of controls. **STRONG**. The documented effects: **nickel release regulation** in the European Union reduced nickel allergy prevalence; **adding ferrous sulfate to cement** to reduce hexavalent chromate largely eliminated cement chromate dermati-

**Treatment.** 1. **Identifying and removing the cause.** The definitive treatment; everything else is adjunctive. Cost: an occupational history, and patch testing where the allergen is not obvious. 2. **Patch testing** — the only way to identify an allergen. Not a medicine. It requires a standard allergen series and three clinic visits; the capital cost is modest and the series is reusable. 3. **Topical corticosteroids**, po-

**Simple means.** Very strong, and almost entirely behavioural and organisational.

———

- **Finding and removing the cause.** Free. An occupational and hobby history, plus the distribution of the rash, identifies the culprit in many cases without any test. - **Reducing hand washing frequency and using lukewarm rather than hot water.** Free, and the action is omission. - **Removing rings before wet work**, since they trap water and detergent against the skin. Free. - **Cotton glove**

What the chain minimally requires: for allergen identification where the cause is not obvious, a patch test series and a clinic — otherwise nothing but soap discipline, paraffin and a cheap steroid.

**Gaps.** Contact dermatitis is not separately quantified in Global Burden of Disease or World Health Organization sources read; only the combined dermatitis total is available. The roughly 80 per cent irritant share of occupational cases is unverified. Patch test positive-allergen frequencies come from clinic series, which are selected populations and not population prevalence. **The effect sizes of the nickel, chromate and**

## Urticaria (hives)

**What it is.** Itchy raised weals that come up and fade within a day, often with deeper swelling of lips or eyelids. Most episodes are short-lived. In the chronic form they keep appearing for months or years and no cause is ever found.

**Measured.** No global figure was retrievable, and a Global Burden of Disease 2021 allergic-related skin disease analysis exists and was unreachable. Lifetime prevalence of any urticaria is commonly reported at about **20 per cent**, and point prevalence of chronic spontaneous urticaria at roughly **0.5 to 1 per cent**†.

Chronic spontaneous urticaria peaks in ages 20 to 40 and is about twice as common in women†. It remits spontaneously within one year in roughly **half** of patients, and persists more than five years in a substantial minority. Sleep disruption and quality-of-life impairment are measurably severe — comparable to ischaemic heart disease in some quality-of-life studies — which is disproportionate to how the condition is usually regarded.

**Where it starts.** - **Mast cell degranulation with histamine release** — the final common mechanism for all forms. - **Acute urticaria:** viral infection is the commonest trigger, especially in children, and also drugs, foods and insect stings. - **Chronic spontaneous urticaria:** autoimmune in a substantial share, with IgG autoantibodies against IgE or its receptor, demonstrated by the autologous serum skin test and by basophil activation, and associated with autoimmune thyroid disease. **No external trigger is found in the majority**, and that is the defining feature. - **Chronic inducible urticaria:** physical triggers reproducibly provoke weals — dermographism, cold, heat, delayed pressure, solar, vibratory, and cholinergic from heat, exercise or stress. - **Drugs:** NSAIDs and aspirin exacerbate existing urticaria in roughly a third of chronic patients, which is pharmacological rather than allergic. ACE inhibitors cause bradykinin-mediated angio-oedema, a different mechanism that does **not** respond to antihistamines. - **Food** — a genuine cause of acute urticaria in true IgE food allergy, and rarely the cause of chronic urticaria, contrary to widespread belief; extensive dietary investigation in chronic urticaria is usually unrewarding.

Genuinely not known: why chronic spontaneous urticaria starts, and why it stops. In most patients no cause is identified despite full investigation, and extensive testing is therefore not recommended — a rare instance where the evidence-based action is to **not** investigate. Why it remits after months or years in most people is unexplained. Why some patients need fourfold antihistamine doses and others respond to standard doses is unknown.

**Cure status.** Acute: SELF-LIMITING. Chronic: CONTROLLABLE.

Acute urticaria resolves within days to six weeks by definition, and antihistamines only shorten the symptom while it runs its course. Chronic urticaria is controllable: antihistamines, and omalizumab for refractory disease, suppress the weals effectively, and symptoms return when treatment stops. No treatment removes the underlying tendency. Chronic spontaneous urticaria also remits spontaneously, in roughly half within a year, so a large share of patients are eventually free of it without any treatment having cured it.

**Prevention.** - **Avoiding an identified trigger** where one genuinely exists — a specific food in IgE allergy, a drug, a physical stimulus. **STRONG** where identified, which is a minority of chronic cases. - **Avoiding NSAIDs and aspirin in chronic urticaria**, which prevents exacerbation in about a third. **MODERATE**, free, and the action is omission. - **Stopping an ACE inhibitor** in ACE-inhibitor angio-oedema. **STRONG**, free, and the action is omission. - **Avoiding overheating, tight clothing, hot showers and alcohol**, which lower the weal threshold non-specifically. **WEAK**, free. - **Treating any identified infection or thyroid autoimmunity. WEAK**; treating thyroid disease does not reliably improve the urticaria. - **Not pursuing extensive allergy testing or elimination diets in chronic spontaneous urticaria** — a prevention of harm and cost, since they rarely help and elimination diets risk nutritional damage. **MODERATE**, the action is omission, and it is a saving. - **Nothing prevents chronic spontaneous urticaria.**

**Treatment.** 1. **Second-generation non-sedating H1 antihistamines — cetirizine, loratadine, fexofenadine, desloratadine — at standard dose, increased up to fourfold if needed.** First-line, and the fourfold updosing step is guideline-endorsed and effective in many who fail standard doses. **Loratadine and cetirizine are on the Essential Medicines List** — the list document did not load. Off-patent. **Cents per tablet** generic, among the cheapest effective treatments in this part of the chapter. 2. **Sedating first-generation**

**antihistamines (chlorphenamine, hydroxyzine)** at night only; not preferred because of sedation and anticholinergic effects. Chlorphenamine listed, off-patent, cents. 3. **Omalizumab (anti-IgE)** for antihistamine-refractory chronic spontaneous urticaria. Highly effective. **Omalizumab is not on the Essential Medicines List in any form — not as a selected medicine and not as a therapeutic equivalent**. On-patent, with biosimilars emerging. **Thousands of US dollars per patient-year**. 4. **Ciclosporin** for refractory disease — effective and far cheaper than omalizumab. **Listed**, off-patent, low cost. It requires blood pressure and renal monitoring. 5. **A short course of oral corticosteroid** for a severe flare only, and **not for maintenance**, because of cumulative harm. Prednisolone listed, off-patent, cents per day. 6. **Montelukast** as an add-on — weak evidence. 7. **Adrenaline (epinephrine) intramuscularly** for urticaria with anaphylaxis or airway angio-oedema. **Listed**, off-patent, low cost, and life-saving. Adrenaline does **not** work for bradykinin-mediated ACE-inhibitor angio-oedema. 8. **Not indicated:** routine extensive allergy testing, elimination diets, and antihistamine creams. **The action is omission.**

**Simple means.** Good, and the first-line drug is already nearly free.

- **Generic cetirizine or loratadine** at **cents per tablet**, listed and off-patent, controls most urticaria. Fourfold updosing costs four times almost nothing.
- **Cool compresses, cool showers, loose cotton clothing, keeping the room cool.** Free, and it genuinely reduces weal formation because heat lowers the threshold.
- **Calamine lotion** for symptomatic relief — **listed**, off-patent, pennies.
- **Stopping NSAIDs and aspirin.** Free, the action is omission, and it is effective in about a third of chronic patients.
- **Stopping an ACE inhibitor** in angio-oedema. Free, and definitive.
- **A symptom and exposure diary.** A notebook. It identifies the physical triggers in inducible urticaria better than any laboratory test, and it also demonstrates to the patient that no food is responsible — which is often the main therapeutic gain.
- **Explanation:** that it is not usually an allergy, that extensive testing will not help, that it is not dangerous unless the airway is involved, and that it usually goes away in time. Free, and it prevents years of futile dietary restriction.
- **Not paying for allergy test panels or elimination diets.** The action is omission and it is a direct saving.
- **Knowing when it is dangerous:** lip, tongue or throat swelling, or breathing difficulty, means immediate care. Free knowledge that prevents death.

What the chain minimally requires: a cheap antihistamine. Only the refractory minority need ciclosporin with monitoring, or omalizumab at thousands per year.

**Gaps.** No verified global prevalence or burden figure; the Global Burden of Disease 2021 allergic-skin analysis was unreachable and no World Health Organization source quantifies urticaria. All prevalence figures above are unverified. The autoimmune share of chronic spontaneous urticaria is estimated differently across studies depending on the assay used. Remission rates vary substantially between cohorts. The evidence base for fourfold antihistamine updosing is accepted in guidelines and rests on limited trial data. Montelukast add-on evidence is weak and sources disagree. Popular belief and the evidence diverge sharply on food as a cause of chronic urticaria; the evidence position is recorded here.

---

## Rosacea

**What it is.** Persistent redness of the central face, with flushing, visible small blood vessels, and often spots that look like acne. In some people the nose thickens over years. It affects fair-skinned adults most and runs a relapsing course.

**Measured.** No global figure was retrievable. Prevalence is commonly reported at around **5 per cent** of adults globally, with much higher figures in northern European populations and lower reported figures in Asian and African populations — although under-recognition in darker skin is a known problem and likely explains part of that difference.

Onset is typically between **30 and 50** and it is rare before 20†. It is more commonly diagnosed in women, and **phymatous rosacea (rhinophyma) occurs almost exclusively in men**. Associations are reported with cardiovascular risk factors, inflammatory bowel disease, migraine and depression.

**Ocular rosacea** affects a substantial share — commonly reported around **50 per cent** — and causes dry eye, blepharitis, meibomian gland dysfunction and, rarely, corneal damage. This connects directly to the dry eye and keratitis entries earlier in this chapter.

**Where it starts.** - **Neurovascular dysregulation** — abnormal vasodilatation and flushing responses, the earliest feature. - **Innate immune activation** — raised cathelicidin and kallikrein-5 in affected skin†. - ***Demodex folliculorum*** mite density is increased in rosacea skin, and anti-Demodex treatment with ivermectin is effective — and whether the mite is cause or consequence is **not established**. - **Fair skin, Fitzpatrick types I to II; northern European ancestry; family history**. - **Cumulative ultraviolet exposure**. - **Trigger factors that provoke flushing episodes rather than cause the disease:** heat, sun, hot drinks, spicy food, alcohol and especially red wine, exercise, emotional stress, cold wind, and topical corticosteroids. - **Topical corticosteroid use on the face** — causes steroid-induced rosacea and perioral dermatitis, and worsens existing rosacea. An important iatrogenic cause, and the reason facial steroids must be used cautiously. - ***Helicobacter pylori* and small intestinal bacterial overgrowth** — associations reported, causal role **CONTESTED**.

Genuinely not known: the cause. Whether the vascular, immune and microbial findings are one process or several. Whether *Demodex* is causal. Why rhinophyma affects men almost exclusively. Whether rosacea subtypes are stages of one disease or distinct conditions — the classification was revised from subtypes to a phenotype-based approach precisely because this is unresolved.

**Cure status.** CONTROLLABLE. No treatment cures rosacea. Inflammatory papules and pustules respond well and can be cleared; background **erythema and telangiectasia respond poorly to drugs** and need laser or light treatment, which improves and does not remove them; and **rhinophyma is permanent** and requires surgical reduction. Relapse after stopping treatment is the rule, so maintenance is usually required. The fixed vascular and phymatous changes are not reversible medically at all.

**Prevention.** - **Sun protection — daily broad-spectrum sunscreen, hats, shade.** The most consistently recommended preventive measure; cumulative ultraviolet exposure drives the vascular change. **MODERATE**. - **Identifying and avoiding personal flush triggers** — heat, hot drinks, alcohol, spicy food, extremes of temperature. Reduces flare frequency. **MODERATE**, and free. - **Avoiding topical corticosteroids on the face.** Prevents steroid-induced rosacea and prevents worsening. **STRONG**, free, and the action is omission. - **Gentle skin care — a mild non-soap cleanser, no astringents, no abrasive scrubs, no alcohol-containing toners. MODERATE**, and free. - **Early treatment to prevent progression to rhinophyma** — plausible and **not demonstrated**; there is no trial evidence that treating papulopustular disease prevents phymatous change. **WEAK**. - **Nothing prevents the disease itself.**

**Treatment.** 1. **Topical ivermectin 1 per cent.** Among the most effective topical agents for papulopustular rosacea. **Ivermectin is on the Essential Medicines List**, listed as a 3 mg tablet under intestinal anthelminthics, antifilarials and medicines for ectoparasitic infections; the topical cream's status was not confirmed. Off-patent as a molecule. The licensed cream is priced far above the bulk cost of the drug. 2. **Topical metronidazole 0.75 to 1 per cent.** Long-standing first-line, effective for papulopustular disease. **Metronidazole is listed** in oral and intravenous form. Off-patent, low cost generic. 3. **Topical azelaic acid 15 to 20 per cent.** Comparable efficacy to metronidazole. Off-patent, low cost. 4. **Oral tetracyclines — doxycycline**, including the sub-antimicrobial 40 mg modified-release dose, which is anti-inflammatory without antibiotic selection pressure. **Doxycycline is listed**, off-patent, and the standard generic costs **cents per day**. 5. **Oral isotretinoin, low dose**, for severe or refractory papulopustular disease. Not listed. Off-patent. Teratogenic. 6. **Topical brimonidine or oxymetazoline** for transient erythema reduction; the effect lasts hours and rebound erythema occurs. 7. **Vascular laser or intense pulsed light** for telangiectasia and fixed erythema — the only effective treatment for these features. Not listed. Expensive, repeated sessions, rarely available. 8. **Surgical or laser reduction of rhinophyma** — the only treatment for established phymatous change. 9. **Ocular rosacea:** lid hygiene, warm compresses, artificial tears, oral doxycycline, topical ciclosporin. The lid hygiene measures in the dry eye entry apply directly and are free.

**Simple means.** Reasonable, and the behavioural measures carry real weight because flushing drives the disease.

- **Trigger identification with a simple diary**, then avoidance. A notebook. Triggers are individual, and identifying them is more useful than any test.
- **Sun protection:** a wide-brimmed hat and shade cost nothing; sunscreen is a few dollars a bottle. This is the main preventive measure.
- **Gentle cleansing with a mild non-soap cleanser, lukewarm water, no scrubbing, no alcohol-based toners.** Free, and it stops a common aggravating practice.
- **Stopping topical steroids on the face.** Free, the action is omission, and in steroid-induced rosacea it is curative — with a withdrawal flare to warn the patient about.
- **Cool compresses and cool drinks** during flushing, and avoiding hot drinks, alcohol and spicy food where they are personal triggers. Free.
- **Generic topical metronidazole and oral doxycycline** — both cheap, both with listed parent molecules, both effective for the papulopustular component.
- **Lid hygiene for ocular rosacea:** warm compresses with a clean cloth and lid margin cleaning, twice daily. Free, and it is the primary treatment for the eye involvement.
- **Green-tinted cosmetic camouflage** for fixed redness — cheap, and it addresses the feature that drugs do not.

What the chain minimally requires: for erythema and telangiectasia, a vascular laser; for rhinophyma, surgery. These are the components with no simple substitute. The inflammatory component is manageable with cents-per-day generics.

**Gaps.** No verified global prevalence figure. The 5 per cent figure is unverified. Prevalence in darker skin is probably substantially underestimated because erythema is harder to see, and this is a recognised measurement problem rather than a true difference. The role of *Demodex* is unresolved despite effective anti-Demodex treatment. Whether treating early disease prevents rhinophyma has never been tested. The *Helicobacter pylori* association is contested. Reported ocular involvement rates vary widely depending on how carefully the eyes are examined. The topical ivermectin price gap between bulk drug and licensed cream could not be quantified.

---

## Vitiligo

**What it is.** The cells that make skin pigment are destroyed, leaving sharply defined white patches that spread unpredictably. It does no physical harm. In many societies it carries severe social stigma, which is the real burden.

**Measured.** No global figure was retrievable. Prevalence is commonly reported at about **0.5 to 2 per cent** of the world population, with remarkable consistency across populations and ethnicities. Onset is before age 30 in about half and can begin at any age†. It affects men and women about equally, though women present more often.

Prevalence is broadly similar worldwide, and **visibility and therefore stigma are far greater in darker skin**, with reported burden highest in South Asia and parts of Africa. The measured burden is almost entirely psychosocial — depression, anxiety, social and marital discrimination, and in some settings documented effects on employment and marriage prospects. In parts of South Asia vitiligo has historically been confused with leprosy, compounding the stigma.

**Where it starts.** - **Autoimmune destruction of melanocytes** — the established mechanism; CD8+ T cells targeting melanocyte antigens, with interferon-gamma and CXCL10 signalling, which is why JAK inhibitors work†. - **Genetic predisposition** — over 50 susceptibility loci identified, including *HLA*, *TYR*, *NLRP1* and *PTPN22*; family history in roughly a fifth†. - **Other autoimmune disease** — autoimmune thyroid disease is substantially more common in vitiligo patients, and thyroid function testing is standard; also type 1 diabetes, pernicious anaemia, alopecia areata, Addison disease†. - **The Köbner phenomenon** — new patches appear at sites of skin trauma, friction or pressure. - **Chemical depigmentation** — phenolic compounds, including some hair dyes and occupational chemicals, can trigger it. - **Emotional stress** — commonly reported by patients as preceding onset or spread; **CONTESTED** as a cause.

Genuinely not known: why melanocytes are targeted, and why in the distribution they are. Why it spreads in bursts and then stops for years. Why segmental vitiligo behaves completely differently from the generalised form — stabilising early and responding to grafting — and

whether it is a different disease. No test predicts who will progress. Whether stress is causal or merely remembered is unresolved.

**Cure status.** CONTROLLABLE. Repigmentation is genuinely achievable in many patients, which deserves emphasis because vitiligo is widely believed to be untreatable. Narrowband ultraviolet B with topical therapy produces substantial repigmentation in a large share of patients, and topical and oral JAK inhibitors — ruxolitinib cream, ritlecitinib — have produced high repigmentation rates in trials and are now licensed.

Against that: the face and neck respond well while **hands, feet and areas with white hair respond poorly or not at all**; repigmentation takes months; and relapse after stopping treatment is common, so maintenance is needed. The autoimmune predisposition remains.

Surgical melanocyte grafting can be definitive in stable **segmental** vitiligo — the one subgroup approaching cure. Depigmentation of the remaining normal skin with monobenzone is an option in very extensive disease, and that is an irreversible alternative endpoint rather than a cure.

**Prevention.** - **No primary prevention is established.** Nothing prevents vitiligo. - **Avoiding skin trauma, friction and pressure** at affected and at-risk sites, given the Köbner phenomenon — including avoiding tight clothing and aggressive scrubbing. **MODERATE**, and free. - **Avoiding phenolic depigmenting chemicals** — occupational, and some hair dyes. **MODERATE**. - **Sun protection of depigmented patches**, which have no melanin protection and burn readily, and sunburn can itself trigger spread. **STRONG** for burn prevention, **MODERATE** for preventing spread. - **Early treatment of active spreading disease to arrest progression** — short courses of systemic corticosteroid or JAK inhibition can halt rapid spread. **MODERATE**. - **Screening for and treating associated autoimmune thyroid disease** — this does not affect the vitiligo and prevents a separate treatable disease. **STRONG** for that purpose.

**Treatment.** 1. **Topical corticosteroids** — first-line for limited disease, particularly in children. **Betamethasone and hydrocortisone are listed**. Off-patent. **Cents to a few dollars per tube.** Facial use requires caution and periodic breaks. 2. **Topical calcineurin inhibitors — tacrolimus, pimecrolimus** — preferred for face, eyelids and children, with comparable efficacy to steroids on the face without atrophy. Not listed. Off-patent. Higher cost than steroids. 3. **Narrowband ultraviolet B phototherapy, two to three times weekly for months.** The most effective widely available treatment for generalised vitiligo. Not a medicine. Capital equipment, low running cost; the constraint is attendance two to three times weekly for many months. 4. **Topical JAK inhibitor — ruxolitinib cream; and oral ritlecitinib**. **Not listed.** On-patent. **Thousands of US dollars per patient-year**. 5. **Combining phototherapy with a topical agent** — more effective than either alone. 6. **A short-course systemic corticosteroid, as an oral mini-pulse**, to arrest rapidly spreading disease. Prednisolone and dexamethasone listed, off-patent, cents. 7. **Surgical melanocyte transfer — punch, split-thickness or suction blister grafting, melanocyte-keratinocyte suspension** — for stable disease, especially segmental. Can be definitive. 8. **Depigmentation with monobenzone** for very extensive disease. Irreversible. 9. **Cosmetic camouflage, self-tanning preparations containing dihydroxyacetone, medical tattooing.** These address the actual complaint directly and immediately. 10. **Psychological support.** Given that the burden is overwhelmingly psychosocial, this is not an adjunct but a core treatment.

**Simple means.** Substantial, and they target the real burden.

- **Sunlight.** Natural ultraviolet with a topical agent produces repigmentation, and in settings without phototherapy cabinets this is the available route — with careful, graduated exposure, because depigmented skin burns readily and burning can worsen the disease. Free.
- **Sun protection of the patches** — hat, clothing, shade, and sunscreen where affordable. It prevents painful burns and reduces contrast between affected and normal skin by stopping the normal skin from tanning darker. Free to cheap, and the contrast reduction matters cosmetically more than it sounds.
- **Topical hydrocortisone or betamethasone** — listed, off-patent, **cents per tube** — for limited disease.

- **Cosmetic camouflage:** ordinary foundation or concealer matched to the normal skin, and **self-tanning lotion** containing dihydroxyacetone, which stains the depigmented skin brown for several days and is cheap, needs no prescription and works immediately regardless of disease activity. For the patient whose complaint is appearance, this is often the most useful single measure available.
- **Avoiding trauma and friction** to affected areas. Free.
- **Explanation:** that it is not infectious, not leprosy, not contagious, not caused by diet, and does no physical harm. Free — and in high-stigma settings this is the intervention with the largest effect on the patient's actual life.
- **Family and community education, and support groups.** Free, and they address the discrimination directly.
- **Thyroid function testing** where available — cheap, and it finds a treatable associated disease.

What the chain minimally requires for repigmentation: either a phototherapy cabinet with months of twice-weekly attendance, or sunlight plus a topical agent, or JAK inhibitors at thousands per year. For the stigma, nothing but words and cheap cosmetics.

**Gaps.** No verified global prevalence figure; the Global Burden of Disease 2021 immune-skin analysis was unreachable. The 0.5 to 2 per cent range is unverified. Whether psychological stress triggers onset or spread is contested — consistently reported by patients, not demonstrated in controlled study. Repigmentation rates with phototherapy and with JAK inhibitors vary widely by body site and could not be verified. Relapse rates after stopping treatment are not well established. Whether segmental vitiligo is the same disease as generalised vitiligo is unresolved. The psychosocial burden is extensively documented qualitatively and not quantified in any source read, and it is the principal burden of the condition.

---

### Alopecia areata

**What it is.** The immune system attacks hair follicles, so hair falls out in sharply defined round patches. It can regrow by itself, and it can also progress to loss of all scalp or all body hair. The hair follicle is not destroyed, which is why regrowth remains possible for years.

**Measured.** No global figure was retrievable. Lifetime risk is commonly reported at about **2 per cent**, with point prevalence around **0.1 to 0.2 per cent**†. It can begin at any age, with onset before 30 in a majority, and childhood onset carries a worse prognosis†. Incidence is roughly equal between the sexes and prevalence is broadly similar worldwide.

---

Most patients have limited patchy disease. **Alopecia totalis**, all scalp hair, and **alopecia universalis**, all body hair, affect a minority — commonly reported around **5 to 10 per cent** of cases — and carry a much poorer prognosis†. Spontaneous regrowth within a year occurs in a substantial share of limited patchy disease, commonly reported at around **50 per cent or more**, and recurrence over a

The burden is entirely psychosocial and severe — depression, anxiety and quality-of-life impairment comparable to that in serious physical disease.

**Where it starts.** - **Autoimmune attack on the hair follicle**, with collapse of follicular immune privilege. CD8+ T cells and the JAK-STAT and interferon-gamma pathway are the established effectors, which is why JAK inhibitors work and why they were a mechanistically predicted success. - **Genetic predisposition** — *HLA* associations, *IL2/IL21*, *CTLA4*, *ULBP3/6*; family history in roughly a fifth, and high concordance in

Genuinely not known: the trig- ger. Why the attack is patchy and why patches ap- pear where they do. Why it re- mits spon- ta- neously and then re- curs. Why some pa- tients progress to uni- ver- salis and most do not, with no pre- dic- tive test. Whether stress is causal. The folli- cle itself sur- vives, which is why hair can re- grow after decades — and why the folli- cle is spared de- struc- tion while being at- tacked is not ex- plained.

**Cure status.** CONTROLLABLE. No treatment removes the disease, and two facts must be stated together. Spontaneous regrowth is common in limited patchy disease — around half or more within a year — so a substantial share of patients recover without treatment. That is self-limiting behaviour within a relapsing condition.

JAK inhibitors produce substantial regrowth in severe disease, including alopecia totalis and universalis that was previously untreatable: baricitinib, ritlecitinib and deuruxolitinib are licensed, with a large share of treated patients achieving major scalp hair regrowth. That is a genuine therapeutic advance. Relapse on stopping is usual, so treatment is indefinite, and the cost is tens of thousands

**Prevention.**

- **Nothing prevents alopecia areata.** No primary prevention is established.
- **Treating associated autoimmune disease.** This does not prevent or improve the alopecia and it finds separate treatable conditions. **STRONG** for that purpose; thyroid function testing is standard.
- **Correcting iron and vitamin D deficiency** where present. **WEAK/CONTESTED** for the alopecia itself.
- **Avoiding un-**

**Treatment.** 1. **Topical corticosteroids, potent or very potent.** First-line for limited patchy disease and in children. **Betamethasone is listed**. Off-patent. **Cents to a few dollars per tube.** 2. **Intralesional corticosteroid injection (triamcinolone acetonide)** — the most effective treatment for limited patchy disease, injected into the patch every 4 to 6 weeks†. Triamcinolone and dexamethasone are listed,

**Simple means.** Reasonable, and the highest-value option is a cheap injection.

———

- **Watchful waiting with explanation.** Free, and correct for limited disease, where around half or more regrow within a year. The explanation — that the follicle is not dead, that regrowth is common, that it is not infectious and not caused by anything the patient did — is itself the main intervention for many.
- **Intralesional triamcinolone.** The drug costs cents per session and it is the

What the chain minimally requires: a needle and a vial of triamcinolone for patchy disease. For severe disease, either a JAK inhibitor at tens of thousands per year, or methotrexate with blood monitoring at a few dollars a month.

**Gaps.** No verified global prevalence figure; the Global Burden of Disease 2021 immune-skin analysis was unreachable. All prevalence figures above are unverified, including the 2 per cent lifetime risk, the 5 to 10 per cent totalis and universalis share, and the 50 per cent spontaneous regrowth rate — this last varies substantially between sources and depends heavily on disease extent at presenta-

## Fungal skin infections (tinea and cutaneous candidiasis)

**What it is.** Fungi growing in the dead outer layer of skin, hair or nails. Ringworm on the body, athlete's foot between the toes, jock itch in the groin, scalp ringworm in children, and thrush in warm moist skin folds. Itchy, scaly, and usually easy to clear.

**Measured.** Fungal skin disease has high global prevalence, and the Global Burden of Disease 2021 fungal skin analyses were unreachable, so no condition-level global count was retrievable. Fungal skin diseases are consistently among the **most prevalent diseases of any kind** in Global Burden of Disease analyses, with prevalence commonly reported in the **hundreds of millions to over a billion** people, and tinea pedis alone affecting a very large share of adults.

Tinea capitis, of the scalp, is predominantly a disease of children, especially in sub-Saharan Africa; tinea pedis and onychomycosis rise with age; candidal intertrigo concentrates in infants, older people, people with obesity and people with diabetes. Tinea capitis prevalence in school surveys in parts of sub-Saharan Africa has been reported very high, frequently tens of per cent of schoolchildren.

**Terbinafine-resistant *Trichophyton indotineae*** has emerged and spread internationally from South Asia, causing extensive treatment-refractory tinea — a significant recent development.

**Where it starts.** - **Dermatophyte fungi** — *Trichophyton*, *Microsporum* and *Epidermophyton* species — invading keratin. *T. rubrum* is the commonest cause of tinea pedis and corporis worldwide. - ***Candida albicans*** and related yeasts for candidal intertrigo and thrush — commensals that overgrow in warm, moist, occluded skin. - **Warmth, moisture, occlusion and sweating** — the key modifiable conditions: occlusive footwear, shared showers, prolonged glove wear, skin folds in obesity. - **Direct contact** — person to person, as in tinea capitis in households and schools; animal to person, as with *M. canis* from cats and dogs; and via soil. - **Shared items** — combs, clippers, hats, towels, barbers' tools, bedding and shared bathroom floors. Barbering is a documented transmission route for tinea capitis. - **Diabetes, obesity, immunosuppression, and topical corticosteroid use on an undiagnosed rash.** The last produces *tinea incognito*, where steroids suppress the inflammation, allow the fungus to spread, and make the diagnosis much harder. - **Crowding and limited access to washing facilities**.

Genuinely not known: why some people are repeatedly and extensively affected while household contacts with identical exposure are not — host susceptibility to dermatophytes is poorly characterised. Why *T. rubrum* causes chronic, barely inflamed infection while zoophilic species cause florid inflammation. The drivers of *T. indotineae* resistance emergence — unregulated topical steroid-antifungal combination use in South Asia is the leading explanation and is not established. Whether treating asymptomatic carriers of tinea capitis prevents community transmission is unresolved.

**Cure status.** CURABLE, and cheaply. Topical antifungals cure the great majority of tinea corporis, cruris and pedis, and candidal intertrigo, with cure rates commonly reported at **70 to 90 per cent** for a two- to four-week course†. Treatment stops and the infection does not return unless reinfection occurs.

Qualifications. **Tinea capitis requires oral treatment** — topicals do not penetrate the hair shaft — and oral griseofulvin or terbinafine cures it. **Onychomycosis**, of the nail, requires months of oral treatment with cure rates well below those for skin, commonly reported around **50 to 70 per cent** mycological cure with relapse common†; it is the least curable form. Reinfection is common where the predisposing conditions persist, so the episode is cured while the tendency is not. *T. indotineae* is terbinafine-resistant and requires itraconazole, often prolonged.

**Prevention.** Nearly all free, and effective. - **Keeping skin dry — drying carefully between the toes and in skin folds after washing. MODERATE**, and free. - **Footwear measures — breathable shoes, changing socks, alternating shoes, sandals in communal showers, going barefoot where safe. MODERATE**. - **Not sharing towels, combs, clippers, hats or bedding; sterilising barbers' clippers. MODERATE** for tinea capitis. - **Treating household contacts and pets.** The animal source is frequently the reservoir, and treating the child without the cat guarantees recurrence. **MODERATE**. - **Screening and treating in schools where tinea capitis is prevalent. MODERATE**. - **Washing and**

**drying clothing and bedding at adequate temperature. MODERATE**. - **Avoiding topical corticosteroids on an undiagnosed scaly rash**, which prevents tinea incognito and extensive spread. **STRONG**, free, and the action is omission. - **Avoiding unregulated steroid-antifungal combination creams**, implicated in resistance emergence. **MODERATE/CONTESTED** as a resistance measure, **STRONG** as good practice. - **Glycaemic control in diabetes. MODERATE**. - **Access to soap and washing water. MODERATE**, and a structural prerequisite.

**Treatment.** 1. **Topical azoles — miconazole, clotrimazole, ketoconazole**, twice daily for two to four weeks, continued a week beyond clearance. First-line for tinea corporis, cruris, pedis and candidal intertrigo. **Miconazole and clotrimazole are on the Essential Medicines List** — the list document did not load and the index showed the dermatological section incompletely. Off-patent. **Well a few US dollars to a few US dollars per tube.** 2. **Topical terbinafine** — slightly higher cure rates and shorter courses than azoles for dermatophytes, and not effective against *Candida*. Off-patent, low cost. 3. **Topical selenium sulfide or ketoconazole shampoo** — for pityriasis versicolor, and as an adjunct in tinea capitis to reduce shedding and transmission. Selenium sulfide is listed. Off-patent, cheap. 4. **Oral griseofulvin** — the long-standing treatment for tinea capitis, particularly for *Microsporum*; it requires six to eight weeks and absorption improves with fatty food. **Listed**. Off-patent. **Low cost, a few US dollars per course**. 5. **Oral terbinafine** — shorter courses than griseofulvin for *Trichophyton* tinea capitis, and the standard for onychomycosis. **Listed**. Off-patent, low cost. 6. **Oral itraconazole or fluconazole** — alternatives, and **itraconazole is the agent for terbinafine-resistant *T. indotineae***. Fluconazole is listed, off-patent, cheap. 7. **Oral or topical nystatin** for candidal infection — listed, off-patent, very cheap. 8. **Treating the reservoir** — household contacts, pets, footwear and shared items. Without this, recurrence is near-certain. 9. **Avoid combination steroid-antifungal creams** as routine therapy. **The action is omission.**

**Simple means.** One of the best simple-means entries in this part of the chapter: a cheap tube cures a very common disease.

- **Topical clotrimazole or miconazole** at **well under a dollar to a few dollars per tube**, listed and off-patent, curing 70 to 90 per cent of common tinea†. Available without prescription in most countries. This is the key cheap-intervention-large-burden combination in the entry.
- **Keeping the skin dry.** Drying carefully between the toes and in skin folds, letting skin folds air, using a cloth rather than leaving moisture. Free, and both preventive and therapeutic.
- **Sunlight and air exposure** to affected skin fold areas. Free.
- **Changing and washing socks and clothing; alternating footwear so shoes dry out; sandals or bare feet where practical.** Free to very cheap, and it removes the warm moist occlusion the fungus requires.
- **Not sharing combs, towels, hats and clippers; cleaning barbers' clippers between customers.** Free, and it interrupts tinea capitis transmission at the point where it mostly happens.
- **Selenium sulfide or ketoconazole shampoo** — cheap, listed, and it reduces shedding and transmission from a child with tinea capitis while oral treatment works.
- **Treating the household and the pet.** Costs another tube.
- **Oral griseofulvin for tinea capitis** at a few dollars a course — listed, off-patent. This is the one form needing an oral drug, and it is still cheap.
- **Not using steroid creams on an undiagnosed scaly itchy rash.** Free, the action is omission, and it prevents extensive tinea incognito.
- **Soap and water.** The structural prerequisite, and where it is absent these infections persist regardless of what else is done.

What the chain minimally requires: a tube of clotrimazole. For scalp and nail disease, an oral antifungal — still cheap and listed, and needing a several-week supply and, for nails, months.

**Gaps.** No condition-level global prevalence figure was retrievable — both Global Burden of Disease 2021 fungal skin analyses were unreachable, and this is one of the most prevalent disease groups in the world, so the gap is material. All prevalence figures above are unverified. Cure rates, 70 to 90 per cent topical for skin and 50 to 70 per cent for nails, are widely cited and unverified. The prevalence and geographic spread of terbinafine-resistant *T. indotineae*

is changing rapidly and no reliable figure exists. Whether topical steroid-antifungal combination misuse caused that resistance is a plausible and unproven explanation. Whether school screening and treating asymptomatic tinea capitis carriers reduces community prevalence is unresolved. The Essential Medicines List status of individual topical antifungals could not be confirmed because the list document did not load.

---

## Bacterial skin infections (impetigo and cellulitis)

**What it is.** Impetigo is a contagious crusted infection of the top layer of skin, mostly in children. Cellulitis is a deeper, spreading infection of the skin and the tissue under it, with redness, heat, swelling and fever. Cellulitis can become dangerous.

**Measured.** No global figure was retrievable for impetigo or cellulitis as such. Impetigo is commonly reported to affect roughly **140 million** people at any one time, with the great majority of cases in children in low- and middle-income countries.

The scabies link is the best-evidenced figure in the entry. Scabies affects **at least 200 million** people at any one time (World Health Organization fact sheet, *Scabies*, 31 May 2023), and scabies mass drug administration trials consistently reduced community impetigo prevalence by **60 to 88 per cent** across three studies in Fiji and the Solomon Islands, which quantifies how much impetigo is scabies-driven in those settings. In Fiji, skin and soft tissue infection **hospitalisations fell 17 per cent** in the year after ivermectin mass administration integrated with lymphatic filariasis control, in a population of about 135,000.

Cellulitis incidence in high-income settings is commonly reported at about **200 per 100,000** person-years, and it is a frequent cause of hospital admission†. Impetigo concentrates in children aged 2 to 5; cellulitis rises with age, obesity, lymphoedema and diabetes†.

The downstream burden is the most consequential measured link in the entry. *Streptococcus pyogenes* skin infection contributes to acute post-streptococcal glomerulonephritis — **acute renal damage appears in up to 10 per cent** of children with scabies in resource-poor settings and can persist for years — and the World Health Organization notes growing evidence that *S. pyogenes* impetigo contributes to rheumatic fever and rheumatic heart disease.

**Where it starts.** - ***Staphylococcus aureus*** and ***Streptococcus pyogenes*** — the two causative organisms for both conditions. - **A break in the skin** — the necessary condition. The commonest breaches are scabies excoriations, quantified above, insect bites, eczema, tinea pedis fissures, cuts, abrasions and burns. - **Scabies** — the dominant precursor of impetigo in endemic settings; scratching breaches the skin and mite activity affects local immunity. - **Crowding, shared bedding, limited water and soap, hot humid climate**. - **For cellulitis specifically:** lymphoedema and chronic oedema, the strongest risk factor and the driver of recurrence; obesity; diabetes; venous insufficiency and leg ulcers; tinea pedis as the portal of entry; and previous cellulitis, which carries a high recurrence rate. - **Intravenous drug use**. - **Atopic dermatitis** — *S. aureus* colonisation and barrier breach.

Genuinely not known: why cellulitis recurs so readily in some people. Lymphatic damage from the first episode predisposing to the next is the leading account, and it is a vicious cycle without a clear entry point for interruption beyond oedema control. Why some *S. pyogenes* strains cause glomerulonephritis or rheumatic sequelae and others do not. How much of the global rheumatic heart disease burden originates in skin rather than throat infection — an open question with real implications, and the scabies mass administration impetigo reductions are the natural experiment that might answer it. Diagnosis of cellulitis is clinical and frequently wrong; misdiagnosis rates against venous eczema, lymphoedema and gout are substantial.

**Cure status.** CURABLE. Both are curable with antibiotics.

Impetigo is also substantially self-limiting — it resolves without treatment in most cases over two to three weeks — and treatment speeds resolution and, importantly, reduces transmission. Topical antibiotics are at least as effective as oral for limited impetigo.

Cellulitis resolves with appropriate antibiotics in the great majority. Untreated, it can progress to abscess, necrotising infection, bacteraemia and death — so it is curable and it is also the entry in this part of the chapter most capable of killing.

Qualifications: recurrence is common in cellulitis where the predisposing oedema persists; and antibiotic prophylaxis reduces recurrence only while it is taken — the PATCH I trial found penicillin prophylaxis reduced recurrence, with the benefit diminishing after stopping.

**Prevention.** - **Treating scabies, including by mass drug administration.** The best-quantified preventive measure in this entry: scabies mass administration reduced community impetigo prevalence by **60 to 88 per cent** in three studies, and reduced skin and soft tissue infection hospitalisations by **17 per cent** in one Fijian population. **STRONG**. - **Soap, water and washing. MODERATE** for impetigo. - **Treating the entry portal** — tinea pedis, eczema, insect bites, wounds. **MODERATE** for cellulitis; treating athlete's foot prevents leg cellulitis. - **Oedema and lymphoedema control — compression, elevation, exercise, skin care.** The key measure for preventing recurrent cellulitis. **MODERATE**. This links directly to the venous leg ulcer entry. - **Emollients to maintain skin integrity in dry or oedematous legs. MODERATE**. - **Weight reduction; glycaemic control. MODERATE**. - **Antibiotic prophylaxis with low-dose penicillin for recurrent cellulitis**, which reduces recurrence while taken. **MODERATE**, with the benefit ending on discontinuation. - **Not sharing towels and bedding; keeping nails short; covering impetigo lesions; excluding from school until crusted or treated. MODERATE** for transmission. - **Prompt wound cleaning. MODERATE**, free.

**Treatment.** For impetigo: 1. **Topical antibiotic — mupirocin or fusidic acid** — for limited disease, at least as effective as oral antibiotics. Mupirocin is listed. Off-patent. A few US dollars per tube. 2. **Topical antiseptics — povidone-iodine, chlorhexidine, hydrogen peroxide** — cheap alternatives with evidence of benefit. Very low cost. 3. **Oral antibiotics — flucloxacillin, cephalexin or amoxicillin-clavulanate** for extensive or bullous impetigo; all listed, all off-patent, **a few US dollars to a few dollars per course**. 4. **Treating concurrent scabies.** Without this, impetigo recurs.

For cellulitis:

5. **Oral flucloxacillin, cephalexin or penicillin** for uncomplicated cellulitis, typically five to seven days. **Listed**, off-patent, **a few US dollars to a few dollars per course**. Oral is as effective as intravenous for most uncomplicated cases, which matters for cost and admission avoidance.
6. **Intravenous antibiotics** for systemic illness, rapid spread or failure of oral therapy. Listed agents, off-patent.
7. **Elevation of the affected limb**, which reduces oedema and speeds resolution. Free, and routinely under-used.
8. **Marking the edge of the erythema** to track progression objectively. A pen.
9. **Analgesia** — paracetamol, ibuprofen; listed, off-patent, cents.
10. **Surgical drainage** for abscess; **urgent surgical exploration** for suspected necrotising infection, which is a surgical emergency and not an antibiotic problem.
11. **Treating the predisposing cause** — tinea pedis, ulcer, oedema. Without this, recurrence follows.

**Simple means.** Strong, and the scabies link makes it exceptional value.

- **Soap and water, and washing.** Free to near-free, and it addresses impetigo directly.
- **Treating scabies with permethrin or ivermectin.** The measured effect on impetigo is a **60 to 88 per cent** community reduction. Ivermectin is donated or very low cost in mass administration programmes, at roughly a few US cents per dose. This is the highest-leverage cheap intervention in the entry: treating a mite removes most of the bacterial skin infection in endemic settings, and with it part of the glomerulonephritis and possibly the rheumatic heart disease burden.
- **Topical antiseptics — povidone-iodine, dilute chlorhexidine, or even clean water and soap with crust removal** — for limited impetigo. Pennies.
- **Covering lesions, keeping nails short, not sharing towels or bedding.** Free.
- **Limb elevation** for cellulitis. Free, effective and under-used.
- **Compression and oedema control** for recurrent leg cellulitis — a bandage, costed in the venous ulcer entry. Cheap, and it attacks the cause of recurrence rather than each episode.
- **Treating athlete's foot** with a tube of clotrimazole under a dollar, which closes the portal of entry for leg cellulitis.

- **A pen to mark the erythema margin**, so progression or improvement is objective. Cents.
- **Oral flucloxacillin or penicillin** — listed, off-patent, under a dollar a course. A life-threatening infection treated for the price of a loaf of bread.
- **Knowing the danger signs** — pain out of proportion, rapid spread, skin necrosis, systemic illness — which indicate necrotising infection needing surgery. Free knowledge that saves lives.

What the chain minimally requires: soap, an antiseptic, and a cheap oral antibiotic. For necrotising infection, an operating theatre urgently.

**Gaps.** No verified global prevalence figure for impetigo or cellulitis; no World Health Organization or Global Burden of Disease source read quantifies them. The roughly 140 million impetigo figure and the roughly 200 per 100,000 cellulitis incidence are unverified. The scabies mass administration impetigo reductions are well sourced and the source reports **no confidence intervals** for any of those figures, which limits their precision. How much global rheumatic heart disease originates in skin rather than throat infection is unknown and potentially large. Cellulitis is frequently misdiagnosed and no source read quantifies the misdiagnosis rate. The duration of benefit of antibiotic prophylaxis after stopping is not established. Topical against oral treatment for impetigo is settled in favour of topical for limited disease, and prescribing practice does not follow it.

---

###
Sca-
bies

**What it is.** A mite burrows into the top layer of skin and lays eggs. The body reacts with ferocious itching, worst at night, and a rash in the finger webs, wrists, waist and genitals. It spreads by prolonged skin contact and runs through households.

ICD-11 codes scabies in chapter 1, among the infectious and parasitic diseases, because it is an infestation passed from person to person. The full entry is there, under Scabies, in the chapter on certain infectious or parasitic diseases.

A reader in the skin chapter is sent there because scabies is met here first, as itch, rash and the impetigo that follows scratching, and the whole condition is in one place there. That entry carries the burden figures, the population-scale results of mass drug administration in Fiji and the Solomon Islands, the treatments and their listing, and the simple means. The infestation is CURABLE, and

## Seborrhoeic dermatitis

**What it is.** Scaly, greasy, slightly red patches where the skin is oiliest — scalp, eyebrows, sides of the nose, chest. Dandruff is its mild form. It is driven by a normal skin yeast and it comes and goes for life.

**Measured.** Counted within the dermatitis group at **15.2 million** years lived with disability, 95% uncertainty interval 8.9 to 24.2; seborrhoeic dermatitis is not separately quantified in any source read. Prevalence is commonly reported at about **3 to 5 per cent** for seborrhoeic dermatitis proper, while **dandruff, its mild form, affects up to half of adults**.

The age pattern is trimodal: infantile cradle cap in the first months, then onset after puberty with a peak in the thirties and forties. It is more common in men, consistent with androgen-driven sebum production. It is substantially more common and more severe in **HIV infection**, reported in a large share of people with advanced HIV, where it can be the presenting sign, and in **Parkinson disease** and other conditions with increased sebum.

**Where it starts.** - ***Malassezia*** yeasts — normal skin commensals, metabolising sebum triglycerides into free fatty acids that irritate the skin. This is the established driver, and it explains why antifungals work. It is **not an infection**; the organism is present on everyone. - **Sebum production.** The disease occurs only in sebaceous areas and tracks androgen activity, which is why it starts at puberty and affects men more. - **Individual susceptibility to *Malassezia* metabolites** — the key variable, since everyone carries the yeast. - **Immunosuppression, especially HIV**. - **Neurological disease — Parkinson disease, stroke, facial nerve palsy**. - **Cold dry weather; stress; fatigue** — reported to worsen it. - **Some drugs**, including those that alter sebum or dopamine signalling.

Genuinely not known: why only some people react to a universal commensal. Why it is associated with Parkinson disease — whether through sebum changes from reduced dopaminergic activity or something else. Why it remits in childhood between the infantile and post-pubertal phases. Why infantile seborrhoeic dermatitis resolves spontaneously and permanently while the adult form does not.

**Cure status.** Adults: CONTROLLABLE. Infants: SELF-LIMITING.

Infantile seborrhoeic dermatitis, cradle cap, resolves spontaneously within weeks to months and does not recur in childhood; treatment is for appearance and comfort only.

Adult seborrhoeic dermatitis is controllable. Topical antifungals and anti-inflammatories clear it reliably and quickly, and it returns within weeks of stopping, because the yeast and the sebum remain. Maintenance treatment, typically once or twice weekly, keeps it suppressed. Nothing eliminates the predisposition, and control is easy, cheap and reliable, which makes this one of the more satisfactory entries in this part of the chapter.

**Prevention.** - **Regular use of an antifungal or medicated shampoo as maintenance**, once or twice weekly, which prevents relapse. **STRONG** for relapse prevention. This is prevention of flares rather than of the condition. - **Nothing prevents the condition itself.** - **Avoiding harsh soaps, hot water and alcohol-containing products on affected skin. WEAK**, free. - **Avoiding heavy occlusive hair oils and pomades** on an affected scalp. **WEAK** . - **Managing HIV with antiretroviral therapy**, which improves seborrhoeic dermatitis along with immune function. **STRONG** in that group. - **Sunlight exposure** — reported to improve it, consistent with ultraviolet suppressing *Malassezia*. **WEAK**. - Poor hygiene does **not** cause it, and excessive washing does not prevent it. Correcting that belief is useful and free.

**Treatment.** 1. **Topical antifungal shampoos and creams — ketoconazole 2 per cent, ciclopirox, selenium sulfide, zinc pyrithione.** First-line and effective. **Selenium sulfide is listed**; topical ketoconazole's status could not be confirmed from the index displayed. Off-patent. **A few US dollars per bottle**, and one bottle lasts months at maintenance frequency. 2. **Topical corticosteroids**, mild to moderate potency, for short courses to settle inflammation and itch. **Hydrocortisone and betamethasone are listed**. Off-patent. **Cents to a few dollars per tube.** Not for prolonged facial use, because of atrophy and steroid-induced rosacea. 3. **Topical calcineurin inhibitors — tacrolimus, pimecrolimus** — steroid-sparing for the face and useful for maintenance. Not listed. Higher cost. 4. **Coal tar shampoo and salicylic acid** — keratolytic and antiscaling; old, cheap, effective. Off-patent, very low cost. 5. **Oral antifungal (itraconazole, fluconazole)** for severe or widespread

disease. Fluconazole listed, off-patent, cheap. 6. **Emollients and oil to soften scale** before removal. 7. **Infantile disease:** softening with an emollient or plain vegetable oil, gentle brushing, mild shampoo. **Treatment is optional**, because it resolves anyway. **The action is omission.** 8. **Antiretroviral therapy** where HIV-associated.

**Simple means.** Very strong — almost everything effective is cheap and available without prescription.

- **An antifungal or medicated shampoo** — ketoconazole, selenium sulfide or zinc pyrithione — at **a few dollars a bottle**, lasting months on once- or twice-weekly maintenance. This is the whole treatment for most patients, needs no prescription in most countries, and is the key cheap intervention in the entry.
- **Using the shampoo on the face and chest, not just the scalp**, left on a few minutes before rinsing. A free extension of an existing cheap product to the other affected sites.
- **Coal tar or salicylic acid shampoo** — among the cheapest effective options.
- **Plain vegetable oil or petroleum jelly** to soften scale before gentle removal, particularly for cradle cap and for thick scalp scale. Pennies.
- **Soft brushing of softened scale** in infants, with a soft brush or cloth. Free.
- **Sunlight.** Free, and reported to improve it.
- **Topical hydrocortisone** — listed, off-patent, cents per tube, for flares.
- **Avoiding harsh soaps, very hot water and alcohol-based toners** on affected skin. Free.
- **Explanation:** that it is not caused by poor hygiene, is not contagious, is not an infection to be eradicated, and that maintenance rather than cure is the realistic goal. Free, and it prevents both over-washing and disappointment.
- **For infants: doing little or nothing**, because it resolves on its own. The action is omission, and it is free.

What the chain minimally requires: a bottle of medicated shampoo. No component of this condition's management requires an industrial supply chain beyond that, except for the severe minority needing an oral antifungal, itself a cheap listed generic.

**Gaps.** Not separately quantified in Global Burden of Disease or World Health Organization sources read; only the combined dermatitis total is available. The 3 to 5 per cent prevalence figure and the "up to half of adults" dandruff figure are unverified. The relationship to *Malassezia* is established and why susceptibility varies is unknown. The association with Parkinson disease is documented and unexplained. Prevalence in HIV is reported as substantially elevated and no verified figure was obtainable. Comparative efficacy between the various antifungal shampoos is not well established and differences are probably small. Optimal maintenance frequency has not been determined by trial. The Essential Medicines List status of topical ketoconazole could not be confirmed.

---

### Pressure ulcers (decubitus ulcers)

**What it is.** Skin and the tissue beneath it die because the weight of the body has pressed on them too long and cut off the blood supply. They form over bony points — heel, hip, buttock, base of the spine — in people who cannot move themselves. Almost all of them are preventable.

**Measured.** No global figure was retrievable. Hospital point prevalence is commonly reported at roughly **5 to 15 per cent** of inpatients in high-income settings, with higher figures in intensive care and in long-term care. The affected are overwhelmingly older people, and people of any age with spinal cord injury or immobility.

Pressure ulcer treatment is consistently reported as a major health system cost, with national cost estimates in the billions of US dollars for individual high-income countries, and treatment costing many times prevention. Pressure ulcers are associated with substantially increased mortality, though much of that reflects the underlying illness and immobility rather than the ulcer itself.

A measurement problem bears on all of these figures: pressure ulcer rates are used as a care-quality indicator, which creates reporting incentives and makes between-institution comparison unreliable.

**Where it starts.** - **Sustained pressure over a bony prominence** — the necessary cause. Tissue tolerance is a function of pressure magnitude and duration together: high pressure for a short time or low pressure for a long time both cause damage. - **Shear and friction** — sliding down a bed, or being dragged rather than lifted. Shear damages deeper tissue at lower pressures. - **Immobility** — the dominant clinical risk factor: un-

Genuinely not known: the exact pressure-time threshold for tissue damage in an individual, which is why risk scores perform only moderately. Why some immobile patients never develop ulcers. **Deep tissue injury** begins at the bone-muscle interface and may be invisible at the skin surface for days, so the moment of injury cannot be identified. Whether the widely used risk assessment scales improve outcomes over

| |
|---|
| **Cure status.** Superficial ulcers, stages 1 to 2: CURABLE. Deep ulcers, stages 3 to 4: RELIEF ONLY. Superficial ulcers, affecting epidermis and dermis, heal completely when pressure is removed, often within weeks, with no residual deficit. |

Deep ulcers, through subcutaneous fat to muscle, tendon or bone, heal by **scar contraction rather than tissue regeneration**, take months, frequently do not heal at all in frail or malnourished people, and recur readily at the same site because scar tissue tolerates pressure poorly. Surgical flap closure can close them and has a substantial recurrence rate.

The decisive point: healing requires that the pressure be removed. No dressing, drug or nutritional supplement heals an ulcer that is still being sat or lain on. This is why the condition is, functionally, a nursing and positioning problem rather than a pharmaceutical one.

**Prevention.** This is the entry where prevention most dominates treatment, and it is almost entirely non-pharmaceutical.

**Repositioning on a schedule.** The foundation of prevention. The conventional two-hourly interval is **convention rather than established evidence**, and the optimal frequency is unknown. **STRONG** as a principle, **uncertain** as to interval. Cost: staff time only.

**Pressure-redistributing support surfaces.** Higher-

———

**Treatment.** 1. **Pressure relief — complete offloading of the ulcer site.** The treatment. Nothing else works without it. Cost: positioning, pillows, staff time, a support surface. 2. **Wound cleansing with water or saline**. Near-zero cost. 3. **Debridement of dead tissue** — sharp, autolytic under a moisture-retaining dressing, or larval. Necessary for deep ulcers. **Dry stable heel eschar is generally left alone.**

**Simple means.** Almost everything that works is simple, and that is the central fact about this condition.

- **Turning the person.** Free. It is the single most effective intervention in existence for this disease, and it requires no equipment, no drug and no supply chain — only someone to do it, and the knowledge that it must be done.
- **Pillows and rolled blankets** to redistribute pressure, offload heels, and position at 30 degrees rather than directly on the hip. Free or near-free, and heel offload-

A disease that costs health systems billions is prevented by moving people and looking at their skin. The binding constraint is staffing, attention and knowledge — not money or technology.

**Gaps.** No global prevalence or burden figure exists on the sources read. All prevalence figures above are unverified, and hospital prevalence figures are distorted by the condition's use as a quality indicator. **The optimal repositioning interval has never been established** — two-hourly is convention, and this is a remarkable evidence gap for the world's most commonly recommended nursing inter-

## Venous leg ulcers

**What it is.** A shallow, often large open sore on the lower leg, usually near the ankle, caused by blood pooling in damaged leg veins. They weep, they ache, they last months or years, and they come back. Compression bandaging heals most of them.

**Measured.** No global figure was retrievable; venous leg ulcers are not quantified on any World Health Organization or Global Burden of Disease source read. Point prevalence is commonly reported at roughly **0.1 to 0.3 per cent** of the general adult population, rising to around **1 to 3 per cent** in people over 80†. The condition is strongly age-related, with a mean age at presentation in the seventies, and it is more common in women.

Duration and recurrence are the defining measured features: a large share have been open for **more than six months** at presentation, and recurrence after healing is commonly reported at **25 to 50 per cent within a year** without continued compression†.

Venous ulcers consume a very large share of community nursing time in high-income health systems, and the dominant cost is nursing visits rather than materials. Venous disease accounts for the majority of all leg ulcers, commonly reported around **70 per cent**, with arterial, mixed, diabetic and other causes making up the rest.

**Where it starts.** - **Chronic venous hypertension** — the necessary cause. Incompetent valves in superficial, deep or perforating veins, or venous outflow obstruction, mean that venous pressure in the leg stays high on standing and walking. - **Previous deep vein thrombosis** — post-thrombotic syndrome. - **Varicose veins and superficial venous incompetence**. - **Calf muscle pump failure** — immobility, ankle stiffness, obesity. The calf pump is what normally lowers venous pressure during walking, so its failure is central. - **Obesity**. - **Age; prolonged standing occupations; previous leg fracture or surgery; family history**.

Genuinely not known: why skin ulcerates in some people with severe venous hypertension and not others with equivalent haemodynamics. The microvascular mechanism connecting venous pressure to skin breakdown is incompletely described — leucocyte trapping, fibrin cuffs and pericapillary fibrin are described without a settled causal sequence. Why some ulcers remain open for years despite optimal compression, and no predictor identifies them in advance. Whether the many adjunctive agents and dressings add anything to compression is largely unresolved.

**Cure status.** The ulcer: CURABLE in roughly 65 to 70 per cent at 24 weeks with adequate compression†. Venous hypertension after healing: CONTROLLABLE, with lifelong compression hosiery.

Venous ulcers heal, and compression is what heals them. Reported healing with adequate compression is roughly **65 to 70 per cent at 24 weeks**, against substantially lower rates without it†. The Cochrane review of compression for venous leg ulcers **could not be retrieved** — the Cochrane Library did not load — and it is the standard reference; its conclusions as commonly reported are that compression heals more ulcers than no compression, that multi-component systems outperform single-component, and that systems containing an elastic component outperform inelastic ones.

The qualification that defines the condition: the venous hypertension remains, so recurrence is **25 to 50 per cent within a year** without continued compression†. The ulcer is cured; the disease is not. Lifelong compression hosiery after healing is therefore part of the control.

Correcting superficial venous incompetence by surgery or endovenous ablation reduces recurrence — the ESCHAR trial found surgery plus compression reduced 12-month recurrence substantially compared with compression alone, and the EVRA trial found early endovenous ablation shortened healing time. That is the nearest thing to curing the underlying disease.

**Prevention.** - **Compression hosiery after healing** — the principal measure against recurrence, which is the main preventable event. **STRONG**. - **Treating superficial venous incompetence** — surgery or endovenous ablation reduces recurrence and speeds healing. **MODERATE**. - **Leg elevation above heart level when resting.** **MODERATE**, free. - **Walking and ankle exercises** to work the calf pump. **MODERATE**, free. - **Weight reduction.** **MODERATE**. - **Skin care — emollients for venous eczema, avoiding trauma, treating tinea pedis.** **MODERATE**, cheap. - **Preventing and properly treating deep vein thrombosis**, including anticoagulation and compression, which prevents post-thrombotic syndrome. **STRONG** for that pathway. - **Pentoxifylline as an adjunct to compression**

— improves healing in Cochrane assessment. **MODERATE**. Off-patent and cheap. - **Treating any arterial component** — and, critically, **measuring the ankle-brachial pressure index before applying compression**, because compression on a severely ischaemic leg causes necrosis. **STRONG** as a safety measure.

**Treatment.** 1. **Graduated compression — multi-component bandaging, typically four-layer, achieving around 40 mmHg at the ankle.** The treatment. Reported healing roughly **65 to 70 per cent at 24 weeks**†. Multi-component systems outperform single-component, and elastic outperforms inelastic. A device, not listed. Off-patent. **Bandage materials are inexpensive — on the order of a few US dollars to low tens of dollars per application, reusable in part — while the dominant cost is the nurse's time.** 2. **Ankle-brachial pressure index measurement before compression** — a Doppler probe and a blood pressure cuff. A mandatory safety step. 3. **A simple non-adherent dressing under the compression.** The dressing choice makes little difference; **compression is the active component** and no dressing type has demonstrated superiority. This is an important cost finding: expensive dressings add cost without demonstrated benefit. 4. **Emollients for surrounding venous eczema; topical corticosteroid** for active eczema. Betamethasone and hydrocortisone listed, off-patent, cents. 5. **Pentoxifylline** as an adjunct, which improves healing. Off-patent, low cost. Not listed. 6. **Early endovenous ablation or surgery for superficial incompetence**. 7. **Debridement** of slough where present; **larval therapy** as an option. 8. **Antibiotics only for clinical infection** — not for colonisation, malodour or slow healing. Routine antibiotic use is common, unhelpful and drives resistance. **The action is omission.** 9. **Analgesia** — listed agents, cents. Venous ulcer pain is substantial and under-treated. 10. **Pneumatic compression** where bandaging is not tolerated. 11. **Skin grafting** for large or refractory ulcers. 12. **Not useful:** most proprietary advanced dressings, honey as a primary agent, topical antiseptics on granulating tissue, and antibiotics without infection.

**Simple means.** Strong, and the active ingredient is a bandage.

- **Compression bandaging.** The single intervention that heals these ulcers, achieving roughly 65 to 70 per cent healing at 24 weeks†. The materials are **inexpensive cotton wadding, crepe and elastic bandage** — a few dollars to low tens of dollars per application — and the skill is learnable by a trained non-specialist or a family member. Where four-layer kits are unavailable, **two-layer crepe-and-elastic bandaging or reusable inelastic wraps** deliver compression at low cost.
- **Leg elevation above heart level** whenever resting, and raising the foot of the bed. Free, and it directly reverses the venous hypertension that causes the ulcer.
- **Walking and ankle flexion exercises** to activate the calf pump. Free, and mechanistically targeted at the actual defect.
- **A simple non-adherent dressing — even clean gauze with petroleum jelly** — under the compression. Since dressing type makes little difference and compression is the active component, this is where large savings are available without losing effectiveness.
- **Washing the leg with clean water and soap**, and emollient to the surrounding skin. Pennies.
- **Reusable compression wraps and hosiery** after healing, which prevent the 25 to 50 per cent annual recurrence†. Cheap relative to repeated ulcer episodes.
- **Treating tinea pedis** with a tube of clotrimazole under a dollar, which removes a portal for cellulitis in an already-compromised leg.
- **Training the patient or a family member to apply compression**, where nurse visits are the dominant cost. This is the main route to affordability.
- **Not buying expensive dressings or antibiotics that do not help.** The action is omission and it is a direct and substantial saving.

What the chain minimally requires: bandage material, and a Doppler probe plus cuff to check the ankle-brachial index before compressing. That safety check is the one genuine equipment requirement, and skipping it on an ischaemic leg causes harm.

**Gaps.** No global prevalence or burden figure exists on the sources read. All prevalence figures above are unverified. **The Cochrane compression review could not be retrieved**, so the compression effect sizes — the central numbers of this entry — are carried as commonly reported rather than verified, and should be retrieved. Healing rates and recurrence rates vary widely between studies and populations. Comparative evidence between compression

systems is moderate and between dressings is weak. The ESCHAR and EVRA effect sizes are unverified. Whether patient-applied compression achieves the same results as nurse-applied is not well established, and this matters greatly for cost. The proportion of leg ulcers that are purely venous against mixed arterial-venous differs between series.

### Diabetic foot ulcers

**What it is.** An open sore on the foot of someone with diabetes. Nerve damage means they cannot feel the injury, and poor circulation means it will not heal. It is the commonest reason for amputation of a leg anywhere in the world outside of accidents.

**Measured.** The denominator is **830 million** people with diabetes in 2022, up from 200 million in 1990, and **14 per cent** of adults aged 18 and over, up from 7 per cent, rising faster in low- and middle-income countries. That is the World Health Organization all-ages figure; other chapters of this book use the International Diabetes Federation figure of **589 million adults aged 20 to 79**†, and the two give sub-

The World Health Organization diabetes fact sheet names lower limb amputation and foot ulcers as consequences and **gives no figures for either**.

---

Lifetime incidence of foot ulceration in people with diabetes is commonly reported at roughly **19 to 34 per cent**, with annual incidence around **2 per cent**†. Diabetes is commonly reported as the cause of a large majority of non-traumatic lower limb amputations, and an amputation is commonly cited as occurring somewhere in the world every 20 to 30 seconds as a consequence of diabetes†.

Five-year mortality after a diabetic foot ulcer is commonly reported at around **30 per cent**, and substantially higher after major amputation — figures comparable to or worse than many cancers. That is the figure that most changes how the condition should be regarded. Recurrence runs roughly **40 per cent within a year** of healing and around **60 per cent within three years**†.

**Where it starts.** Three components, usually combined: - **Peripheral neuropathy** — loss of protective sensation. The person does not feel the blister, the stone in the shoe or the burn. This is the necessary precondition in the large majority. - **Peripheral arterial disease** — impairs healing and determines whether the ulcer progresses to amputation. Present in a large share. - **Repetitive mechanical**

Additional factors: - **Foot deformity** — clawed toes, Charcot neuroarthropathy, prominent metatarsal heads, limited ankle motion. - **Previous ulcer or amputation** — the strongest single predictor of a new ulcer. - **Callus and nail pathology.** Callus concentrates pressure, and untreated callus is a direct precursor. - **Poor glycaemic control; duration of diabetes; smoking; chronic kidney disease, especially dialysis;**

Genuinely not known: why some people with severe neuropathy never ulcerate. Why Charcot neuroarthropathy develops in a few. The relative contribution of neuropathy against ischaemia in a given patient is often hard to determine and it determines treatment. Whether intensive glycaemic control prevents ulceration — it clearly reduces neuropathy progression, and direct ulcer-prevention trial evidence is

**Cure status.** The ulcer: CURABLE — total contact casting heals roughly 80 to 90 per cent of neuropathic plantar ulcers within 6 to 12 weeks†. The foot at risk: CONTROLLABLE — recurrence is around 40 per cent at one year and 60 per cent at three years†.

Ulcers heal when pressure is removed and perfusion is adequate. **Total contact casting** heals roughly **80 to 90 per cent** of neuropathic plantar ulcers within 6 to 12 weeks, and it is the most effective offloading method†. Revascularisation heals ischaemic ulcers that would not otherwise heal.

But recurrence is around **40 per cent at one year and 60 per cent at three years**†, because the neuropathy, the deformity and the pressure distribution are unchanged. The ulcer is curable; the foot at risk remains at risk for life. The condition is better regarded as a lifelong remission-and-relapse state with each episode curable. Where perfusion cannot be restored or infection reaches bone, the out-

---

The label is split, with the recurrence and mortality figures attached, because treating the ulcer and ignoring the foot guarantees the next one.

**Prevention.** This is one of the strongest prevention-against-treatment contrasts in the book.

- **Annual foot screening — testing sensation with a 10 g monofilament, palpating pulses, inspecting for deformity and callus — and risk stratification.** It identifies the at-risk foot before it ulcerates. **STRONG**. The monofilament costs a few US dollars and lasts for hundreds of examinations.
- **Structured patient educa-**

**Treatment.** 1. **Offloading — a total contact cast or non-removable walker.** The most effective treatment: **80 to 90 per cent** healing of neuropathic plantar ulcers in 6 to 12 weeks†. **Non-removable devices outperform removable ones principally because they cannot be removed** — an adherence effect, which is an important and uncomfortable finding. A device, not listed. Materials are plaster or fibreglass cast-

**Simple means.** Strong, and concentrated almost entirely in prevention, which is where the amputations are actually prevented.

- **A 10 g monofilament.** A few US dollars, reusable for hundreds of examinations, and it identifies the insensate foot — the single precondition for almost all diabetic foot ulceration. This is one of the highest-value diagnostic items in the entire book.
- **Looking at the feet.** Free. At every clinic visit, shoes and socks off. The commonest reason ulcers are found late is that nobody looked.
- **Teaching daily self-inspection**,

A monofilament, a pair of shoes that fit, and the habit of looking at the feet prevent a large share of the world’s non-traumatic amputations. What the chain minimally requires for the ischaemic foot is vascular imaging and revascularisation, and that is the component with no cheap substitute.

---

**Gaps.** The diabetes fact sheet names foot ulcers and amputation as consequences and **gives no figure for either**, despite giving the 830 million denominator — a striking gap. All the figures in *Measured* above are unverified: lifetime ulcer incidence, the amputation frequency claim, five-year mortality and recurrence rates are all widely cited and were not verifiable here. The five-year mortality

## Chronic wounds

**What it is.** Any break in the skin that fails to heal in the expected time — conventionally taken as four to six weeks — and which stays open for months or years. The main types are venous, pressure, diabetic foot and arterial, and they share the feature that healing is blocked by something that must be identified and removed.

**Measured.** No global figure was retrievable. Chronic wounds are not a single ICD-11 entity and are not quantified as a group on any World Health Organization or Global Burden of Disease source read. Prevalence is commonly reported at roughly **1 to 2 per cent** of the population in high-income countries over a lifetime, with point prevalence around **0.2 to 1 per cent** rising steeply with age†.

Chronic wound care is consistently reported to consume on the order of **2 to 4 per cent of total health expenditure** in high-income health systems, with **nursing time, not materials, as the dominant component**. Venous ulcers are the largest group, commonly around 70 per cent of leg ulcers, followed by diabetic foot, pressure and arterial ulcers. The burden is rising with population ageing, diabetes prevalence and obesity.

**Where it starts.** Healing fails because of an identifiable, usually persisting, cause. The established blockers: - **A continuing mechanical cause** — pressure not relieved, venous hypertension not compressed, plantar pressure not offloaded. The commonest reason a wound does not heal, and the most frequently overlooked. - **Ischaemia** — peripheral arterial disease. A wound cannot heal without perfusion, and no dressing substitutes for blood supply. - **Infection and high bacterial burden**, including biofilm. - **Necrotic tissue and slough**, which mechanically obstruct healing. - **Oedema.** - **Malnutrition** — insufficient protein, energy, vitamin C, zinc. - **Diabetes and hyperglycaemia.** - **Immunosuppression; systemic corticosteroids; chemotherapy.** - **Smoking.** - **Repeated trauma; self-inflicted or factitious injury.** - **An unrecognised different diagnosis.** This matters: a non-healing wound may be **pyoderma gangrenosum**, a **vasculitic ulcer**, a **malignancy** including squamous cell carcinoma in a long-standing scar or ulcer, **calciphylaxis**, or an atypical infection — mycobacterial, deep fungal, cutaneous leishmaniasis, **Buruli ulcer**. Several of these are made worse by debridement and compression, and pyoderma gangrenosum in particular is characteristically worsened by surgical debridement. **Any wound not healing as expected should be biopsied.**

Genuinely not known: why biofilm impedes healing and how to eradicate it clinically — no anti-biofilm agent has established clinical benefit. Why some wounds remain static for years despite correction of every identifiable factor. Whether the many adjunctive therapies — growth factors, skin substitutes, electrical stimulation, ultrasound, hyperbaric oxygen — add anything beyond standard care is largely unresolved, and the commercial literature is substantial and of poor quality.

**Cure status.** CURABLE where the cause is correctable; RELIEF ONLY where it is not.

Chronic wounds are not a disease but a failure state. When the blocking factor is identified and corrected, most heal — compression heals venous ulcers, offloading heals neuropathic ulcers, pressure relief heals pressure ulcers, revascularisation heals ischaemic ulcers.

Where the cause cannot be corrected — unreconstructable arterial disease, continuing unavoidable pressure, profound immobility, terminal illness — the honest classification is RELIEF ONLY, and the goal becomes symptom control, odour and exudate management, and avoiding futile aggressive treatment. Nothing applied to the surface of a wound heals it if the cause remains active.

**Prevention.** - **Identifying and treating the specific cause** — venous disease, diabetes, pressure, arterial disease. The whole of prevention. **STRONG**. - **Compression hosiery in chronic venous insufficiency. STRONG** for venous ulcer prevention. - **Pressure redistribution and repositioning in immobility. STRONG**. - **Diabetic foot screening and protective footwear. STRONG**. - **Smoking cessation. STRONG** for arterial disease. - **Nutritional adequacy — protein, energy, vitamin C, zinc. MODERATE**. - **Glycaemic control. MODERATE**. - **Early skin care and emollients on fragile at-risk skin. MODERATE**. - **Prompt, correct treatment of acute wounds** — cleaning, closure where appropriate, and not applying harmful traditional remedies. **MODERATE**. - **Biopsy of any wound not healing as expected**, which prevents months of wrong treatment and diagnoses malignancy and pyoderma gangrenosum. **STRONG**, and the cost is a punch biopsy. - **Avoiding**

**harmful practices** — strong antiseptics on granulating tissue, routine antibiotics for colonisation, and debridement of pyoderma gangrenosum. **MODERATE**, free improvements, and the action is omission.

**Treatment.** The standing approach, in order of evidence: 1. **Correct the cause.** Compression, offloading, pressure relief, revascularisation, glycaemic control, nutrition. Everything below is secondary to this. 2. **Debridement** of necrotic tissue and slough — sharp, autolytic, larval or mechanical. Cheap. Contraindicated in pyoderma gangrenosum and in dry stable heel eschar. 3. **Cleansing with clean water or saline.** Cochrane found **no evidence that any particular cleansing solution outperforms water**. Near-zero cost. 4. **A moist wound dressing.** The principle of moisture retention is supported; **no specific dressing type has demonstrated superiority over another**. This is the single most important cost finding in wound care. Not listed. Off-patent. Cost ranges from pennies to tens of dollars per dressing for no demonstrated difference in healing. 5. **Infection management** — systemic antibiotics for clinical infection only, and **not for colonisation, malodour or slow healing**. Listed generics, off-patent, under a dollar to a few dollars per course. 6. **Topical antimicrobials — iodine, silver, honey** — for heavy bacterial burden. The evidence is modest, and **silver dressings in particular have not demonstrated healing benefit proportional to their cost**. **Not using them is the evidence-based action and it is a direct saving.** 7. **Pain management** — listed analgesics, cents. Chronic wound pain is severe and routinely under-treated, particularly at dressing changes. 8. **Nutritional support.** 9. **Negative pressure wound therapy** for deep cavity and post-surgical wounds — moderate evidence. Equipment and consumables. 10. **Skin grafting and flap reconstruction** for large or refractory wounds. 11. **Biopsy** where the diagnosis is uncertain or healing stalls. 12. **Palliative wound care** where the cause is uncorrectable — odour control with metronidazole, exudate management, comfort. A legitimate and under-used goal. 13. **Weak or unproven adjuncts:** growth factors, bioengineered skin substitutes, electrical and ultrasound stimulation, and hyperbaric oxygen in general use.

**Simple means.** Very strong, and the evidence actively supports the cheap options.

- **Clean water for cleansing.** Cochrane found no solution superior to water. Potable, or boiled and cooled water, or saline made from salt and boiled water. Near-zero cost, and it replaces every proprietary wound cleanser. **The action is omission as much as substitution**: the proprietary cleanser is simply not bought.
- **Clean cloth or gauze with petroleum jelly** as a non-adherent moisture-retaining dressing. Since no dressing type has demonstrated superiority, this delivers the one supported principle — moisture retention — at pennies per dressing. Boiled and sun-dried cotton cloth is a serviceable dressing material where gauze is unavailable.
- **Compression bandaging** with crepe and elastic bandage for venous wounds — a few dollars to low tens of dollars per application, reusable in part.
- **Pillows, repositioning and heel offloading** for pressure wounds — free.
- **Plaster-and-felt total contact casting, or crutches and bed rest**, for neuropathic foot wounds.
- **Honey or sugar dressings** where nothing manufactured is available — both have antimicrobial and osmotic debriding action and a long documented history, with modest trial evidence. Sugar is available everywhere.
- **Larval (maggot) therapy** for debridement — effective, and produced without an industrial pharmaceutical chain.
- **Elevation, exercise and walking** for venous and oedematous wounds. Free.
- **Adequate food, with protein.** The cost of food.
- **Metronidazole for malodour** in fungating and palliative wounds. Metronidazole is listed and off-patent, and odour control transforms the patient's social life. The form and use are a clinician's decision and are not given here.
- **Not spending on what does not work:** silver and advanced dressings, antiseptic cleansers, antibiotics for colonisation, and most adjunctive devices. In a condition consuming 2 to 4 per cent of health expenditure†, with nursing time as the dominant cost, this is where the money actually is. **Not using silver dressings is an omission that saves money with no loss of healing.**
- **Training patients and families to redress their own wounds**, since nursing visits are the main cost.

What the chain minimally requires: clean water, a cloth, a bandage, and the correct identification of why the wound is not healing. For ischaemia, vascular surgery — the one component with no simple substitute.

**Gaps.** Chronic wounds are not a defined ICD-11 entity, so there is no coherent global burden figure and none was obtainable. All the figures in *Measured*, including the 2 to 4 per cent of health expenditure claim, are unverified and derive largely from high-income health-system analyses that may not generalise. **The Cochrane reviews on cleansing solutions and on dressing comparisons could not be retrieved**, so the central negative findings — water is as good as any cleanser, no dressing type is superior — are carried as commonly reported rather than verified. These are the most economically consequential findings in the entry and should be retrieved. The commercial wound care literature is large, of variable quality, and systematically favours the products being sold; good sources and marketing claims disagree sharply, and the Cochrane position is recorded here. Biofilm's clinical significance is unresolved. Hyperbaric oxygen is genuinely contested.

---

## Hidradenitis suppurativa

**What it is.** Recurrent painful boils and abscesses in the armpits, groin, under the breasts and around the buttocks. They join into tunnels under the skin and discharge. It scars badly.

It is not an infection and it is not caused by poor hygiene. Both beliefs are common, and both are wrong.

**Measured.** No global figure exists. Prevalence is commonly reported at 0.05 to 1 per cent†, a twenty-fold spread. Both ends are printed because neither can be discounted.

Onset is usually in the twenties and thirties, after puberty. It is about three times commoner in women.

The measured failure in this condition is delay. Seven to ten years commonly pass between first symptom and diagnosis, among the longest for any skin disease. Repeated misdiagnosis as recurrent boils is the proximate reason.

Quality-of-life impairment is consistently among the worst of any skin disease, exceeding psoriasis and eczema, driven by pain, discharge and the sites involved. Associations with obesity, smoking, metabolic syndrome, Crohn disease, spondyloarthropathy, depression and suicidality are all strong.

**Where it starts.** A hair follicle occludes and ruptures in skin bearing apocrine glands, and inflammation spreads into the dermis and forms sinus tracts. The apocrine gland is affected second, not first.

Smoking is the strongest modifiable association and is present in a large majority of patients. Obesity is associated with both incidence and severity, through friction and moisture in skin folds and through metabolic inflammation. About a third of cases are familial, with gamma-secretase mutations in a small subset. Perimenstrual flares indicate a hormonal influence. Lithium is implicated.

It is not caused by shaving, deodorant or washing habits. Stating that is clinically useful, because patients are routinely told otherwise.

*Genuinely not known.* What initiates the occlusion. Why these sites and not other hair-bearing ones. Why it begins after puberty and often settles after the menopause. Whether the bacteria cultured from lesions have any causal role at all — antibiotics help, but they may be working as anti-inflammatories, and the question is open. That matters, because the courses are months long.

**Cure status.** CONTROLLABLE.

No medical treatment cures it. Adalimumab and secukinumab are licensed and produce a clinically meaningful response in around half of patients on a defined measure for adalimumab, and relapse follows withdrawal.

Wide surgical excision of an affected area can be definitive for that area, with low recurrence inside the excised field, though disease can appear at new sites. That is locally curative, not systemically so.

Scarring and sinus tracts, once formed, are permanent. Only surgery removes them. This is why a seven-to-ten-year delay costs so much.

**Prevention.** No primary prevention of the disease is established.

Smoking cessation is the most important modifiable factor and improves severity. MODERATE, and free. Weight reduction improves severity and flare frequency in observational and bariatric cohorts. MODERATE.

Reducing friction — loose clothing, avoiding tight seams and waistbands, keeping folds dry. WEAK, free.

Early diagnosis and early effective treatment, to prevent the permanent scarring. MODERATE on principle; no trial has tested whether early treatment prevents progression.

Screening for and treating depression, given the measured suicidality. STRONG for that purpose.

What does not help: antiseptic washes, hair removal and stopping deodorant. All three follow from the mistaken belief that this is an infection or a hygiene problem.

**Treatment.** Topical clindamycin for mild localised disease.

Oral doxycycline or lymecycline for three months or more in mild to moderate disease. Doxycycline is on the Essential Medicines List, off-patent, and costs cents a day. It is the first-line systemic treatment and much the cheapest.

Clindamycin with rifampicin for ten weeks in moderate disease. Both are listed and off-patent, though rifampicin's use here sits against tuberculosis stewardship.

In women, spironolactone, combined oral contraceptives or metformin. All three are listed, off-patent, and cost cents a day.

Intralesional corticosteroid for a single inflamed nodule gives rapid relief for a drug cost of cents.

Adalimumab, with about half achieving a defined response. It is on the Essential Medicines List, and biosimilar prices have fallen to a fraction of the originator's in competitive markets. That combination — listed, and biosimilar — is the most consequential access fact in this entry. Secukinumab is licensed, not listed, and expensive.

Incision and drainage relieves acute pain but recurs at the same site and does not alter the disease. Deroofing a tract is more durable. Deroofing and wide local excision remove established tracts, and recurrence inside the excised field is low.

Pain management is the dominant unmet need and is routinely under-treated. Paracetamol, ibuprofen and amitriptyline are all listed, off-patent, and cost cents.

**Simple means.** Correct diagnosis and explanation is free and, given a delay measured in years, the highest-value single action. Telling someone this is a named inflammatory disease — not recurrent boils, not an infection, not a consequence of being unclean — changes their care and their self-regard at once.

Doxycycline at cents a day. Spironolactone, a combined oral contraceptive or metformin in women, all at cents a day. Smoking cessation, free. Weight reduction, free. Loose cotton clothing and avoiding tight waistbands, free. Keeping folds dry with a cloth, pennies. Warm compresses for an acutely inflamed nodule, free. Absorbent gauze or clean cloth for discharge and odour, which is often the most socially disabling problem, pennies. Metronidazole gel for malodour, cents. Adequate analgesia, cents, and routinely omitted. Peer support, free.

What the chain minimally requires: for established tunnels and scarring, an operating theatre and a surgeon who knows the condition. There is no simple substitute for excising a tract. Everything before that point is cheap generics.

**Gaps.** No verified global prevalence. The 0.05 to 1 per cent range is a twenty-fold spread and both ends stand. The diagnostic delay figures are unverified. The adalimumab response rate is unverified. Whether bacteria play a causal role is unresolved, and it determines whether months of antibiotics are antimicrobial treatment or anti-inflammatory treatment. Whether early treatment prevents scarring has never been tested.

## Bullous pemphigoid

**What it is.** An autoimmune disease of older people. The body attacks the layer anchoring the skin's surface to what lies beneath, and large tense blisters form on itchy red skin.

It is not contagious. Treatment controls it, and in many people it eventually burns out.

**Measured.** Annual incidence is commonly reported at 4 to 22 per million in European studies, and is rising in several countries†. The rise is attributed to population ageing and to wider use of the drugs that trigger it.

The defining feature is age. Incidence climbs steeply, most patients are over seventy, and in those over ninety it is many times the population average.

One-year mortality is substantial: commonly between 20 and 40 per cent in European cohorts†, far above age-matched controls. Deaths are mostly from infection, cardiovascular events and the complications of immunosuppression, not from the skin disease.

Whether that figure is caused by the disease or the treatment is unresolved; see Gaps.

It is the commonest autoimmune blistering disease in most populations. Data from outside Europe are sparse.

**Where it starts.** Autoantibodies form against BP180 and BP230, proteins anchoring the epidermis to the basement membrane. Complement activates, eosinophils arrive, and the skin splits at the junction.

Age is the dominant risk factor. Neurological disease is a consistent and striking association — dementia, Parkinson disease, stroke, multiple sclerosis — with substantial reported odds ratios. Shared BP180 expression in neural tissue is offered as the explanation and is not established.

Drugs are the key modifiable cause. Gliptins carry a well-documented several-fold increased risk; spironolactone, furosemide, some antibiotics and checkpoint inhibitors are also implicated. Drug-associated cases may remit on withdrawal, which makes the drug history potentially curative.

Burns, radiotherapy, ultraviolet exposure, surgery and trauma can localise the disease.

*Genuinely not known.* Why tolerance to BP180 is lost, and why in late life. The basis of the neurological association. Why gliptins trigger it. Why the disease frequently remits permanently when other autoimmune diseases do not. And the central unresolved question: whether the high mortality is caused by the disease, by the immunosuppression used against it, or by the frailty of the population. The answer determines whether treatment should be more aggressive or less.

**Cure status.** Drug-induced: CURABLE — withdrawing the implicated drug can produce resolution, which is why the drug history is the most important part of the assessment.

Idiopathic: CONTROLLABLE. Treatment stops new blistering in most patients within weeks. And unusually among autoimmune diseases, a share achieve lasting drug-free remission after one to several years, and the proportion is not given.

Against both: the one-year mortality of 20 to 40 per cent† is the dominant clinical fact. The disease is controllable. The patient often is not saved.

**Prevention.** Nothing prevents idiopathic bullous pemphigoid.

Avoiding or withdrawing implicated drugs, above all gliptins in older patients with diabetes, is the only meaningful primary prevention, and it is a prescribing decision. MODERATE.

Reviewing and withdrawing the implicated drug at diagnosis may resolve the disease without immunosuppression at all. STRONG where a drug cause exists, and free.

Using topical rather than systemic corticosteroid where feasible. The Joly trial found potent topical corticosteroid gave better survival than oral prednisolone in extensive disease. This is prevention of iatrogenic death and it is among the most important findings in the entry. The grade is MODERATE here, not STRONG, because this entry could not open that trial.

Infection prevention and prompt treatment during immunosuppression, since infection is a leading cause of death. STRONG. Bone, gastric and glycaemic protection during corticosteroid therapy. STRONG for preventing treatment harm. Protecting fragile skin from friction and shear. MODERATE, free.

**Treatment.** Potent topical corticosteroid applied to the whole body surface is first-line even in extensive disease, and gave better survival than oral corticosteroid in the Joly trial. Betamethasone is on the Essential Medicines List. The drug is cheap; the constraint is the labour of applying it daily to a frail elderly person, which usually needs a carer or nurse.

Oral prednisolone, tapered, is effective but carried greater mortality than topical treatment in that trial. It is listed, off-patent, and costs cents a day.

Doxycycline is the key affordable and safer option. The BLISTER trial found it non-inferior to oral prednisolone for short-term blister control, with significantly fewer serious adverse events. It is listed, off-patent, and costs cents a day.

Azathioprine, methotrexate and mycophenolate spare corticosteroid; the first two are listed and off-patent. Nicotinamide with tetracycline is an old, cheap, low-toxicity combination. Dapsone is listed and cheap. Rituximab is used in refractory disease, is listed, and biosimilars have cut its cost substantially. Omalizumab and dupilumab are emerging options, not listed, and expensive.

Withdrawing the causative drug is free and potentially definitive.

**Simple means.** Better than expected for an autoimmune blistering disease, because the two best-evidenced treatments are both cheap generics.

Taking a drug history and stopping a gliptin or other implicated drug. Free, and in drug-induced cases it can resolve the disease entirely. The single highest-value action.

Doxycycline at cents a day, non-inferior to prednisolone for short-term control with fewer serious adverse events. For a frail elderly population in a low-resource setting this is close to ideal: oral, cheap, available, and safer than the alternative.

Topical corticosteroid, a few dollars a tube, associated with better survival than oral steroids. Prednisolone at cents a day where topical application is impractical. Emollients for the itch, a few dollars. Non-adherent dressings of clean cloth with petroleum jelly for eroded areas, pennies, since dressing type does not determine outcome.

Leaving intact blisters alone, because the roof acts as a biological dressing. Free, and it reduces infection and pain. Where a large tense blister needs decompressing, that is a clinical procedure and not a household one. Protecting skin from shear, careful lifting, soft bedding, repositioning. Free. Short nails to limit scratching. Free. Watching for infection and treating it promptly, since infection is a leading cause of death.

What the chain minimally requires: a diagnosis. Confirmation needs a skin biopsy with direct immunofluorescence, and therefore a histopathology laboratory. That is the one genuine infrastructure requirement, because the differential includes conditions treated completely differently. Where it is unavailable, clinical diagnosis plus doxycycline is a defensible and cheap course.

**Gaps.** No verified global incidence or prevalence; no WHO or burden source quantifies bullous disorders. The 4 to 22 per million range is unverified and almost entirely European. One-year mortality is carried as a single unsourced range of about 20 to 40 per cent. Whether that width reflects disagreement between sources or the spread within one is not established here. Whether that mortality is caused by the disease, the treatment or the population's frailty is unresolved, and it is the question that should set how aggressively to treat. The Joly survival finding and the BLISTER non-inferiority result are both central to this entry and neither could be verified against its primary report.

---

## Burns and their skin consequences

**What it is.** Injury to the skin from heat, chemicals, electricity or radiation. Shallow burns heal. Deep ones destroy the layer that regenerates skin, and heal only by scarring or by grafting.

The lasting problems are thick contracting scars that pull joints out of position, disfigurement, and itch.

**Measured.** About 180,000 deaths a year, mostly in lower- and middle-income countries.

No global count of non-fatal burns is given. Country figures: over a million people moderately or severely burned each year in India; nearly 173,000 children in Bangladesh; over 410,000 burn injuries in the United States in 2008, about 40,000 needing hospital admission.

Almost two-thirds of burn deaths occur in the African and South-East Asia regions. Child burn death rates are over seven times higher in lower- and middle-income countries. Burn incidence requiring medical care is nearly twenty times higher in the Western Pacific than in the Americas.

Burns are the fifth commonest cause of non-fatal childhood injury.

And the figure that defines the skin consequence: among burned children in Bangladesh, Colombia, Egypt and Pakistan, 17 per cent have a temporary disability and 18 per cent a permanent one.

In community surveys in Bangladesh and Ethiopia, 80 to 90 per cent of burns happen at home.

A 2014 systematic review found a mean healthcare cost of US$88,218 per burn patient, with a range from US$704 to US$717,306. South Africa spends an estimated US$26 million a year treating burns from kerosene cookstove incidents.

**Where it starts.** Open fires, unsafe cookstoves and cooking at floor level, which is why most burns in surveyed populations happen at home. Kerosene appliances. Hot liquid scalds, the commonest mechanism in young children. Loose clothing near open flames.

Age under five, where crawling and reaching combine with thinner skin that burns deeper at lower temperatures and shorter exposure. Female sex and domestic kitchen exposure. Occupational exposure to fire, scalds, chemicals and electricity.

Epilepsy, neuropathy, intoxication and impaired mobility, all of which prevent escape from the heat source. Diabetic neuropathy and leprosy-related sensory loss cause unnoticed contact burns.

Acid violence. Crowding, poverty and lack of electricity.

*Genuinely not known.* Why some people form thick and keloid scars and others heal flat after comparable burns. Ancestry and site are associated, with darker skin at higher keloid risk, but no predictor is clinically usable. The mechanism of post-burn itch, which is severe, prolonged and poorly treatable. The optimal timing of excision and grafting. And why a superficial burn sometimes deepens over the first forty-eight hours, or whether anything prevents it.

**Cure status.** Superficial and superficial partial thickness: CURABLE. They heal completely within one to three weeks from surviving epidermal appendages, with normal or near-normal skin and no scar.

Deep partial and full thickness: RELIEF ONLY for the consequences. The regenerating layer is destroyed. The wound heals by contraction and scar, or it is grafted. Grafting closes the wound and saves life and limb, which is a major achievement — but grafted skin is not normal skin. It lacks normal sweat glands, hair and sensation, it looks different, and the donor site scars too.

Thick scars and contractures are the permanent consequence. Pressure garments, silicone, splinting, physiotherapy, steroid injection, laser and surgical release improve them and do not restore them. A released contracture tends to recur, and often needs repeated surgery through a child’s growth.

That split is where the 18 per cent permanent disability figure in burned children comes from.

**Prevention.** One thing must be said first: WHO states that prevention and care would substantially reduce burn deaths and disability, and gives no quantified effect size for any preventive measure. The grades below reflect that absence.

Raised cooking surfaces, cooking separated from living and sleeping areas, enclosed stoves, stable cookware. This addresses the majority of burns that happen at home. MODERATE on mechanism; effect size not quantified.

Replacing kerosene appliances and open fires with safer stoves or electricity. MODERATE. Hot water temperature limits, which prevent bath scalds. MODERATE in high-income set-

tings. Keeping hot liquids, kettle cords and matches out of reach, and supervising children in kitchens. MODERATE, free. Smoke alarms and an escape plan. MODERATE where there is electricity. Flame-resistant nightwear. MODERATE. Occupational guarding and protective equipment. MODERATE. Regulation of fireworks, acid sales and appliance standards. MODERATE.

Treating epilepsy, which reduces burns from seizures near fires. MODERATE; anticonvulsants cost cents a day.

And first aid education — cool running water immediately. This prevents depth, and therefore prevents the disability that constitutes the burden. MODERATE, on the depth evidence; the population effect of teaching it has not been quantified.

**Treatment.** Immediate cooling with cool running water for twenty minutes, within the first three hours. It reduces burn depth, pain and the need for grafting. The cost is water.

Fluid resuscitation for burns over about 10 to 20 per cent of body surface, with oral rehydration solution usable where intravenous access is unavailable. Both are listed, off-patent, and cost cents to a few dollars.

Analgesia. This is a severely painful injury and pain control is routinely inadequate. Paracetamol, ibuprofen, morphine and ketamine are all listed, off-patent and low cost.

Wound cleansing and debridement. Topical antimicrobial dressing, though silver sulfadiazine may delay healing and the evidence favours simple non-adherent or paraffin gauze for superficial burns. Tetanus prophylaxis, listed, cents.

Early excision and skin grafting for deep burns — the definitive treatment, requiring an operating theatre. Escharotomy for circumferential full thickness burns compromising circulation or breathing, performed with a scalpel.

Nutritional support, since burn hypermetabolism demands high protein and energy. Antibiotics for infection only, not prophylactically.

Scar management: pressure garments, silicone sheeting, massage, splinting, sustained physiotherapy, intralesional corticosteroid and surgical release. Itch management, often inadequate. Physiotherapy and occupational therapy from day one, which determines whether a contracture forms at all. Psychological support.

**Simple means.** Exceptionally strong at the point of injury, because the single most effective burn intervention is water.

Cool running water for twenty minutes, immediately. It reduces depth, pain and the need for grafting. It costs nothing and needs no training beyond knowing to do it. And it must happen in the first minutes, which makes it public knowledge rather than a health service. Given that most burns happen at home and that 18 per cent of burned children in four countries are left permanently disabled, teaching this one instruction is among the highest-value free interventions in this book.

Stop, drop and roll; smothering flames with a blanket; removing smouldering clothing and jewellery. Free.

Not applying ice, toothpaste, oil, butter, eggs, mud or ash. Ice deepens the injury; the rest introduce infection. Free, and widely needed as instruction.

Covering the burn with a clean cloth or cling film for transport, pennies. Oral rehydration solution where intravenous fluids are unavailable, cents, addressing the main early cause of death in a large burn. Paraffin gauze or clean cloth with petroleum jelly as a non-adherent dressing, cheap, and the evidence does not favour expensive alternatives. Honey as a burn dressing where manufactured dressings are unavailable.

Splinting in the anti-contracture position with locally made splints, and daily range-of-movement exercises from the start. This is the measure that prevents contracture, and it needs a piece of plastic or plaster and a trained family member, not a surgeon. Preventing a contracture is far cheaper and far more effective than releasing one later.

Pressure therapy with elastic bandage or locally sewn garments for thick scars.

What the chain minimally requires: for a deep burn, an operating theatre, a surgeon and a graft. There is no simple substitute for replacing destroyed skin.

**Gaps.** The source states about 180,000 annual deaths†. There is no global count of non-fatal burns, and no numeric disability-burden value, although the mortality figure exists. WHO quantifies no preventive effect size at all, which is why every prevention grade in this entry rests on mechanism rather than on a measured reduction. Why some people scar thickly and others do not is unknown and unpredictable. The mechanism of post-burn itch is unexplained. The optimal timing of excision and grafting is debated.

---

*End of chapter.*

# ICD-11 Chapters 11 and 12 — The Circulatory System and the Respiratory System

Thirty-five entries. Twenty-one circulatory, fourteen respiratory. Heart failure is two entries, so the entries cover thirty-four conditions.

---

## Introduction

These two chapters carry a large share of measured death. Cardiovascular disease killed 19.8 million people in 2022, about 32 per cent of all deaths, of which 85 per cent were heart attack and stroke. The Global Burden of Disease study gives 19.2 million for 2023 and 626 million people living with cardiovascular disease, against 311 million in 1990. Ischaemic heart disease is the first cause of death in the world at 9.5 million, and the first cause of lost healthy life at 193 million disability-adjusted life years. Chronic obstructive pulmonary disease is third at 3.4 million, pneumonia fourth at 2.7 million. Against that, the therapy that carries almost all of the measured benefit is old, off-patent and costs a few euro a year.

Five interventions in this chapter pair a measured mortality benefit with a low price, and the first is a drug that keeps running out. Benzathine benzylpenicillin, given by intramuscular injection every three to four weeks, reduces recurrence of rheumatic fever by 80 to 90 per cent and holds back the valve disease that affects 54.8 million people. A vial costs a fraction of a euro and a patient-year costs a few euro. It has been on the market since the 1950s, it is on the WHO Essential Medicines List, it is off-patent, and it has suffered repeated global supply shortages because the margin is too small to hold manufacturers in the market. Next comes aspirin: one chewed 300 mg tablet at the onset of a myocardial infarction reduces 35-day vascular mortality by 23 per cent, for a cost under one cent. Then oral amoxicillin for childhood pneumonia, which reduces child pneumonia mortality by 35 to 42 per cent when delivered by a trained community health worker, and which is as effective as injectable penicillin even in severe disease. Then dexamethasone, under five euro a course, with a number needed to treat of about eight for mortality in ventilated COVID-19 pneumonia. Then spironolactone, five to thirty euro a patient-year, with a number needed to treat of nine over two years in severe heart failure with reduced ejection fraction.

| Rank | Intervention | Measured benefit | Cost |
|---|---|---|---|
| 1 | Benzathine benzylpenicillin, secondary prophylaxis | Rheumatic fever recurrence down 80–90 per cent; prevents the valve disease affecting 54.8 million people | Under one euro per injection; a few euro per patient-year. UNICEF indicative price October 2026: US$29.49 per box of 50 vials of 2.4 million IU, so about US$0.59 a vial |
| 2 | Aspirin, 300 mg chewed in acute myocardial infarction | 23 per cent reduction in 35-day vascular mortality, ISIS-2 | Under one cent a dose |
| 3 | Oral amoxicillin, childhood pneumonia | Child pneumonia mortality down 35–42 per cent; oral as effective as injectable even in severe disease | UNICEF indicative price October 2026: US$0.54 for ten 250 mg dispersible tablets, about US$0.054 a tablet |

| Rank | Intervention | Measured benefit | Cost |
|---|---|---|---|
| 4 | Dexamethasone, ventilated COVID-19 pneumonia and severe community-acquired pneumonia | NNT about 8 in ventilated patients, 29.3 against 41.4 per cent; NNT about 18 in severe pneumonia, 6.2 against 11.9 per cent | Under five euro a course. UNICEF indicative price October 2026: US$24.00 for 100 tablets of 4 mg, about US$0.24 a tablet |
| 5 | Spironolactone, heart failure with reduced ejection fraction | Mortality 35 against 46 per cent, RR 0.70, NNT 9 over 24 months, RALES | a few to tens of euro per patient-year |

Equal weight belongs to the things that match those effects and are not drugs at all. Bystander cardiopulmonary resuscitation doubles to triples the chance of surviving a cardiac arrest, requires two hands, and costs nothing; it is performed in 40.2 per cent of out-of-hospital arrests in the United States, so most of the available benefit is currently unrealised. Prone positioning in severe acute respiratory distress syndrome has a number needed to treat of 6 to prevent one death, and needs four or five people, some pillows and a protocol. Low tidal volume ventilation has a number needed to treat of 11, and is a setting on a machine already in use. A large-bore cannula costing under five euro, pushed through the chest wall, converts a tension pneumothorax from an immediately fatal condition into a survivable one within seconds. A pulse oximeter costing twenty to two hundred euro, applied once to a newborn's hand and foot, detects critical congenital heart disease with a sensitivity of about 76 per cent, and the American states that mandated the screening recorded roughly a third fewer infant deaths from critical congenital heart disease.

| Intervention | Measured benefit | What it requires |
|---|---|---|
| Bystander CPR | Doubles to triples survival | Nothing |
| Prone positioning, severe ARDS | 28-day mortality 16.0 against 32.8 per cent, NNT 6 | Four or five staff, pillows, a protocol |
| Low tidal volume ventilation | Mortality 31.0 against 39.8 per cent, NNT 11 | A ventilator setting and a tape measure |
| Needle decompression, tension pneumothorax | Immediately life-saving | A cannula, a few to a few euro |
| Pulse oximetry screening of newborns | Sensitivity about 76 per cent for critical congenital heart disease, false positives about 0.14 per cent; about a third fewer infant deaths from it in mandating US states | A device, tens to hundreds of euro |

A large gap in this chapter's data has to be stated at the front. Retrieved GBD 2023 tables carry no global burden figure at all — no deaths, no disability- adjusted life years — for seventeen conditions treated here. They are: heart failure as a syndrome; venous thromboembolism; aortic aneurysm; endocarditis; pericarditis; pulmonary hypertension; cardiac arrest; varicose veins and chronic venous insufficiency; arrhythmias other than atrial fibrillation and flutter; bronchiectasis; chronic rhinosinusitis; allergic rhinitis; pleural effusion; pneumothorax; acute respiratory distress syndrome; cystic fibrosis; and sleep-disordered breathing. "No figure" here means none was retrieved in the GBD 2023 tables used, which is a limit of retrieval and not a statement about GBD itself, and several of the seventeen carry modelled prevalence elsewhere in their own entries. Heart failure alone affects about 64 million people. Pulmonary hypertension of all causes is estimated at roughly 1 per cent of the world's population; chronic rhinosinusitis at about 10 per cent of adults; allergic rhinitis at roughly 400 million people; varicose veins at 20 to 35 per cent of western adults. For several of these the reason is structural rather than accidental. Heart failure is not a GBD level-3 cause. Cardiac arrest is a mode of death counted under its causes, and pleural effusion is a sign rather than a cause. Sleep-disordered breathing sits in ICD-11 chapter 07, in which no condition is a GBD level-3 cause at all. Each affected entry repeats the absence in its own Gaps section, because a reader who opens one entry should not have to come back here to learn that the number does not exist.

The heaviest unresolved question in the chapter is clean cooking, and it must be printed both ways. Household air pollution is attributed 44 per cent of child pneumonia deaths and 22 per cent of adult pneumonia deaths. It is attributed 23 per cent of adult COPD deaths in low- and middle- income countries. Of its own 2.9 million annual deaths, 32 per cent are ischaemic heart disease, which is 12 per cent of all ischaemic heart disease deaths worldwide, and

23 per cent are stroke, which is about 12 per cent of all stroke deaths. Around 2.1 billion people, about a quarter of the world, still cook over open fires or on inefficient stoves, and 923 million people in sub-Saharan Africa lacked access to clean cooking in 2022. Against that: the three large randomised stove-intervention trials all missed their primary endpoints. RESPIRE, in Guatemala, tested chimney stoves and missed its primary childhood pneumonia endpoint, with a reduction in severe pneumonia in per-protocol analysis only. CAPS, in Malawi, randomised cookstoves across 10,750 children and found no reduction in pneumonia. HAPIN randomised liquefied petroleum gas stoves to 3,200 households, verified a 66 per cent reduction in personal fine particulate exposure, and found no effect on birth weight, its primary endpoint. The most-cited explanation is that none of the interventions moved exposure far enough down the steep part of the exposure-response curve. That explanation is plausible and unproven. These results are not reconciled here. The attributable fractions are large and the randomised evidence for the interventions tested is absent, and that is the open question.

Three further disagreements recur across these entries, and each is printed both ways wherever it appears. The salt J-curve. The PURE study reports higher cardiovascular risk at both high and low sodium intake, implying a threshold below which reduction does not help. Cook and colleagues reanalysed the TOHP trials with repeated 24-hour urine collections and found a monotonic relation with no J-curve. The measurement method is itself the contested variable: PURE estimated 24-hour sodium from a single fasting morning urine with the Kawasaki formula. Compression stockings: beneficial in surgical thromboprophylaxis, where Cochrane gives roughly a two-thirds reduction in deep vein thrombosis; null and harmful after stroke in CLOTS-1, which found no benefit and more skin breaks; and null for post-thrombotic syndrome after deep vein thrombosis in the SOX trial. Masks: the 2023 Cochrane review of physical interventions concluded that masks in the community probably make little or no difference to influenza-like illness, a conclusion heavily criticised for pooling heterogeneous trials with low adherence and publicly qualified by Cochrane itself, against observational and mechanistic evidence for source control. One provenance figure belongs here as well. Of the figures in this chapter, 410 were read off their source, 2,120 name a source and year that were not opened again, and 55 carry daggers.

Standing note on the Essential Medicines List. Every statement in this chapter that a medicine is or is not on the WHO Essential Medicines List, and that names no edition, is to be read as carrying a dagger: it was not checked against the 24th List (2025) and needs checking against it. This covers the EML column of every treatment table. Listing claims read from the 24th List are printed plainly.

---

# Both chapters in figures

**Circulatory system, totals.**

| Measure | Figure | Source |
|---|---|---|
| CVD deaths, 2022 | 19.8 million, about 32 per cent of all deaths | WHO fact sheet on cardiovascular diseases, 31 July 2025 |
| CVD deaths, 2023 | 19.2 million | GBD 2023 CVD Collaborators, JACC 2025 |
| CVD deaths, 1990 | 13.1 million, a 47 per cent rise to 2023 | JACC 2025 |
| People living with CVD, 2023 | 626 million, against 311 million in 1990 | JACC 2025 |
| CVD DALYs, 2023 | 437 million, the leading cause of DALYs globally; also cited as 436.2 million | JACC 2025 |
| Share of CVD DALYs attributable to modifiable risk factors | 79.6 per cent | JACC 2025 |
| Share of CVD deaths from heart attack and stroke | 85 per cent | WHO |
| Share of CVD deaths in low- and middle-income countries | Over three-quarters | WHO |

| Measure | Figure | Source |
|---|---|---|
| Share of the 18 million premature under-70 noncommunicable deaths of 2021 caused by CVD | At least 38 per cent | WHO |

The two totals do not agree and are not the same accounting. WHO gives 19.8 million for 2022 and GBD 19.2 million for 2023, and the two bodies redistribute ill-defined cause-of-death codes differently. Both are printed throughout; neither publishes a reconciliation. The WHO page also contradicts itself on one figure: its Key Facts section gives the low- and middle-income share as “over three quarters” and its body gives “approximately 80 per cent”. GBD 2023 puts total global deaths at 60.04 million (59.05 to 61.24 million) and WHO’s Global Health Estimates put them at 61 million for the same year, so every “share of all deaths” figure depends on which denominator is used.

WHO names six basic medicines that should be available everywhere for cardiovascular disease: aspirin, beta-blockers, calcium channel blockers, ACE inhibitors, diuretics and statins. All six are off-patent. That is the single most important economic fact in this chapter.

**Respiratory system, totals.**

| Condition | Deaths | DALYs and YLDs | Source |
|---|---|---|---|
| COPD | 3.4 million, 2023, about 6 per cent of all deaths; 3.6 million on the WHO top-ten page for the same year; 3.72 million (3.36–4.09) for 2021 in GBD 2021 | 74.9 million DALYs (66.2–86.9), rank 7; 15.0 million YLDs (12.6–17.6), rank 19 | WHO COPD fact sheet, 10 June 2026; WHO top ten causes, 2 October 2026; GBD 2023 |
| Asthma | 442,000 | 14.1 million YLDs (8.80–20.3), rank 20 | WHO asthma fact sheet, 28 April 2026; GBD 2023 |
| Lower respiratory infections | 2,501,300 (2,241,000–2,812,200) in GBD 2023; 2.7 million on the WHO top-ten page | 98.7 million DALYs (87.7–112), rank 4 | GBD 2023; WHO |
| Upper respiratory infections | 27,100 (6,100–77,300), down 29.4 per cent since 2000 | — | GBD 2023 |
| Pneumoconiosis, all types | 18,323 (16,041–20,916), 2021 | 507,425 DALYs, 2017 figure | GBD 2021 pneumoconiosis analysis, Frontiers in Public Health 2025 |

Two WHO pages give 3.4 and 3.6 million COPD deaths for the same year, 2023, and GBD 2021 gives 3.72 million. All three are printed. COPD is the third leading cause of death worldwide and the seventh leading cause of lost healthy life, and nearly 90 per cent of COPD deaths under the age of 70 occur in low- and middle-income countries.

---

# The two risk-factor studies behind this chapter

Almost every risk-factor section in the circulatory half of this chapter refers back to two case-control studies. They are given here once, in full.

## INTERHEART

Yusuf S and colleagues, Lancet 2004;364:937–952. Case-control, 15,152 cases of first myocardial infarction and 14,820 controls, 52 countries. Read in a secondary summary of the paper, not in the Lancet original.

| Risk factor | Odds ratio (99% CI) | Population attributable risk |
|---|---|---|
| ApoB/ApoA1 ratio, top against bottom quintile | 3.25 (2.81–3.76) | 49.2 per cent |
| Current or former smoking | 2.04 (1.86–2.25) | 35.7 per cent |
| Psychosocial factors | 2.67; confidence interval† | 32.5 per cent |
| Abdominal obesity, top against bottom tertile | 1.62; confidence interval† | 20.1 per cent |

| Risk factor | Odds ratio (99% CI) | Population attributable risk |
|---|---|---|
| Hypertension | 1.91 (1.74–2.10) | 18 per cent |
| Daily fruit and vegetables, protective | 0.70 (0.62–0.79) | 13.7 per cent |
| Regular exercise, protective | 0.86 (0.76–0.97) | 12.2 per cent |
| Diabetes | 2.37 (2.07–2.71) | 9.9 per cent |
| Alcohol intake, protective | 0.91 (0.82–1.02) | 6.7 per cent |

Combined population attributable risk across all nine factors: 90.4 per cent, 99 per cent confidence interval 88.1 to 92.4.

Two confidence intervals carry daggers, and the reason is specific. The secondary source used here printed an interval for psychosocial factors, 2.21 to 2.32, that does not contain its own point estimate of 2.67, and printed the abdominal obesity interval malformed. Both are transcription failures in that source. Neither malformed interval is reproduced. The point estimates and the attributable risks are consistent across sources and are printed; the two intervals must be taken from the Lancet original, which was not read.

## INTERSTROKE

O’Donnell MJ and colleagues, Lancet 2016;388:761–775. Case-control, 26,919 participants, 32 countries. Abstract read at the Glasgow Enlighten record.

| Risk factor | Odds ratio (99% CI) | PAR, all stroke |
|---|---|---|
| Hypertension, history or BP 140/90 or above | 2.98 (2.72–3.28) | 47.9 per cent |
| Regular physical activity, protective | 0.60 (0.52–0.70) | 35.8 per cent |
| ApoB/ApoA1 ratio, highest against lowest tertile | 1.84 (1.65–2.06) | 26.8 per cent, top two tertiles against lowest |
| Diet, mAHEI highest against lowest tertile, protective | 0.60 (0.53–0.67) | 23.2 per cent, lowest two against highest |
| Waist-to-hip ratio, highest against lowest tertile | 1.44 (1.27–1.64) | 18.6 per cent, top two against lowest |
| Psychosocial factors | 2.20 (1.78–2.72) | 17.4 per cent |
| Current smoking | 1.67 (1.49–1.87) | 12.4 per cent |
| Cardiac causes, including atrial fibrillation | 3.17 (2.68–3.75) | 9.1 per cent |
| Alcohol, high or heavy episodic against never or former | 2.09 (1.64–2.67) | 5.8 per cent, current against never or former |
| Diabetes mellitus | 1.16 (1.05–1.30) | 3.9 per cent |

All rows. Combined attributable risk by stroke type: all stroke 90.7 per cent (95 per cent CI 88.7–92.4); ischaemic stroke 91.5 per cent (89.4–93.2); intracerebral haemorrhage 87.1 per cent (82.2–90.8).

The regional variation inside INTERSTROKE is large and is part of the result. The smoking attributable risk runs from 4.5 per cent in Africa to 18 per cent in western Europe, North America and Australia, and from 16.6 per cent in men to 5.3 per cent in women. Physical inactivity runs from 4.7 per cent in Africa to 59.9 per cent in China. Alcohol gives 10 per cent in men and −0.7 per cent in women. Hypertension was associated with stroke in every region. A higher mAHEI diet score was associated with increased risk in south Asia, a reversal the paper does not explain. ApoB/ApoA1 ratio and atrial fibrillation were associated with ischaemic stroke only, not with intracerebral haemorrhage.

What neither study establishes. Both are case-control. A population attributable risk from a case-control design is the share of cases statistically associated with exposure under the model’s assumptions. It is not an experimentally demonstrated preventable fraction. Neither study randomised anything, and the nine or ten factors are correlated, which is why the combined figure exceeds the sum of plausible independent contributions. The 90 per cent figures are widely quoted as “90 per cent of heart attacks and strokes are preventable.” That is not what either study measured, and the misreading accompanies these figures wherever they are used.

# Chapter 11 — Diseases of the circulatory system

## Blood pressure and the arteries of the heart

### Hypertension (ICD-11 BA00)

**What it is.** Blood pressure in the arteries stays high when the person is at rest. It causes no symptoms for years. The pressure itself damages arteries, heart, kidneys, eyes and brain.

**Measured.** About 1.4 billion adults aged 30 to 79 had hypertension in 2024, 33 per cent of that age group, against 650 million in 1990. Around 600 million, 44 per cent, are unaware; about 630 million, given as 44 per cent, are diagnosed and treated; about 320 million, 23 per cent, have it controlled. Two-thirds live in low- and middle-income countries. An earlier edition of the same WHO page gave 1.28 billion with hypertension, 46 per cent unaware, 42 per cent treated and 21 per cent controlled; the 2025 edition's figures are printed above and both sets circulate. The 2025 page contradicts itself twice: 630 million of 1.4 billion is 45 per cent rather than the 44 per cent printed, and the same 44 per cent is attached to both the 600 million unaware and the 630 million treated.

Hypertensive heart disease caused 1.7 million deaths in 2023 and ranks eighth among all causes of death. It is the fourth leading cause of cardiovascular DALYs in GBD 2023, and thirteenth among all causes of death by age-standardised rate in GBD 2021, at 16.3 per 100,000. High systolic blood pressure is the largest single attributable risk factor for death in the world, about 10.8 million deaths a year, and it heads the GBD 2023 ranking of risks by health loss. Prevalence rises steadily with age and exceeds 60 per cent above age 60 in most populations. Prevalence has fallen in high-income countries since 1990 and risen in sub-Saharan Africa, south Asia and parts of Latin America. Regional prevalence is highest in the Eastern Mediterranean at 38 per cent and lowest in the Western Pacific at 29 per cent. The doubling of the absolute number since 1990 is almost entirely population growth and ageing; the age-standardised prevalence has been roughly flat.

**Where it starts.** Blood pressure itself is the mechanism, and lowering it carries the benefit: each 10 mmHg of systolic reduction cuts major cardiovascular events by 20 per cent, relative risk 0.80 (95 per cent CI 0.77–0.83), from 123 trials and more than 600,000 participants. INTERHEART gives hypertension an odds ratio of 1.91 for myocardial infarction and an attributable risk of 18 per cent; INTERSTROKE gives 2.98 for stroke and 47.9 per cent, the largest single attributable risk in that study. Dietary sodium, body weight, alcohol, physical inactivity and potassium deficiency are the established contributors. Each kilogram of weight lost lowers systolic pressure by roughly 1 mmHg. Twin and family studies give a heritability of 30 to 50 per cent, and genome-wide association studies have identified over a thousand loci that together explain only a small part of population variance.

For more than 90 per cent of cases no specific cause can be identified; the word "essential" records that. Why sodium raises pressure in some people and not others — salt sensitivity — is not explained at a level that predicts it in an individual, and no available test identifies it. The gap between high twin-study heritability and the small variance explained by identified loci is unresolved. Whether the rise in blood pressure with age is intrinsic or entirely environmental is not settled: some hunter-gatherer and remote populations show little or no age-related rise, but those studies are small, non-randomised, and confounded by diet, weight and activity at once.

**Cure status.** CONTROLLABLE.

Antihypertensive drugs lower pressure and event rates while they are taken, and pressure returns toward baseline when they stop. No standing treatment removes the condition. The secondary hypertensions are the exception and account for only around 5 to 10 per cent of all cases: primary aldosteronism is cured by adrenalectomy in roughly 30 to 40 per cent, higher for a unilateral adenoma; renal artery stenosis in selected cases; phaeochromocytoma resection; coarctation repair. Marked weight loss and bariatric surgery produce remission off drugs in a substantial minority, but that remission holds while the new weight holds.

**Prevention.**

*Salt reduction — STRONG for blood pressure, STRONG for events where a substitute has been tested, CONTESTED at the extremes of intake.* The SSaSS trial randomised 20,995 participants in rural China, 10,504 to a potassium-enriched salt substitute and 10,491 to regular salt. Mean age was 65, half were female, and all had either a prior stroke or were aged 60 and over with high blood pressure. Follow-up was 4.74 years. Stroke 29.14 against 33.65 per 1,000 person-years ($p=0.006$); major adverse cardiovascular events 49.09 against 56.29 ($p<0.001$); total mortality 39.28 against 44.61 ($p<0.001$); serious hyperkalaemia 3.35 against 3.30 ($p=0.76$, no increase). This is the strongest evidence in existence that a population salt measure lowers death.

The UK salt reduction programme between 2003 and 2011 cut intake by 1.4 g a day, about 15 per cent, from 9.5 to 8.1 g measured by 24-hour urinary sodium. Systolic pressure fell 3.0 mmHg and diastolic 1.4 mmHg across all adults, and 2.7 over 1.1 mmHg in those not on blood-pressure medication after adjustment. Stroke mortality fell 42 per cent and ischaemic heart disease mortality 40 per cent over the same period. The design is an ecological before-and-after analysis, not a trial, and those years also carried large falls in smoking and large rises in statin and antihypertensive prescribing. The 3.0 mmHg is the programme's measured effect; the mortality falls are concurrent and are not apportioned.

Where it is contested: the PURE study reported a J-shaped or U-shaped association with higher cardiovascular risk at both high intake, above 5 g of sodium a day, and low intake, below 3 g, implying a threshold below which reduction does not help. PURE estimated 24-hour sodium from a single fasting morning urine using the Kawasaki formula, which its critics argue systematically misestimates intake at the extremes and generates the J-curve as an artefact. Cook and colleagues reanalysed the TOHP trial data using repeated 24-hour urine collections and found a monotonic relation with no J-curve. The disagreement is unresolved and neither camp has conceded. The measurement method is itself the contested variable. SSaSS stands independent of it: a randomised substitute lowered death in a high-intake population.

WHO's own position, for comparison. Global mean adult sodium intake in 2021 was 4,278 mg a day, about 11 g of salt, against a recommended limit below 2,000 mg of sodium or 5 g of salt. Excess sodium is linked to 1.7 million deaths a year, and the stated return on sodium reduction is at least US$12 for every US$1 invested.

*Weight reduction — STRONG.* About 1 mmHg systolic per kilogram lost.

*Dietary pattern — STRONG.* The DASH trial lowered systolic pressure by 5.5 mmHg overall and 11.4 mmHg in hypertensive participants against a control diet; DASH with low sodium lowered it further.

*Physical activity — MODERATE.* Aerobic training lowers systolic pressure by about 5 to 8 mmHg in hypertensive adults.

*Potassium supplementation — MODERATE.* About 3 to 5 mmHg systolic in hypertensive adults with low baseline intake.

*Alcohol reduction — MODERATE.* About 3 to 4 mmHg in heavy drinkers who cut down.

*Tobacco control — STRONG for cardiovascular events, WEAK for blood pressure itself.* Smoking raises acute but not much chronic pressure; its cardiovascular benefit runs through other pathways.

*Population hypertension programmes — STRONG and cost-effective*, on evidence from 18 countries. WHO's Global Hearts initiative, launched in September 2016, operates in more

than 40 low- and middle-income countries and has 13.5 million people on protocol-based treatment since 2017.

**Treatment.** Four first-line classes, all off-patent, all on the WHO Essential Medicines List. Pooled and head-to-head trials show no large difference in event reduction between them at equivalent blood-pressure reduction; the reduction itself carries the benefit.

| Drug | EML | Off-patent | Generic cost per patient-year |
|---|---|---|---|
| Hydrochlorothiazide or chlorthalidone, thiazide | yes | yes | €2–15 at MSH international prices, year not stated in the source |
| Amlodipine, calcium channel blocker | yes | yes | €3–20. NHS Drug Tariff September 2026: £0.64 for 28 tablets of 5 mg, about £0.023 a tablet |
| Enalapril, lisinopril or ramipril, ACE inhibitor | yes | yes | a few to tens of euro |
| Losartan or telmisartan, angiotensin receptor blocker | yes | yes | a few to tens of euro |
| Bisoprolol, atenolol or metoprolol, beta blocker | yes | yes | a few to tens of euro |
| Spironolactone, for resistant hypertension | yes, sections 16 and 12.4 | yes | a few to tens of euro |

Effect sizes per 10 mmHg systolic reduction, from 123 trials and over 600,000 participants:

| Outcome | Relative risk (95% CI) | Reduction |
|---|---|---|
| Major cardiovascular events | 0.80 (0.77–0.83) | 20 per cent |
| Coronary heart disease | 0.83 (0.78–0.88) | 17 per cent |
| Stroke | 0.73 (0.68–0.77) | 27 per cent |
| Heart failure | 0.72 (0.67–0.78) | 28 per cent |
| All-cause death | 0.87 (0.84–0.91) | 13 per cent |

Number needed to treat depends entirely on baseline risk. For a 60-year-old at moderate risk it is roughly 100 over five years to prevent one major cardiovascular event; in high-risk secondary prevention, 20 to 30. SPRINT randomised 9,361 participants to a systolic target below 120 against below 140. The primary composite fell with a hazard ratio of 0.75 and all-cause death with 0.73. That gives a number needed to treat of 61 over 3.26 years to prevent one primary outcome event, and 90 to prevent one death, at the cost of more hypotension, syncope and acute kidney injury.

The cheap off-patent drugs are the whole of the therapy. No newer class in hypertension has a demonstrated event-reduction advantage over thiazides, ACE inhibitors, calcium channel blockers and beta blockers at matched blood-pressure reduction. A hypertensive patient can be treated to target for €10 to €40 a year at international generic prices, year not stated in the source.

**Simple means.** Salt reduction and salt substitution carry the largest measured effect here. A potassium-enriched substitute, typically 75 per cent sodium chloride and 25 per cent potassium chloride, lowered total mortality from 44.61 to 39.28 per 1,000 person-years with no excess serious hyperkalaemia. It needs a potassium chloride supply chain and no pharmaceutical one, and costs little more than salt. Weight loss gives about 1 mmHg systolic per kilogram. Walking and other aerobic exercise give 5 to 8 mmHg in hypertensive adults with no equipment. Cutting heavy drinking gives 3 to 4 mmHg. A diet shifted to fruit, vegetables and less processed food gives the DASH effect, 5.5 mmHg overall and 11.4 mmHg in hypertensive participants. Device-guided slow breathing lowers systolic pressure by about 3 to 5 mmHg in trials, with low evidence quality and inconsistent follow-up.

Measurement is the binding constraint, not medicine. The condition causes no symptoms, so without a cuff it is invisible and untreatable, and about 600 million hypertensive adults are unaware. A mechanical aneroid sphygmomanometer and a stethoscope need no electricity and last for decades. That is the minimum chain.

**Gaps.** The salt J-curve is unresolved: PURE against the TOHP reanalysis, with the urine-measurement method the contested variable. Both results stand. The UK programme's 42 per cent stroke and 40 per cent ischaemic heart disease mortality declines are routinely cited as salt-policy effects; the ecological design, concurrent with large changes in smoking

and statin use, cannot support that attribution, and the 3.0 mmHg is the defensible figure. The optimal blood-pressure target is unsettled. SPRINT supports below 120 systolic and ACCORD-BP found no benefit in diabetes. SPRINT excluded diabetes and used unattended automated measurement, which reads several mmHg lower than conventional office measurement, so SPRINT's 120 is not the same quantity as a clinic 120. Guidelines differ, with ACC/AHA at below 130 and ESC/ESH at below 140 for many groups. WHO's own page gives treatment goals of below 130/80 for those with cardiovascular disease, diabetes, chronic kidney disease or high cardiovascular risk and below 140/90 for most others. Salt sensitivity cannot be predicted in an individual by any available test. The heritability gap is unexplained. Global prevalence rests on national survey coverage that is thin in sub-Saharan Africa and parts of Asia, and the headline figure carries wide model uncertainty that is not usually printed. Whether the age-related rise in pressure is intrinsic is not resolved. Two editions of the same WHO fact sheet carry different headline figures — 1.28 billion and 1.4 billion — and the page contradicts itself on the treated percentage.

## Ischaemic heart disease and myocardial infarction (ICD-11 BA40–BA4Z)

**What it is.** The arteries feeding the heart muscle narrow with fatty, fibrous plaque. When flow falls short of demand the muscle hurts. When a plaque ruptures and a clot blocks the artery the muscle dies, and that is a myocardial infarction. It is the largest single cause of death in the world.

**Measured.** Deaths in 2023: 9.5 million, 16 per cent of all deaths, rank 1 of all causes, on WHO's Global Health Estimates; 8.91 million on GBD 2023. The two disagree by about 600,000 and both are printed. DALYs in 2023: 193 million (176–209), rank 1 of all causes globally; GBD 2021 gave 188.3 million, rank 2 behind COVID-19 that year. YLDs in 2023: 10.0 million (7.26–13.5), rank 25. Age-standardised death rate in GBD 2021: 108.7 per 100,000, rank 1. About 240 million people are affected. WHO's top-ten page records the 9.5 million as 3.0 million higher than in 2000.

Deaths rise steeply from age 50. The median age of a first infarction is roughly 65 in men and 72 in women in high-income countries, and about a decade earlier in south Asia. Age-standardised rates are highest in eastern Europe, central Asia and the Middle East and lowest in high-income Asia-Pacific, Andean Latin America and western Europe; absolute numbers are dominated by China and India. Age-standardised mortality has fallen sharply in high-income countries since 1980, roughly 50 to 70 per cent, while absolute global deaths have risen with population growth and ageing. Of that high-income decline, the IMPACT model analyses attribute roughly half to risk-factor change, chiefly smoking and cholesterol, and roughly half to treatment.

**Where it starts.** INTERHEART is the reference study, and the full table sits at the front of this chapter. Nine factors, combined attributable risk 90.4 per cent (99 per cent CI 88.1–92.4), 52 countries, 15,152 cases. ApoB/ApoA1 ratio carries 49.2 per cent (odds ratio 3.25); smoking 35.7 per cent (2.04); psychosocial factors 32.5 per cent (2.67); abdominal obesity 20.1 per cent (1.62); hypertension 18 per cent (1.91); diabetes 9.9 per cent (2.37). Protective: fruit and vegetables 13.7 per cent (0.70); exercise 12.2 per cent (0.86); alcohol 6.7 per cent (0.91). In INTERHEART the lipid ratio and not blood pressure carries the largest attributable risk, the reverse of INTERSTROKE, where hypertension dominates. The two vascular beds have different dominant exposures, and that is a measured difference rather than an artefact of the two designs.

Further measured contributions. LDL cholesterol is causal and dose-dependent: Mendelian randomisation and the Cholesterol Treatment Trialists' meta-analyses together give a relative risk of 0.78 (0.76–0.80) for major vascular events per 1 mmol/L of LDL reduction, across 26 trials and about 170,000 participants. Lipoprotein(a) is largely genetically set and an independent causal risk factor; roughly 20 per cent of people have elevated levels and no approved therapy lowers it with proven outcome benefit. Ambient air pollution caused an estimated 4.2 million premature deaths in 2019, 89 per cent of them in low- and middle-income countries, and 68 per cent of those deaths were ischaemic heart disease and stroke together. Household air pollution attributes 32 per cent of its 2.9 million annual deaths to ischaemic heart disease, which is 12 per cent of all ischaemic heart disease deaths worldwide and over a million deaths a year.

Why a specific plaque ruptures at a specific moment is not predictable. Most infarctions arise from plaques that were not flow-limiting and would not have been detected as significant stenoses beforehand; angiographic stenosis severity predicts angina well and infarction location poorly. The psychosocial attributable risk of 32.5 per cent is the third largest of the nine and the least mechanistically explained; what is measured — stress, depression, locus of control, life events — is heterogeneous and self-reported. Roughly 15 to 20 per cent of infarctions occur in people with none of the standard modifiable risk factors at measured thresholds, and that residual is not accounted for. Why age-standardised rates in some high-income countries have plateaued or risen slightly since about 2011, after three decades of decline, is not explained.

**Cure status.** CONTROLLABLE.

Atherosclerosis is not removed by any standing treatment. Statins and blood-pressure drugs slow progression and reduce events while taken; stopping them returns risk toward baseline. Revascularisation — percutaneous coronary intervention or coronary artery bypass grafting — restores flow past a blockage without removing the disease, and new lesions continue to form. In stable disease, intervention relieves angina but COURAGE, with 2,287 patients, and ISCHEMIA, with 5,179, found no reduction in death or myocardial infarction against optimal medical therapy alone. That is the clearest available evidence that the procedure does not cure the condition.

The exception: primary percutaneous coronary intervention in acute ST-elevation myocardial infarction is genuinely life-saving rather than palliative, and reperfusion within the first hours salvages muscle that would otherwise be lost for good. Meta-analysis against fibrinolysis gives short-term mortality of 7 against 9 per cent with a large reduction in reinfarction and stroke. It cures nothing. It converts a frequently fatal event into a survivable one.

**Prevention.**

*Statins — STRONG.* Per 1 mmol/L LDL reduction: major vascular events relative risk 0.78 (0.76–0.80), all-cause mortality 0.90 (0.87–0.93), coronary death 0.80 (99 per cent CI 0.74–0.87). Stroke death 0.96 (0.84–1.09), not significant.

*Blood pressure lowering — STRONG.* Per 10 mmHg systolic: coronary heart disease relative risk 0.83, a 17 per cent reduction; all-cause death 0.87, 13 per cent.

*Smoking cessation — STRONG, and the largest single modifiable effect after diagnosis.* The CLARIFY registry followed more than 32,000 patients with stable coronary disease for five years. Quitting after diagnosis gave a 44 per cent lower risk of major adverse cardiovascular events, adjusted hazard ratio 0.56 (95 per cent CI 0.42–0.76, $p<0.001$). Cutting down did not help: adjusted hazard ratio 0.96 (0.74–1.26, $p=0.78$). Each additional year of continued smoking raised risk by about 8 per cent, adjusted hazard ratio 1.08 (1.04–1.12) per year. Of those who eventually quit, 73 per cent did so in the first year after diagnosis. Reduction without cessation produced no measurable benefit, and that is the operative finding.

*Tobacco control policy — STRONG.* Tobacco kills more than 7 million people a year, with over 1.6 million non-smoker deaths from second-hand smoke, and there are 1.2 billion tobacco users, around 80 per cent of them in low- and middle-income countries. Counselling and medication can more than double quit success, and more than 60 per cent of smokers intend to quit. Tax is the single most effective measure, and 41 countries, covering 12 per cent of the world's population, tax at least 75 per cent of retail price; a 10 per cent price rise reduces consumption by about 4 per cent in high-income and 5 per cent in low- and middle-income countries. Smoke-free laws cover 79 countries and over a third of the world's population, and smoke-free legislation is followed by falls in acute coronary syndrome admissions of roughly 10 to 20 per cent in before-and-after studies, which are ecological designs with widely varying effect sizes.

*Polypill — MODERATE.* TIPS-3 randomised 5,713 intermediate-risk participants without cardiovascular disease; the polypill plus aspirin reduced cardiovascular events against placebo, with a reported hazard ratio of about 0.69 for that comparison. PolyIran, cluster-randomised across 6,838 participants in Iran, gave a hazard ratio of 0.66 (95 per cent CI 0.55–0.80) for major cardiovascular events with a four-component polypill.

*Trans fat elimination — STRONG where enacted.* Nearly 60 countries have best-practice trans fat policies in effect, covering 46 per cent of the world's population. WHO's REPLACE

programme is stated to have helped protect more than half the global population. One figure needs care: the WHO release states that coronary heart disease is responsible for over 278,000 deaths each year globally in the context of trans fat, and does not present this as the number of deaths attributable to industrially produced trans fat. The widely circulated figure of 500,000 deaths a year from trans fat comes from earlier WHO communications and should not be conflated with the 278,000.

*Clean cooking fuel — STRONG on the attributable fraction, WEAK on randomised prevention evidence.* Household air pollution accounts for 12 per cent of all ischaemic heart disease deaths worldwide, with 2.1 billion people still cooking with solid fuels or kerosene. HAPIN randomised liquefied petroleum gas stoves, verified a 66 per cent reduction in fine particulate exposure, and did not show its primary birth-weight benefit; cardiovascular endpoints have not been established by any trial, and the evidence is attributable-fraction modelling. Both must be stated.

*Outdoor air quality standards — STRONG on burden, MODERATE on policy effect.* In 2019, 99 per cent of the world's population lived above WHO air quality guideline levels, and ambient air pollution caused an estimated 4.2 million premature deaths, 68 per cent of them ischaemic heart disease and stroke. WHO's interim target one, 35 µg/m$^3$, would save around 300,000 deaths a year.

*Mediterranean diet — MODERATE.* PREDIMED, with 7,447 participants, reported a hazard ratio of about 0.70 for major cardiovascular events. The trial was retracted and republished in 2018 after randomisation irregularities were found at some sites, with similar effect estimates on reanalysis. Any citation must carry the retraction and republication.

*Physical activity — STRONG.* INTERHEART exercise odds ratio 0.86, attributable risk 12.2 per cent. For scale: 31 per cent of adults, 1.8 billion people, do not meet recommended activity levels, up five percentage points between 2010 and 2022 and projected to reach 35 per cent by 2030; insufficiently active people carry a 20 to 30 per cent higher risk of death.

*Vitamin, antioxidant, omega-3 and folate supplementation — CONTESTED to negative.* HOPE-2, VITAL, ASCEND, SELECT and Physicians' Health Study II found no cardiovascular benefit for vitamin E, vitamin D, folate or low-dose omega-3 in unselected populations. REDUCE-IT, with 8,179 patients on icosapent ethyl 4 g a day, reported a hazard ratio of 0.75 for the primary composite, but STRENGTH with a different omega-3 formulation was null, and the mineral-oil placebo in REDUCE-IT is disputed as having raised event rates in the control arm. The disagreement is live.

**Treatment.** Four cheap drugs carry secondary prevention after a myocardial infarction.

| Drug | Effect size | EML | Off-patent | Generic cost per patient-year |
|---|---|---|---|---|
| Aspirin 75–100 mg | Serious vascular events reduced about 19 to 22 per cent in secondary prevention; 6.7 against 8.2 per cent per year, p<0.0001, Antithrombotic Trialists' Collaboration, Lancet 2009. **NNT 67 per year and 33 over two years, recomputed by this book from those rates — see the correction below** | yes | yes | a few euro |
| Statin, simvastatin 40 mg or atorvastatin 20–80 mg | Per 1 mmol/L LDL reduction: major vascular events RR 0.78, all-cause death 0.90, coronary death 0.80. In 4S, all-cause mortality 8.2 against 11.5 per cent, NNT 30 over 5.4 years to prevent one death | yes | yes | a few to tens of euro |

| Drug | Effect size | EML | Off-patent | Generic cost per patient-year |
|---|---|---|---|---|
| ACE inhibitor, ramipril, enalapril or lisinopril | HOPE, 9,297 patients: primary composite 14.0 against 17.8 per cent, RR 0.78, NNT 26 over five years; all-cause death 10.4 against 12.2 per cent | yes | yes | a few to tens of euro |
| Beta blocker, metoprolol, bisoprolol or carvedilol | Post-infarction mortality reduced about 20 to 25 per cent in the pre-reperfusion trials, BHAT, ISIS-1 and Norwegian Timolol; NNT about 40 over two years to prevent one death. Benefit in the modern reperfusion era with preserved ejection fraction is now questioned: REDUCE-AMI, 2024, 5,020 patients, found no benefit after infarction with preserved ejection fraction, hazard ratio 0.96 | yes | yes | a few to tens of euro |

**A correction, printed in full so the reader can check it.** The dossier behind this chapter printed “NNT about 50 over 2 years” for aspirin in secondary prevention, citing the Antithrombotic Trialists’ Collaboration, Lancet 2009. That paper publishes two rates, 6.7 against 8.2 per cent per year, and no number needed to treat at all. The figure of 50 was not read off the paper and is not derivable from it; it was invented. Recomputed from the published rates: the absolute risk difference is 8.2 − 6.7 = 1.5 percentage points per year, so the number needed to treat is 1/0.015 = 66.7 per year, which is 33.3 over two years. At the published rates, 50 cannot be reached at either one year or two. The figures printed above — 67 per year, 33 over two years — are this book’s arithmetic on the paper’s published rates, and are labelled as such rather than as figures read off the paper. The 6.7 and 8.2 per cent rates are the paper’s own and are verified.

**The polypill** combines exactly these drugs and is on the Essential Medicines List. The SECURE trial enrolled 2,499 patients, mean age 76, 31 per cent women, across 113 hospitals in seven European countries, with median follow-up of 3.0 years. The polypill was aspirin 100 mg plus ramipril 2.5, 5 or 10 mg plus atorvastatin 20 or 40 mg, with 91.7 per cent receiving the 40 mg statin dose, against usual care. The primary endpoint of cardiovascular death, non-fatal infarction, non-fatal ischaemic stroke or urgent revascularisation was 9.5 against 12.7 per cent, hazard ratio 0.76 (95 per cent CI 0.60–0.96) — a 24 per cent relative and 3.2 percentage point absolute reduction, giving a number needed to treat of about 31 over three years. The secondary endpoint was 8.2 against 11.7 per cent, hazard ratio 0.70 (0.54–0.90). Cardiovascular mortality fell 33 per cent. The trial missed its enrolment target of 3,200.

Three polypill formulations were added to the Model List in 2023, in section 12.7, fixed-dose combinations for prevention of atherosclerotic cardiovascular disease, all on the core list: aspirin with atorvastatin and ramipril; aspirin with simvastatin, ramipril, atenolol and hydrochlorothiazide at 100, 20, 5, 50 and 12.5 mg; and atorvastatin with perindopril and amlodipine.

**Acute myocardial infarction.** Primary percutaneous intervention gives short-term mortality of 7 against 9 per cent compared with fibrinolysis, with large reductions in reinfarction and stroke. It requires a catheterisation laboratory, 24-hour staffing and a stent supply chain, and is not available to most of the world’s population. Fibrinolysis with streptokinase, alteplase or tenecteplase needs no catheter laboratory: in ISIS-2 and GISSI, streptokinase reduced 35-day mortality by about 25 per cent against control, and streptokinase plus aspirin by about 42 per cent. Streptokinase is on the Essential Medicines List, off-patent, and costs tens of euro a dose; tenecteplase is far more expensive and easier to give. Aspirin 300 mg chewed at onset reduced 35-day vascular mortality by 23 per cent on its own in ISIS-2, with a number

needed to treat of about 40. That is a single tablet costing under one cent, given by anyone, and it is a large absolute mortality benefit for a very low cost. Adding clopidogrel gave a composite of 9.3 against 11.4 per cent in CURE, relative risk 0.80, number needed to treat 48; clopidogrel is on the list†, off-patent, tens of euro a year.

**Newer classes, with their measured effect and their price.** PCSK9 inhibitors. FOURIER, with 27,564 patients on evolocumab, gave a primary composite hazard ratio of 0.85, 9.8 against 11.3 per cent, and a number needed to treat of about 67 over 2.2 years, with no significant reduction in cardiovascular or all-cause mortality. ODYSSEY OUTCOMES, with 18,924 patients on alirocumab, gave 0.85. These launched at about US$14,000 a year in the United States in 2015, were cut to about US$5,850 in 2018, and now run roughly €4,000 to €7,000 a year in Europe. Neither is on the Essential Medicines List and both are on patent. Cost per event prevented is on the order of €300,000 to €500,000 at those prices, against €100 to €800 for a statin. Inclisiran, a twice-yearly small interfering RNA, lowers LDL by about 50 per cent; its outcome trial, ORION-4, has not reported, so its effect on events is unmeasured, and it costs €3,000 to €4,500 a year and is not on the list. Ezetimibe: IMPROVE-IT, 18,144 patients, 32.7 against 34.7 per cent, hazard ratio 0.936, number needed to treat 50 over seven years; on the Essential Medicines List as an alternative since 2023†, off-patent, €15 to €60 a year. Colchicine 0.5 mg: COLCOT, 4,745 patients, hazard ratio 0.77; LoDoCo2, 5,522 patients, 0.69. It is off-patent and very cheap at €10 to €50 a year, and is not on the Essential Medicines List for this indication. It has among the most favourable effect-per-euro of any recent addition.

**Simple means.** Smoking cessation is the largest single effect available and requires no supply chain at all: a 44 per cent reduction in major adverse cardiovascular events after a coronary diagnosis, adjusted hazard ratio 0.56, with reduction short of quitting giving nothing, adjusted hazard ratio 0.96. Aspirin at the onset of chest pain gives about a 23 per cent reduction in 35-day vascular death from one chewed 300 mg tablet, at a cost under one cent. Exercise-based cardiac rehabilitation reduces cardiovascular mortality with a risk ratio of about 0.74 and hospital admissions by about 18 per cent, with no clear effect on all-cause mortality in the most recent Cochrane updates; walking-based programmes need no equipment. Habitual physical activity gives the INTERHEART odds ratio of 0.86 and an attributable risk of 12.2 per cent. Salt substitution gives the SSaSS mortality result, 39.28 against 44.61 per 1,000 person-years in a population with prior stroke or hypertension. A diet shifted to fruit and vegetables gives an odds ratio of 0.70 and an attributable risk of 13.7 per cent. Household air pollution accounts for 12 per cent of all ischaemic heart disease deaths, and randomised outcome evidence for the stove interventions tested is absent. Where the infarction causes cardiac arrest, bystander CPR with no equipment doubles to triples survival.

Weight loss needs stating honestly. It acts through blood pressure, lipids and glucose and improves every intermediate measure, and no independent randomised cardiovascular-outcome benefit was shown in Look AHEAD, which randomised 5,145 patients with type 2 diabetes to intensive lifestyle intervention and was stopped early for futility at a hazard ratio of 0.95.

**Gaps.** WHO and GBD disagree by about 600,000 deaths a year for this single condition, 9.5 against 8.91 million in 2023. Both are printed. The disagreement lies in cause-of-death redistribution method and neither organisation publishes a reconciliation. Beta blockers after infarction with preserved ejection fraction: the classical 20 to 25 per cent mortality benefit comes from pre-reperfusion trials and REDUCE-AMI found no benefit in the modern era; guidelines have not fully absorbed this, and both are printed. Revascularisation in stable disease: COURAGE and ISCHEMIA found no reduction in death or infarction, and intervention rates remain high — a disagreement between trial evidence and practice, not between trials. PREDIMED was retracted and republished. Omega-3 is unresolved: REDUCE-IT positive, STRENGTH null, the placebo disputed. Lipoprotein(a) is causal, common and has no outcome-proven therapy; Lp(a)HORIZON and olpasiran trials are running, and any benefit figure now would be an estimate rather than a measurement. The psychosocial attributable risk of 32.5 per cent is the least understood of the nine factors, measured heterogeneously and self-reported in a case-control design in which recall after an infarction is a plausible bias. Between 15 and 20 per cent of infarctions occur with no standard risk factor present, and that is unexplained. A population attributable risk from a case-control study is not a demonstrated

preventable fraction, and the “90 per cent preventable” reading of INTERHEART misstates what the study measured. Generic prices vary by a factor of ten or more between reference classes for the same molecule, so every price here is an order of magnitude rather than a measurement. The Management Sciences for Health price guide that several of these figures were drawn from published its last edition in 2017 and its website was retired after 30 June 2024. It cannot be used as a current source.

## Stable angina (ICD-11 BA40.0)

**What it is.** Chest pain or pressure that comes on with exertion and goes away with rest. It happens when narrowed coronary arteries cannot deliver enough blood for the work the heart is doing. The pattern is stable over months. It is not an infarction.

**Measured.** No separate global prevalence or death count exists in GBD or WHO sources; angina is counted within ischaemic heart disease, and no angina-specific figure was located. The chapter-level ischaemic heart disease figures apply: 9.5 million deaths on WHO 2023 and 8.91 million on GBD 2023, 193 million DALYs, about 240 million people affected. GBD does model angina as a sequela of ischaemic heart disease with its own disability weight, contributing to the 10.0 million ischaemic heart disease YLDs of 2023, without publishing an angina-specific count. Prevalence of angina in high-income populations is roughly 4 to 7 per cent of men and 5 to 7 per cent of women aged 45 to 64, rising with age. Women report angina at least as often as men and have less obstructive disease on angiography. Incidence of new stable angina has fallen in high-income countries alongside ischaemic heart disease mortality.

**Where it starts.** The same risk factors as ischaemic heart disease. INTERHEART applies in full: ApoB/ApoA1 ratio 49.2 per cent, smoking 35.7 per cent, psychosocial factors 32.5 per cent, abdominal obesity 20.1 per cent, hypertension 18 per cent, diabetes 9.9 per cent, combined 90.4 per cent.

The relation between measured stenosis and symptoms is weak in both directions. Severe stenoses are often silent, and a substantial proportion of patients with typical angina have no obstructive coronary disease at all — angina or ischaemia with non-obstructive coronary arteries — reported in up to 50 per cent of women undergoing angiography for angina. The proposed mechanisms, coronary microvascular dysfunction and vasospasm, are not measurable in routine practice, and the condition has no established disease-modifying treatment. Why ischaemia produces pain in some people and none in others, particularly the silent ischaemia of diabetes, is not explained.

**Cure status.** CONTROLLABLE.

Antianginal drugs relieve symptoms while taken. Percutaneous intervention relieves angina better than medical therapy in the short term and does not reduce death or infarction, in COURAGE and ISCHEMIA. The blinded evidence on symptoms is split and both results must be printed. ORBITA randomised 200 patients to intervention against a placebo procedure with sham sedation and angiography, and found no significant difference in exercise time increment, though intervention did improve stress-echocardiographic ischaemia. ORBITA-2, with 301 patients and antianginal drugs withdrawn, did show a significant symptom benefit of intervention over the placebo procedure. Bypass grafting improves survival in specific anatomies — left main disease, and three-vessel disease with reduced ejection fraction — and does not remove atherosclerosis.

**Prevention.** Identical to ischaemic heart disease, with the same grades: statins STRONG, blood-pressure lowering STRONG, smoking cessation STRONG, physical activity STRONG, diet MODERATE, polypill MODERATE, supplements CONTESTED to negative. The effect sizes and their sources are in that entry.

**Treatment.** Symptom relief and event prevention are separate tracks. No antianginal drug has been shown to reduce mortality.

| Drug | Purpose | Effect | EML | Off-patent | Cost per year |
|---|---|---|---|---|---|
| Glyceryl trinitrate, sublingual | Abort an attack | Relief in 1–3 minutes | yes | yes | a few to tens of euro |

| Drug | Purpose | Effect | EML | Off-patent | Cost per year |
|---|---|---|---|---|---|
| Beta blocker, bisoprolol, metoprolol, atenolol | First-line prophylaxis | Reduces attack frequency; no mortality benefit in stable angina | yes | yes | a few to tens of euro |
| Calcium channel blocker, amlodipine, diltiazem, verapamil | First-line alternative | Equivalent symptom control to beta blockers | yes | yes | a few to tens of euro |
| Long-acting nitrate, isosorbide mononitrate | Add-on | Symptom relief; tolerance develops | yes | yes | a few to tens of euro |
| Ivabradine | Add-on when heart rate is high | SIGNIFY, 19,102 patients: no benefit on the primary composite, and an increase in the angina subgroup | no | partly | hundreds of euro |
| Ranolazine | Add-on | Modest symptom benefit, TERISA | no | yes in some markets | hundreds to thousands of euro |
| Nicorandil | Add-on | IONA: composite reduced | no | yes | hundreds of euro |

All effect figures in this table except where the ischaemic heart disease entry marks them otherwise. Event prevention sits on top: aspirin, a statin and an ACE inhibitor, all on the Essential Medicines List, all off-patent, a few to tens of euro each a year. Revascularisation gives angina relief with no mortality benefit in stable disease; bypass grafting gives a survival benefit in left main and three-vessel disease with impaired ventricular function.

**Simple means.** Exercise training has been tested against intervention directly: Hambrecht and colleagues randomised 101 patients and reported better event-free survival with training, 88 against 70 per cent at twelve months, at lower cost. That is a small single-centre trial. Smoking cessation gives the 44 per cent reduction in major adverse cardiovascular events after a coronary diagnosis. Pacing exertion and avoiding cold exertion after meals reduces attack frequency, with no trial quantification located. Weight loss, salt reduction and diet shift act as in the ischaemic heart disease entry. Glyceryl trinitrate is the only acute relief and cannot be improvised: it is a cheap, off-patent, listed tablet or spray, and it needs a pharmaceutical chain.

**Gaps.** No angina-specific global burden figure exists; GBD counts it inside ischaemic heart disease. The blinded evidence on whether intervention relieves angina is split, ORBITA null on exercise time and ORBITA-2 positive on symptoms, and both are printed. Angina without obstructive coronary disease, possibly up to half of angina in women referred for angiography, has no established treatment and no agreed diagnostic standard. Whether the choice of antianginal affects outcome at all beyond symptoms is unresolved, and ivabradine increased events in the angina subgroup of SIGNIFY. Sex differences in presentation and in angiographic findings are documented and unexplained.

# The failing pump

## Heart failure with reduced ejection fraction (ICD-11 BD10–BD1Z)

**What it is.** The heart muscle pumps too weakly, so blood backs up and the body gets too little. Breathlessness, swollen legs and exhaustion follow. “Reduced ejection fraction” means the left ventricle empties 40 per cent or less of its contents with each beat.

**Measured.** About 64 million people worldwide have heart failure of all types, from a 2023 review in Cardiac Failure Review. That review does not state the data year or the dataset behind the figure, and the figure is carried with that caveat.

GBD does not publish heart failure as a level-3 cause, so there is no GBD death count and no DALY figure for heart failure as a syndrome. Its burden is distributed across ischaemic heart disease, hypertensive heart disease, cardiomyopathy and valvular disease. For a condition affecting roughly 64 million people, the global mortality burden is not measured directly anywhere.

Heart failure with reduced ejection fraction is roughly 50 per cent of all heart failure, with preserved ejection fraction making up most of the remainder and a mid-range group between. The primary review does not state that split; the 50 per cent comes from registry series — ESC-HF-LT, Get With The Guidelines-HF, the Swedish Heart Failure Registry. Incidence has stabilised worldwide and is apparently declining in developed countries, with no figures given in the source. Lifetime risk from age 40 is roughly 20 per cent. Mortality is roughly 50 per cent at five years after diagnosis across registries, with one-year mortality of about 25 to 30 per cent after a hospitalisation for heart failure; the review states only that heart failure carries high mortality, without rates. Prevalence rises from under 1 per cent below age 50 to over 10 per cent above 80, and is rising from ageing and from improved survival after myocardial infarction.

**Where it starts.** Ischaemic heart disease is the commonest cause in high-income countries, roughly two-thirds of cases. Hypertension is both a major cause and the most responsive target: per 10 mmHg of systolic reduction, heart failure relative risk is 0.72 (0.67–0.78), a 28 per cent reduction and the largest of the five outcomes in the blood-pressure meta-analysis. Valvular disease, cardiomyopathy both genetic and acquired, myocarditis, alcohol, anthracycline and trastuzumab chemotherapy, uncontrolled tachyarrhythmia, thyroid disease, iron overload and Chagas disease, a leading cause in Latin America, all contribute. Diabetes roughly doubles heart failure risk independent of coronary disease. Up to 30 to 40 per cent of dilated cardiomyopathy is familial, with truncating variants in the titin gene the commonest single finding, about 15 to 25 per cent of familial cases.

Why two people with the same infarct size end up with very different ventricular remodelling is not predictable. The transition from compensated ventricular dysfunction to symptomatic failure has no reliable biomarker of timing. In a substantial proportion of dilated cardiomyopathy no cause is found. Whether modern drug therapy genuinely reverses remodelling or only slows it is argued from surrogate imaging endpoints.

**Cure status.** CONTROLLABLE.

The four-drug foundation reduces mortality substantially while the ventricular dysfunction persists, and withdrawal is followed by deterioration. TRED-HF randomised 51 patients with recovered dilated cardiomyopathy to withdraw therapy and found 44 per cent relapsed within six months against none in the continuation arm. That is the clearest direct evidence that treatment holds the state rather than removing it.

Genuine cures exist where the cause is removable. Tachycardia-induced cardiomyopathy: ablation or rate control of the causative arrhythmia normalises ejection fraction in the majority. Valvular disease: valve repair or replacement can restore function if done before irreversible remodelling. Alcoholic cardiomyopathy: substantial recovery with sustained abstinence in a large minority. Peripartum cardiomyopathy: ejection fraction recovers in roughly 50 to 70 per cent. Iron overload and thyrotoxic cardiomyopathy are reversible on treating the cause. Heart transplantation removes the failing organ, with median survival after transplant of roughly 12 to 13 years; donor supply limits it to a few thousand procedures a year worldwide and it is not a population-level option.

**Prevention.**

*Blood pressure lowering — STRONG, and the largest effect of any prevention measure here.* Per 10 mmHg systolic reduction, heart failure relative risk 0.72 (0.67–0.78), a 28 per cent reduction, from 123 trials and over 600,000 participants.

*SGLT2 inhibitors in diabetes — STRONG.* EMPA-REG, CANVAS and DECLARE-TIMI 58 showed about a 30 per cent reduction in hospitalisation for heart failure in people with type 2 diabetes and no heart failure at baseline.

*Treating myocardial infarction promptly and completely — STRONG*, by limiting infarct size.

*Statins — MODERATE* for preventing heart failure, chiefly by preventing infarction.

*Alcohol limitation — MODERATE*. *Avoiding and monitoring cardiotoxic chemotherapy — MODERATE*.

*Rheumatic fever prevention with penicillin — STRONG* where rheumatic valve disease is the dominant cause. *Chagas vector control and screening — STRONG* in endemic Latin America.

**Treatment.** Four pillars. The first three are off-patent and on the Essential Medicines List; the fourth and the SGLT2 inhibitors are not.

| Drug class | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| ACE inhibitor, enalapril, ramipril, lisinopril | SOLVD-Treatment: mortality 35.2 against 39.7 per cent, RR 0.84, NNT 22 over 41 months; CONSENSUS in severe failure: one-year mortality 36 against 52 per cent, NNT 6 | yes | yes | a few to tens of euro |
| Beta blocker, carvedilol, bisoprolol, metoprolol succinate | CIBIS-II: all-cause mortality 11.8 against 17.3 per cent, HR 0.66, NNT 18 over 1.3 years; MERIT-HF 7.2 against 11.0 per cent, NNT 26 over one year; COPERNICUS in severe failure 11.4 against 18.5 per cent, NNT 14. About a 34 per cent relative mortality reduction across the three | yes | yes | a few to tens of euro |
| Mineralocorticoid receptor antagonist, spironolactone, eplerenone | RALES, spironolactone, severe failure, 1,663 patients: mortality 35 against 46 per cent, RR 0.70, NNT 9 over 24 months, among the lowest in cardiology; EMPHASIS-HF, eplerenone, HR 0.63 | yes | yes | a few to tens of euro |
| Loop diuretic, furosemide | Symptom relief. No mortality trial has ever been done and none will be | yes | yes | a few to tens of euro |
| Sacubitril/valsartan | PARADIGM-HF, 8,442 patients: primary composite 21.8 against 26.5 per cent, HR 0.80 (0.73–0.87); cardiovascular death 13.3 against 16.5 per cent, HR 0.80; all-cause death HR 0.84. NNT 21 over 27 months for the composite, about 32 for cardiovascular death | yes, added 2023 | no; generics emerging in some markets 2025–2026 | €1,000–5,000 branded; €300–900 early generic |
| SGLT2 inhibitor, dapagliflozin, empagliflozin | DAPA-HF, 4,744 patients: composite HR 0.74 (0.65–0.85), 16.3 against 21.2 per cent, NNT 21 over 18 months; all-cause death HR 0.83. EMPEROR-Reduced, 3,730 patients: HR 0.75 (0.65–0.86) | yes, dapagliflozin, 2021 and 2023 for heart failure and chronic kidney disease | no; patents expiring 2025–2028 | €400–1,500 branded; €50–200 generic where available |
| Ivabradine | SHIFT, 6,505 patients with heart rate 70 and above in sinus rhythm: composite HR 0.82, driven by hospitalisation and not death | no | partly | hundreds of euro |

| Drug class | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Digoxin | DIG, 6,800 patients: no mortality effect, HR 0.99; hospitalisation reduced | yes | yes | a few to tens of euro |
| Hydralazine with isosorbide dinitrate | A-HeFT, 1,050 self-identified Black patients: mortality 6.2 against 10.2 per cent, a 43 per cent relative reduction, NNT 25 over ten months | yes, both components | yes | tens of euro |
| Vericiguat | VICTORIA: HR 0.90, no mortality benefit | no | no | thousands of euro |

Devices. An implantable defibrillator for primary prevention of sudden death: SCD-HeFT, 2,521 patients, mortality 22 against 29 per cent, hazard ratio 0.77, number needed to treat 14 over five years; DANISH, 1,116 patients with non-ischaemic cardiomyopathy, found no all-cause mortality benefit, hazard ratio 0.87, p=0.28. Both must be printed: the benefit in non-ischaemic cardiomyopathy is disputed. Device cost tens of thousands of euro plus implantation. Cardiac resynchronisation therapy with left bundle branch block and a wide QRS: COMPANION and CARE-HF, with a mortality reduction of about 36 per cent in CARE-HF and a number needed to treat of 9 over 29 months, at tens of thousands of euro. A left ventricular assist device: REMATCH gave one-year survival of 52 against 25 per cent against medical therapy in transplant-ineligible patients, at hundreds of thousands of euro and upward.

The four cheap pillars together carry the measured mortality benefit in heart failure with reduced ejection fraction. An ACE inhibitor with a beta blocker and spironolactone costs tens of euro a patient-year at generic prices and reduces mortality by well over a third in combination. Adding sacubitril/valsartan and an SGLT2 inhibitor adds a further measured reduction at 20 to 100 times the cost.

**Simple means.** Exercise training: HF-ACTION randomised 2,331 patients and gave a hazard ratio of 0.93 for all-cause mortality or hospitalisation, p=0.13, not significant unadjusted, and 0.89, p=0.03, after prespecified adjustment, with consistent improvements in exercise capacity and quality of life. The null primary result is printed as it stands. Cochrane reviews of exercise-based rehabilitation report reduced heart-failure-specific hospitalisation and improved quality of life with no clear all-cause mortality benefit.

Salt and fluid restriction is long-standing advice, and the trial evidence is weak and inconsistent. SODIUM-HF randomised 806 patients to below 1,500 mg of sodium a day and found no reduction in death, cardiovascular hospitalisation or emergency visits, hazard ratio 0.89, p=0.53, with a small quality-of-life improvement. Grade CONTESTED. This contradicts decades of standard advice.

Daily weight monitoring to catch fluid accumulation early costs a bathroom scale and is recommended in all guidelines, and the trial evidence of benefit is weak: the telemonitoring trials TIM-HF and BEAT-HF are mostly null. Leg elevation and compression for peripheral oedema are symptomatic with no outcome data. Alcohol abstinence in alcoholic cardiomyopathy gives substantial recovery in a large minority. Smoking cessation has no heart-failure-specific randomised data and the benefit is inferred from coronary disease. Sitting upright during acute breathlessness reduces the work of breathing; universal practice, unquantified.

Furosemide is the one indispensable drug and cannot be improvised. It is cheap, off-patent and on the Essential Medicines List at €2 to €15 a year; the UNICEF indicative price in October 2026 for injection 10 mg/mL in 2 mL ampoules was US$2.05 for a box of ten on one page of the catalogue and US$1.84 on another. Decompensated heart failure cannot be managed without a diuretic, and that requires a pharmaceutical supply chain.

**Gaps.** GBD publishes no heart failure death count and no DALY figure, because heart failure is not a GBD level-3 cause. The syndrome’s global mortality burden is therefore not measured directly anywhere; it is distributed across other causes. For a condition affecting about 64 million people this is one of the largest holes in the global data, and it is part of the seventeen-

condition gap set out in this chapter's introduction. The 64 million figure comes from a 2023 review that does not state its data year or dataset. The split between reduced and preserved ejection fraction is not given in that review, and the 50 per cent figure comes from registries with selection bias toward hospitalised patients. Defibrillator benefit in non-ischaemic cardiomyopathy is unresolved, SCD-HeFT positive and DANISH null. Sodium restriction is unresolved, SODIUM-HF null against universal guideline advice. Exercise training's primary endpoint in HF-ACTION was not significant and guidelines recommend it anyway. Whether the four-pillar effect sizes are additive or overlapping is modelled rather than measured: no trial has randomised all four simultaneously against none. Most trial populations are predominantly male, white and under 75, while the median real-world patient is older and carries more comorbidity than any trial cohort.

## Heart failure with preserved ejection fraction (ICD-11 BD1Z)

**What it is.** The heart's pumping fraction looks normal but the stiff ventricle cannot fill properly at normal pressures. The person is breathless and swollen with an ejection fraction of 50 per cent or more. It is now about half of all heart failure.

**Measured.** Roughly 50 per cent of all heart failure, and rising as a proportion, from registry series. Against the roughly 64 million people with heart failure that implies something of the order of 30 million people, but no source publishes a global count for preserved ejection fraction and the arithmetic is not presented here as a measurement.

No GBD death count and no DALY figure, because heart failure is not a GBD level-3 cause. The age pattern is markedly older than reduced ejection fraction: trial mean age 70 to 75, and a majority female, unlike reduced ejection fraction. Mortality is comparable in most registries, around 50 per cent at five years, with a larger share of deaths non-cardiovascular. Incidence is rising both absolutely and as a share of heart failure, tracking obesity, hypertension, diabetes and ageing.

**Where it starts.** Hypertension is the dominant antecedent, present in about 80 to 90 per cent of cohorts; per 10 mmHg systolic reduction, heart failure of all types carries a relative risk of 0.72. Obesity, and visceral adiposity in particular, is now regarded as a driver rather than a comorbidity, and the obese phenotype is distinct. Diabetes, chronic kidney disease, atrial fibrillation present in up to 65 per cent, anaemia and sleep-disordered breathing all contribute. Transthyretin cardiac amyloidosis accounts for roughly 10 to 15 per cent of cases in men over 60 referred with left ventricular hypertrophy, and is a recognised and specifically treatable subgroup. The condition is more common in women and the reason is not established.

This is a diagnosis of exclusion with no agreed positive test, and different scoring systems — H2FPEF and HFA-PEFF — classify different people. It is widely held to be several diseases pooled under one label, and the subgroups have not been separated prospectively. Whether diastolic stiffness is the primary lesion or a consequence of systemic extracardiac disease is unresolved. Why almost every drug that works in reduced ejection fraction failed here is unexplained, and that is the central unanswered question in the field.

**Cure status.** Transthyretin cardiac amyloidosis subgroup, roughly 10 to 15 per cent: CONTROLLABLE. Remaining preserved-ejection-fraction disease: CONTROLLABLE in the sense that SGLT2 inhibitors reduce hospitalisation while taken, and no treatment has been shown to reduce mortality

For decades no treatment reduced mortality. Candesartan in CHARM-Preserved, irbesartan in I-PRESERVE, perindopril in PEP-CHF, spironolactone in TOPCAT and sacubitril/valsartan in PARAGON-HF, hazard ratio 0.87, p=0.06, all failed their primary endpoints. The SGLT2 inhibitors are the first class to succeed, and they reduce hospitalisation and not mortality. No treatment has been shown to reduce mortality in preserved ejection fraction, and that is the honest statement of the evidence.

In the transthyretin amyloidosis subgroup tafamidis is a genuine exception: ATTR-ACT, 441 patients, reduced all-cause mortality from 42.9 to 29.5 per cent, hazard ratio 0.70, and reduced cardiovascular hospitalisation. It costs hundreds of thousands of euro a year, is on patent and is not on the Essential Medicines List. A genuine mortality benefit in a defined subgroup at an extreme price. Rate control or ablation of atrial fibrillation improves symptoms substantially in the large overlap group.

**Prevention.**

*Blood pressure lowering — STRONG, and the main lever.* Heart failure relative risk 0.72 per 10 mmHg systolic. SPRINT found a 38 per cent reduction in incident heart failure with intensive targets.

*SGLT2 inhibitors in diabetes — STRONG* for preventing incident heart failure, about 30 per cent fewer heart failure hospitalisations in EMPA-REG, CANVAS and DECLARE.

*Weight management — MODERATE*, the grade limited by the absence of outcome trials for prevention. *Physical activity — MODERATE*. *Atrial fibrillation management — MODERATE*.

No trial has ever used heart failure with preserved ejection fraction as the primary prevented endpoint. Every figure above comes from a trial with a different primary purpose.

**Treatment.**

| Drug | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| SGLT2 inhibitor — the only class with a positive primary endpoint | EMPEROR-Preserved, empagliflozin, 5,988 patients with ejection fraction above 40 per cent: composite of cardiovascular death or heart failure hospitalisation 13.8 against 17.1 per cent, HR 0.79 (0.69–0.90), NNT 31 over 26 months, driven by hospitalisation with no significant reduction in cardiovascular death, HR 0.91, or all-cause death. DELIVER, dapagliflozin, 6,263 patients: HR 0.82 (0.73–0.92), same pattern | yes, dapagliflozin | no | hundreds to thousands of euro branded; tens to hundreds of euro generic |
| Loop diuretic, furosemide | Symptom relief; no outcome trial | yes | yes | a few to tens of euro |
| Spironolactone | TOPCAT, 3,445 patients: primary endpoint not met overall, HR 0.89, p=0.14; a much larger effect in the Americas than in Russia and Georgia, where event rates were implausibly low and drug-metabolite testing suggested some patients never took the drug. The regional discrepancy is unresolved and the trial is cited both ways | yes | yes | a few to tens of euro |
| Sacubitril/valsartan | PARAGON-HF, 4,822 patients: HR 0.87 (0.75–1.01), p=0.06, primary endpoint not met; benefit suggested in lower-ejection-fraction and female subgroups | yes | no | thousands of euro |
| Tafamidis, amyloidosis subgroup only | ATTR-ACT: all-cause mortality 29.5 against 42.9 per cent, HR 0.70 | no | no | hundreds of thousands of euro |
| Candesartan, irbesartan, perindopril, digoxin, nitrates, sildenafil | All failed their trials: CHARM-Preserved, I-PRESERVE, PEP-CHF, the DIG ancillary study, NEAT-HFpEF, RELAX | Most yes; **sildenafil is NOT on the 24th List in any form** | Most yes | a few to tens of euro |
| Semaglutide, obesity phenotype | STEP-HFpEF, 529 patients: large improvements in symptom score, KCCQ up 7.8 points, and in six-minute walk distance; not powered for mortality | no | no | thousands to tens of thousands of euro |

Treatment of the comorbidities — hypertension, atrial fibrillation, obesity, anaemia, sleep apnoea — is the practical substance of care, and all of it uses the cheap off-patent drugs listed in the hypertension and atrial fibrillation entries.

**Simple means.** Exercise training is the best-evidenced non-drug measure here. Meta-analyses report improvements in peak oxygen uptake of roughly 2.0 to 2.7 mL/kg/min and in six-minute walk distance of about 30 to 60 m, consistently larger relative to drug effects than in reduced ejection fraction. There are no mortality data. Weight loss in obese patients: caloric restriction plus exercise, in a 100-patient trial by Kitzman and colleagues, improved peak oxygen uptake and quality of life, with the combination best, and needs no equipment. Walking is the lowest-cost form of that. A diuretic remains indispensable for congestion and cannot be improvised. Salt reduction is plausible given the hypertension dependence, and SODIUM-HF, in a mixed population, was null: grade CONTESTED. Sleeping propped up, leg elevation and compression for oedema are symptomatic and unquantified.

**Gaps.** No GBD death count and no DALY figure exist for heart failure as a syndrome, and therefore none for the preserved-ejection-fraction half of it; this entry is part of the seventeen-condition gap in this chapter's introduction. No global prevalence figure for preserved ejection fraction exists either — the 50 per cent share is from registries. No treatment reduces mortality, 25 years after the syndrome was named, and the SGLT2 benefit is hospitalisation only. TOPCAT's regional discrepancy is unresolved and the trial is cited as both positive and negative depending on which population is treated as valid. There is no agreed diagnostic standard, and the H2FPEF and HFA-PEFF scores disagree on who has the condition, which makes prevalence figures and trial populations non-comparable. The hypothesis that this is several diseases has not been tested prospectively. Why every drug class effective in reduced ejection fraction failed here is unexplained. Cardiac amyloidosis is likely still underdiagnosed within these cohorts, and the 10 to 15 per cent figure comes from referral series with selection bias. Sildenafil is not on the 24th Model List in any form, and any statement to the contrary is wrong.

# Rhythm

## Atrial fibrillation (ICD-11 BC81.3)

**What it is.** The upper chambers of the heart quiver instead of beating, so the pulse is fast and irregular. Blood pools and can clot, and the clot can travel to the brain. It is the commonest sustained heart rhythm disorder.

**Measured.** From the GBD 2023 Results Tool, cause category atrial fibrillation and atrial flutter, as analysed in the International Journal of Stroke in 2026: prevalence in 2023, 59,045,058 cases; incidence, 5,021,980 new cases; deaths, 377,258; DALYs, 9,265,726. The burden rose sharply in absolute terms since 1990, which the source states qualitatively without giving the 1990 figures.

In INTERSTROKE, cardiac causes — predominantly atrial fibrillation — carried an odds ratio of 3.17 (2.68–3.75) and an attributable risk of 9.1 per cent for all stroke, and were associated with ischaemic stroke only, not with intracerebral haemorrhage. Lifetime risk from age 55 is roughly one in three in European-ancestry populations. The condition is rare below 50 and prevalence roughly doubles per decade thereafter, exceeding 10 per cent above age 80. Age-standardised rates are highest in high-income North America and western Europe, and part of that is detection intensity rather than true incidence. Atrial fibrillation multiplies stroke risk about fivefold overall and accounts for roughly 20 to 30 per cent of all ischaemic strokes.

**Where it starts.** Age is the strongest determinant. Hypertension carries an attributable risk for atrial fibrillation of roughly 20 per cent, the largest single modifiable contributor. Each 5 unit rise in body mass index raises risk about 10 to 29 per cent across cohorts. Alcohol is dose-dependent, each additional daily drink raising risk about 8 per cent. The abstinence trial by Voskoboinik and colleagues randomised 140 moderate drinkers with atrial fibrillation. Recurrence was 53 against 73 per cent and the atrial fibrillation burden was 0.5 against 1.2 per cent of time, with abstinence against continued drinking. That is a randomised result, and the clearest lifestyle effect in the condition. Obstructive sleep apnoea is associated with incidence and with recurrence after ablation. Endurance exercise shows a U-shaped relation:

very high-volume endurance athletes carry two- to fivefold higher risk while moderate activity is protective. Hyperthyroidism, valvular disease, heart failure, chronic kidney disease, diabetes and smoking all contribute. Over a hundred genetic loci have been identified, the strongest near PITX2 on 4q25.

What initiates a given episode at a given moment is not predictable. The relation between atrial fibrillation and stroke is not a simple pump-failure story: anticoagulation prevents stroke, and stroke risk does not track fibrillation burden closely, and patients with device-detected subclinical fibrillation have far lower stroke rates than the clinical risk scores predict. NOAH-AFNET 6 and ARTESiA both tested anticoagulation for device-detected subclinical fibrillation with divergent results: NOAH stopped early for futility and bleeding, ARTESiA showed stroke reduction with more major bleeding. Whether atrial fibrillation causes the stroke or marks an atrial myopathy that causes both is an open question with direct treatment consequences.

**Cure status.** CONTROLLABLE in general. Paroxysmal atrial fibrillation treated by catheter ablation: CURABLE in 75 per cent free of arrhythmia without antiarrhythmic drugs in the second worldwide survey, 2003 to 2006, with success definitions that vary across studies. Atrial fibrillation secondary to hyperthyroidism, to alcohol, or to an accessory pathway or atrial tachycardia driving it: CURABLE by removing the cause.

The ablation figures come from a compilation of the Heart Rhythm Society consensus document and the worldwide surveys. Early studies, per the 2017 consensus: paroxysmal fibrillation, 60 per cent or better single-procedure success and 70 per cent or better with multiple procedures; persistent fibrillation, 30 per cent or less single-procedure and 50 per cent or better with multiple. The first worldwide survey, covering procedures from 1995 to 2002 across 181 centres, gave 52 per cent successful and symptom-free without antiarrhythmic drugs, 75.5 per cent successful including those still on drugs, with 24.3 per cent needing a second procedure and 3.1 per cent a third; it did not report by fibrillation type. The second worldwide survey, covering 2003 to 2006, gave success without antiarrhythmic drugs of 75 per cent for paroxysmal, 65 per cent for persistent and 63 per cent for longstanding persistent fibrillation, with 70 per cent overall without drugs and 80 per cent including drug users. Some centres report 80 to 85 per cent for first ablations and 95 per cent for second procedures, and the compiling source notes that these are not measured consistently and that success definitions, follow-up length and monitoring method vary across all these studies, so the figures are not directly comparable. That caveat belongs with any ablation success rate.

What ablation does and does not do. CABANA, with 2,204 patients randomised to ablation or drug therapy, did not meet its primary composite endpoint, hazard ratio 0.86, p=0.30, though it reduced recurrence and improved quality of life. CASTLE-AF, 363 patients with atrial fibrillation and heart failure, found ablation reduced death or heart failure hospitalisation, hazard ratio 0.62. EAST-AFNET 4, 2,789 patients, found early rhythm control, whether by drugs or ablation, reduced cardiovascular death, stroke or hospitalisation, hazard ratio 0.79. So ablation abolishes the arrhythmia in a majority of paroxysmal cases, which is a cure of the rhythm disorder, while the stroke risk and the anticoagulation decision are not abolished with it: successful ablation does not license stopping anticoagulation in a patient with a high stroke-risk score on current evidence.

**Prevention.**

*Blood pressure control — MODERATE.* Hypertension is the largest modifiable contributor, attributable risk about 20 per cent.

*Alcohol reduction or abstinence — STRONG for recurrence, and randomised.* Recurrence 53 against 73 per cent with abstinence.

*Weight loss — MODERATE, with observational support.* The LEGACY and ARREST-AF studies, registry and observational designs with structured weight management, reported substantially higher arrhythmia-free survival with 10 per cent or more weight loss.

*Treating obstructive sleep apnoea — WEAK.* Observational support for reduced recurrence; no adequately powered randomised trial.

*Moderate physical activity — MODERATE*. *Avoiding extreme endurance training volumes — WEAK*, observational only.

**Treatment.** Almost all the mortality benefit lies in anticoagulation.

| Drug | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Warfarin | Against placebo or control: stroke reduced about 64 per cent, RR 0.36; all-cause mortality reduced 26 per cent, Hart and colleagues, Annals of Internal Medicine 2007 meta-analysis. NNT about 25 a year in high-risk fibrillation to prevent one stroke | yes | yes | a few to tens of euro for the drug, but INR monitoring costs tens to hundreds of euro a year and is the real constraint |
| Aspirin | Stroke reduced only about 22 per cent against control; clearly inferior to warfarin and no longer recommended for stroke prevention in atrial fibrillation | yes | yes | a few euro |
| Apixaban | ARISTOTLE, 18,201 patients, against warfarin: stroke or systemic embolism 1.27 against 1.60 per cent a year, HR 0.79; all-cause mortality HR 0.89; major bleeding HR 0.69; intracranial haemorrhage HR 0.42 | yes, added 2019 | generics from 2026 in several markets | €500–3,000 branded; €30–150 early generic |
| Dabigatran | RE-LY, 18,113 patients: 150 mg gave stroke HR 0.66 against warfarin | yes | partly | hundreds to thousands of euro; generic lower |
| Rivaroxaban | ROCKET-AF, 14,264 patients: HR 0.88, non-inferior | yes | generics available | hundreds to thousands of euro branded; tens to hundreds of euro generic |
| Beta blocker, rate control | Symptom and rate control; no mortality benefit in atrial fibrillation itself | yes | yes | a few to tens of euro |
| Digoxin, rate control | Rate control at rest; observational signals of harm at higher serum levels, disputed | yes | yes | a few to tens of euro |
| Amiodarone, rhythm control | The most effective antiarrhythmic for maintaining sinus rhythm; thyroid, pulmonary, hepatic and ocular toxicity limit long-term use; no mortality benefit | yes | yes | tens of euro |
| Flecainide, propafenone, sotalol, dronedarone | Rhythm control; contraindicated with structural disease, per the CAST trial | Sotalol and flecainide partly | Mostly yes | tens to hundreds of euro |

Rate against rhythm control. AFFIRM, with 4,060 patients, and RACE found no mortality difference between rate control and rhythm control with the drugs of that era. EAST-AFNET 4, in 2020, found early rhythm control better, hazard ratio 0.79. The two results are reconciled by timing and by ablation availability rather than contradicted.

Procedures. Catheter ablation costs €8,000 to €25,000 a procedure in Europe and the United States, year not stated in the source and requires an electrophysiology laboratory; the success rates are above. Left atrial appendage occlusion, in PROTECT-AF and PREVAIL, was non-inferior to warfarin for stroke prevention in selected patients, at tens of thousands of euro. Ablation of the atrioventricular node with pacing gives symptom control for an uncontrollable rate and commits the patient to pacemaker dependence.

Warfarin is the single most important off-patent drug in this condition: stroke reduced about 64 per cent, mortality about 26 per cent, drug cost a few to tens of euro a year. Its constraint is not price but INR monitoring. Where point-of-care INR testing exists, warfarin delivers nearly the whole benefit of a direct oral anticoagulant at a fraction of the price, and the measured advantage of the newer drugs is chiefly in intracranial haemorrhage, hazard ratio 0.42 for apixaban, and in not needing monitoring.

**Simple means.** Pulse-taking is the cheapest cardiovascular screening test in existence. Atrial fibrillation can be detected by a finger on the wrist — an irregularly irregular pulse — with no equipment at all, and pulse palpation has a sensitivity for atrial fibrillation of roughly 87 to 97 per cent with a specificity of 70 to 81 per cent in screening studies. It detects the condition that causes 20 to 30 per cent of ischaemic strokes.

Alcohol abstinence gives recurrence of 53 against 73 per cent, randomised, and nothing is required but stopping. Weight loss of 10 per cent or more is associated with substantially higher arrhythmia-free survival. Blood pressure control by salt reduction, weight loss and exercise acts as in the hypertension entry. Vagal manoeuvres — Valsalva, cold water to the face — terminate some supraventricular tachycardias and do not terminate atrial fibrillation; that is worth stating plainly, because the error is common.

Anticoagulation cannot be improvised, and that is where this condition needs an industrial chain: warfarin plus INR measurement, or a direct oral anticoagulant. Without it the stroke risk stands. Rate control with a cheap beta blocker relieves symptoms and does nothing for stroke.

**Gaps.** Prevalence figures depend heavily on detection intensity. Screening with wearables finds large amounts of subclinical fibrillation whose clinical meaning is unsettled — STROKESTOP, mSToPS, Apple Heart, LOOP — and the 59 million figure is a modelled estimate from diagnosed disease. Subclinical device-detected fibrillation is unresolved and directly consequential: NOAH-AFNET 6 and ARTESiA gave divergent answers on whether to anticoagulate. Ablation success rates are not comparably measured; definitions of success, monitoring intensity and follow-up duration all vary, and the compiling source says so explicitly, so a single quoted percentage is not interpretable without its definition. Whether successful ablation permits stopping anticoagulation is not established by trial. CABANA missed its primary endpoint while CASTLE-AF and EAST-AFNET 4 were positive; the populations differ and the field cites selectively. The causal relation between atrial fibrillation and stroke against a shared atrial myopathy is open. Digoxin harm signals are observational and confounded by indication.

## Other arrhythmias (ICD-11 BC63–BC9Z)

**What it is.** Any heartbeat that is too fast, too slow or out of sequence other than atrial fibrillation. Some are harmless extra beats. Others stop the circulation within seconds.

**Measured.** GBD publishes no separate burden figures for arrhythmias other than atrial fibrillation and flutter. No global prevalence, death or DALY figure exists for supraventricular tachycardia, ventricular tachycardia, heart block or sick sinus syndrome. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Supraventricular tachycardia of the atrioventricular nodal reentrant and accessory-pathway types has a prevalence of roughly 2.25 per 1,000 population and an incidence of 35 per 100,000 person-years, from the Marshfield epidemiology study of 1998. The Wolff-Parkinson-White pattern on an electrocardiogram has a prevalence of 1 to 3 per 1,000, with a sudden death risk of roughly 0.1 per cent a year in those carrying the pattern and lower in asymptomatic individuals. Pacemaker implantation rates for complete heart block and bradyarrhythmia run roughly 500 to 1,200 per million population a year in high-income countries. Ventricular arrhythmia burden is counted within cardiac arrest and ischaemic heart disease. Nodal reentrant tachycardia presents typically between 20 and 50 and more often in women; accessory-pathway tachycardia presents younger; bradyarrhythmias and heart block rise steeply with age. Pacemaker and ablation rates differ by a factor of 50 or more between high- and low-income countries, which reflects access rather than disease frequency.

**Where it starts.** Accessory pathways and dual atrioventricular nodal physiology are congenital anatomical variants present from birth. Structural heart disease, and prior infarction scar in particular, is the commonest substrate for sustained ventricular tachycardia. The inher-

ited channelopathies: long QT syndrome, prevalence about 1 in 2,000, with more than fifteen genes of which KCNQ1, KCNH2 and SCN5A are commonest; Brugada syndrome, about 1 in 2,000 and higher in southeast Asia; catecholaminergic polymorphic ventricular tachycardia; short QT syndrome. Drugs that prolong the QT interval make a long and clinically important list. Electrolyte disturbance — low potassium, magnesium or calcium — contributes, as do thyroid disease, caffeine and stimulants, alcohol, fever and sleep deprivation as triggers of benign ectopy and of some tachycardias. Degenerative fibrosis of the conduction system causes most acquired heart block. Infective causes include Chagas disease, Lyme carditis, diphtheria, rheumatic carditis and viral myocarditis.

Why an accessory pathway present since birth conducts dangerously in one person and never in another is not predictable. Risk stratification in asymptomatic Wolff-Parkinson-White, Brugada and long QT syndrome is weak: most sudden deaths in these conditions occur in people who would not have been selected for a defibrillator by current criteria, and most people meeting the criteria never have an event. The timing of a lethal ventricular arrhythmia is unpredictable even with full knowledge of the substrate.

**Cure status.** Pathway-dependent tachycardias — nodal reentrant tachycardia, accessory pathway, atrial tachycardia, typical atrial flutter, idiopathic outflow-tract ventricular tachycardia: CURABLE. Inherited channelopathies: CONTROLLABLE. Heart block and ventricular arrhythmia on a structural substrate: CONTROLLABLE. Arrhythmia from a reversible cause — electrolytes, thyroid, drug, fever: CURABLE by removing the cause.

Catheter ablation of atrioventricular nodal reentrant tachycardia gives acute success of 96 to 99 per cent, recurrence of 2 to 5 per cent, and a risk of requiring a pacemaker from atrioventricular block under 1 per cent, lower still with modern cryoablation. That is a single procedure that permanently removes the condition. Ablation of an accessory pathway gives acute success of 93 to 98 per cent and recurrence of 3 to 8 per cent, and permanently abolishes both the arrhythmia and the sudden-death risk. Ablation of atrial tachycardia and typical atrial flutter gives acute success above 95 per cent and long-term freedom around 90 per cent, among the most reliably curative procedures in medicine. Idiopathic outflow-tract ventricular tachycardia in a structurally normal heart has an ablation success of 80 to 95 per cent and is usually curative.

A pacemaker for complete heart block is not a cure; it substitutes permanently for the failed conduction system, and it restores normal life expectancy in isolated heart block. A defibrillator is not a cure; it terminates events and leaves the substrate. In the channelopathies beta blockade reduces events in long QT syndrome, with nadolol and propranolol most effective, and a defibrillator terminates them; nothing removes the mutation.

**Prevention.**

*Avoiding QT-prolonging drug combinations — STRONG*, and the single most actionable measure; drug-induced torsades de pointes is substantially preventable by prescribing review.

*Correcting potassium and magnesium — STRONG*.

*Beta blockade in diagnosed long QT syndrome — STRONG*: cardiac events reduced by roughly 60 to 80 per cent in registry cohorts.

*Family screening after a sudden cardiac death in a young person — MODERATE* for identifying at-risk relatives; a diagnosis is found in roughly 20 to 50 per cent of first-degree relatives in specialist series.

*Avoiding competitive extreme exertion in diagnosed catecholaminergic polymorphic ventricular tachycardia and some long QT genotypes — MODERATE*, and the restriction advice has loosened as data accumulated.

*Preventing rheumatic fever and Chagas disease — STRONG* where these cause conduction disease.

*Reducing caffeine, alcohol and stimulants — WEAK for benign ectopy, and CONTESTED*: randomised caffeine studies have generally not shown increased ectopy.

**Treatment.**

| Intervention | Effect | EML | Off-patent | Cost |
|---|---|---|---|---|
| Adenosine, acute termination of supraventricular tachycardia | Terminates nodal reentrant and accessory-pathway tachycardia in about 90 per cent of episodes within seconds | yes | yes | a few to tens of euro a dose |
| Verapamil or diltiazem | Effective acutely and as prophylaxis; contraindicated in Wolff-Parkinson-White with pre-excited atrial fibrillation | yes | yes | a few to tens of euro a year |
| Beta blocker | First-line prophylaxis for most supraventricular tachycardia, long QT syndrome, catecholaminergic polymorphic ventricular tachycardia and ectopy | yes | yes | a few to tens of euro a year |
| Amiodarone | The most effective antiarrhythmic; substantial cumulative toxicity; no mortality benefit as primary prophylaxis, since the amiodarone arm of SCD-HeFT was no better than placebo | yes | yes | tens of euro a year |
| Lidocaine, acute ventricular arrhythmia | | yes | yes | a few to tens of euro a dose |
| Flecainide or propafenone | Effective in structurally normal hearts; increased mortality after myocardial infarction in the CAST trial, a landmark negative result | partly | yes | tens to hundreds of euro a year |
| Magnesium sulfate, torsades de pointes | First-line and rapidly effective | yes, section 5.1.1, with a restriction to eclampsia and severe pre-eclampsia on the Model List | yes | €1–5 a dose. UNICEF indicative price October 2026: US$33.11 for 100 ampoules of 5 g in 10 mL, about US$0.33 an ampoule |
| Atropine or isoprenaline, acute bradycardia | | yes, atropine | yes | a few to tens of euro a dose |
| Catheter ablation | Nodal reentrant tachycardia 96–99 per cent, accessory pathway 93–98 per cent, atrial flutter above 95 per cent | n/a | n/a | thousands to tens of thousands of euro a procedure |
| Pacemaker | Restores normal life expectancy in isolated heart block | n/a | n/a | thousands to tens of thousands of euro device plus implantation |
| Implantable defibrillator | Terminates ventricular arrhythmia; SCD-HeFT HR 0.77, NNT 14 over five years; DANISH null in non-ischaemic cardiomyopathy | n/a | n/a | tens of thousands of euro |

Catheter ablation of accessory pathways and of nodal reentrant tachycardia is one of the clearest genuine cures in all of medicine: a single procedure, success above 95 per cent, permanent, and in the Wolff-Parkinson-White case it removes a sudden-death risk.

**Simple means.** Vagal manoeuvres for supraventricular tachycardia cost nothing and terminate a frightening arrhythmia in a substantial minority. Standard Valsalva terminates roughly 20 to 40 per cent of episodes, and the modified Valsalva — supine with leg elevation immediately after straining — raised success to 43 against 17 per cent in the randomised REVERT trial of 428 patients. It is a technique rather than a device. It does not work for atrial fibrillation. Carotid sinus massage and cold water immersion of the face, the diving reflex, terminate some supraventricular tachycardias, and the cold-water method is used in infants. Pulse-taking detects both tachy- and bradyarrhythmia with no equipment. Correcting potassium by diet — fruit, vegetables, legumes — reduces ectopy risk where the deficiency is dietary. Stopping the offending drug is free and is the treatment for drug-induced

arrhythmia. A precordial thump for witnessed monitored pulseless ventricular tachycardia has success rates under 2 per cent in most series and is no longer recommended except in witnessed monitored arrest with no defibrillator immediately available.

Everything else here needs a supply chain. Adenosine, amiodarone, pacemakers, defibrillators and ablation cannot be improvised. For lethal arrhythmia, bystander CPR is the only no-equipment intervention, and it buys time rather than terminating the rhythm.

**Gaps.** No global burden figures exist for arrhythmias other than atrial fibrillation and flutter — no prevalence, no deaths, no DALYs — and this entry is part of the seventeen-condition gap in this chapter's introduction. It is a real hole: conditions curable by a single ablation procedure have no measured global prevalence. Risk stratification in asymptomatic Wolff-Parkinson-White, Brugada and long QT syndrome is weak; most events occur outside the criteria and most people inside the criteria never have an event, and guidelines differ substantially between societies. Ablation success rates come largely from specialist-centre series with publication bias toward good results, and population-level success rates are not measured. Caffeine and ectopy is contested: observational association, randomised studies largely null. Pacemaker and ablation rates differ fiftyfold internationally, and whether the low-rate countries carry untreated disease or lower incidence is not measured. Defibrillator benefit in non-ischaemic cardiomyopathy is unresolved, SCD-HeFT against DANISH.

# The arteries of the brain

## Ischaemic stroke (ICD-11 8B11)

**What it is.** A clot blocks an artery in the brain and the tissue beyond it dies within minutes to hours. The person suddenly loses speech, strength, vision or balance on one side. It is the commonest kind of stroke.

How common a share it is cannot be given as a single number. GBD's stroke series puts ischaemic stroke at roughly 62 to 65 per cent of incident strokes globally and about 87 per cent in high-income countries. A figure of about four in five is widely carried, and another chapter of this book gives roughly 70 to 85 per cent of cases†. Three figures circulate for one quantity and all three stand.

**Measured.** All stroke deaths in 2023: 6.8 million, about 11 per cent of all deaths and rank 2 of all causes, on WHO's Global Health Estimates; 6.79 million on GBD 2023. The two agree closely here, unlike ischaemic heart disease.

All stroke DALYs in 2023: **157 million, 95 per cent uncertainty interval 141 to 172, rank 3 of all causes globally**, from GBD 2023. A figure of 160 million also circulates and is the WHO figure for 2021; it is named here beside the GBD figure rather than printed instead of it. These are not two measurements of the same thing disagreeing: they are two different sources with different reference years, and 157 million is the GBD 2023 figure this book uses. Stroke YLDs in 2023: 16.7 million (12.0–21.2), rank 17. The age-standardised death rate for all stroke in GBD 2021 was 87.4 per 100,000, rank 3. Ischaemic stroke is the third leading cause of cardiovascular DALYs in GBD 2023, behind ischaemic heart disease and intracerebral haemorrhage.

Global incident strokes run at roughly 12 million a year. The number of stroke survivors alive is given as about 101 million in the GBD stroke capstone and as 93.8 million on the WHO stroke fact sheet for 2021 data; the two differ by 7.2 million for the same quantity and both stand. Incidence roughly doubles each decade after 55, and a rising share of strokes occurs under 55, especially in low- and middle-income countries. Age-standardised incidence is highest in east Asia, eastern Europe and central Asia, and over 85 per cent of stroke deaths occur in low- and middle-income countries. Age-standardised stroke mortality has fallen substantially since 1990 while absolute numbers have risen. Lifetime risk of stroke from age 25 is 24.9 per cent globally on the GBD 2016 lifetime-risk analysis, which WHO renders as one in four adults.

**Where it starts.** INTERSTROKE is the reference study and the full table sits at the front of this chapter. The combined attributable risk for ischaemic stroke specifically is 91.5 per cent (95 per cent CI 89.4–93.2). Ranked by attributable risk for all stroke, with the odds ratio in brackets. Hypertension 47.9 per cent (2.98). Physical inactivity 35.8 per cent (0.60

for activity). ApoB/ApoA1 ratio 26.8 per cent (1.84). Diet 23.2 per cent (0.60 for a good diet). Waist-to-hip ratio 18.6 per cent (1.44). Psychosocial factors 17.4 per cent (2.20). Current smoking 12.4 per cent (1.67). Cardiac causes 9.1 per cent (3.17). Alcohol 5.8 per cent (2.09 for heavy intake). Diabetes 3.9 per cent (1.16). This book prints the published one-decimal values; the same table appears elsewhere in the book rounded to integers, and the one-decimal values are the published ones.

The ApoB/ApoA1 ratio and atrial fibrillation were associated with ischaemic stroke in all regions and are the two factors specific to this subtype; neither was associated with intracerebral haemorrhage. Regional variation is large: smoking attributable risk from 4.5 per cent in Africa to 18 per cent in western Europe, North America and Australia; physical inactivity from 4.7 per cent in Africa to 59.9 per cent in China. Waist-to-hip ratio associations were largest in western Europe, North America, Australia and parts of Asia, and larger in women; cardiac causes carried larger odds in women.

Further contributions. Atrial fibrillation multiplies stroke risk about fivefold and causes 20 to 30 per cent of ischaemic strokes. Symptomatic carotid stenosis of 70 per cent or more carries a two-year stroke risk of about 26 per cent untreated, from NASCET. Household air pollution attributes 23 per cent of its 2.9 million annual deaths to stroke, which is about 12 per cent of all stroke deaths worldwide; ambient air pollution's 4.2 million premature deaths are 68 per cent ischaemic heart disease and stroke together. Sickle cell disease, patent foramen ovale in young cryptogenic stroke, cervical artery dissection, vasculitis, antiphospholipid syndrome and Fabry disease are less common causes.

About 25 per cent of ischaemic strokes remain cryptogenic after full investigation. The higher diet-score risk observed in south Asia in INTERSTROKE is a reversal the paper does not explain. Why the same degree of carotid stenosis causes stroke in one person and not another is not predictable. The mechanism of the psychosocial association is not established and the measurement is self-reported in a case-control design. Why stroke incidence is rising in people under 55 is not explained by the measured risk factors.

**Cure status.** CONTROLLABLE as a disease state. The deficit already sustained after the acute event: RELIEF ONLY, since it is permanent tissue loss.

Nothing removes the predisposition. Reperfusion within the therapeutic window salvages threatened but not yet dead tissue, which is why the effect size collapses with time. The infarcted tissue does not regenerate; recovery after the acute phase is reorganisation of surviving networks, not repair. Secondary prevention reduces recurrence while taken.

The acute treatments are genuinely effective and strictly time-dependent. Intravenous thrombolysis with alteplase within 4.5 hours has a number needed to treat of about 10 within three hours for an improved modified Rankin outcome, rising to about 20 at three to 4.5 hours, with symptomatic intracranial haemorrhage rising from about 0.4 to about 6 per cent. Mechanical thrombectomy for large-vessel occlusion has a number needed to treat of 2.6 for any reduction in disability and about 5 for functional independence, from the HERMES meta-analysis of five trials — MR CLEAN, ESCAPE, EXTEND-IA, SWIFT PRIME and REVASCAT — covering 1,287 patients, odds ratio 2.49 for improved functional outcome. That is among the lowest numbers needed to treat of any procedure in medicine. It requires a catheter suite, an interventional team and imaging within hours, and is therefore unavailable to most of the world's population.

**Prevention.**

*Blood pressure lowering — STRONG, and the largest single lever.* Per 10 mmHg systolic reduction, stroke relative risk 0.73 (0.68–0.77), a 27 per cent reduction. Hypertension carries the largest INTERSTROKE attributable risk at 47.9 per cent.

*Salt reduction and salt substitution — STRONG, with randomised mortality evidence.* SSaSS, in 20,995 participants with prior stroke or hypertension over 4.74 years: stroke 29.14 against 33.65 per 1,000 person-years ($p=0.006$), major cardiovascular events 49.09 against 56.29 ($p<0.001$), total mortality 39.28 against 44.61 ($p<0.001$), no excess hyperkalaemia. The UK programme cut salt by 1.4 g a day with systolic pressure down 3.0 mmHg, and stroke mortality fell 42 per cent over the same period — ecological, and not attributable. CONTESTED at low intakes: the PURE J-curve against the TOHP reanalysis, with the urine-measurement method the contested variable. See the hypertension entry.

*Anticoagulation in atrial fibrillation — STRONG.* Warfarin reduces stroke about 64 per cent and mortality 26 per cent, number needed to treat about 25 a year in high-risk fibrillation. This is the highest-yield single prevention action available for ischaemic stroke.

*Statins — STRONG, with one qualification that is usually dropped.* Per 1 mmol/L LDL reduction, major vascular events relative risk 0.78; for more against less intensive therapy, ischaemic stroke reduced 16 per cent (95 per cent CI 5–26). The same meta-analysis found no significant reduction in stroke death, relative risk 0.96 (0.84–1.09), because statins slightly raise haemorrhagic stroke risk. Both are printed.

*Physical activity — STRONG.* INTERSTROKE odds ratio 0.60 for regular activity, attributable risk 35.8 per cent, the second largest in the study.

*Diet — STRONG.* INTERSTROKE mAHEI odds ratio 0.60, attributable risk 23.2 per cent.

*Smoking cessation — STRONG.* INTERSTROKE smoking attributable risk 12.4 per cent, odds ratio 1.67; cessation after a coronary diagnosis gives a 44 per cent reduction in major adverse cardiovascular events.

*Carotid endarterectomy for symptomatic stenosis of 70 per cent or more — STRONG.* NASCET gave two-year ipsilateral stroke of 9 against 26 per cent, number needed to treat 6 over two years. For asymptomatic stenosis the benefit is much smaller and now CONTESTED given improved medical therapy; ACST-2 has reported and CREST-2 is running.

*Polypill — MODERATE.* The SECURE primary endpoint, which includes non-fatal ischaemic stroke, gave a hazard ratio of 0.76, and the aspirin, simvastatin, ramipril, atenolol and hydrochlorothiazide polypill on the Essential Medicines List is indicated for cerebral ischaemic stroke.

*Clean cooking and air quality — STRONG on attributable burden, WEAK on randomised prevention evidence.* Household air pollution accounts for about 12 per cent of stroke deaths; the randomised stove trials missed their primary endpoints.

*Patent foramen ovale closure in young cryptogenic stroke — MODERATE.* CLOSE, REDUCE and the long-term RESPECT follow-up found recurrent stroke reduced with hazard ratios around 0.2 to 0.4 in selected patients under 60, with atrial fibrillation increased.

**Treatment.** Acute:

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Aspirin 160–300 mg within 48 hours | IST and CAST: death or dependency reduced, about 9 fewer deaths or recurrent strokes per 1,000 treated, NNT about 100 | yes | yes | Under under one euro a dose |
| Alteplase, intravenous thrombolysis within 4.5 hours | NNT about 10 within three hours, about 20 at three to 4.5 hours for improved outcome; symptomatic intracranial haemorrhage about 6 against 0.4 per cent | yes | yes; tenecteplase is on patent in most markets | hundreds of euro a dose for generic alteplase; tenecteplase higher |
| Mechanical thrombectomy | NNT 2.6 for reduced disability, about 5 for functional independence, HERMES, 1,287 patients, OR 2.49 | n/a | n/a | tens of thousands of euro a procedure |
| Stroke unit care | Death or dependency reduced by about 20 per cent, odds ratio about 0.79, against a general ward, from the Stroke Unit Trialists Collaboration Cochrane review. NNT about 20. Requires organisation and nursing, not technology | n/a | n/a | Organisational |
| Decompressive craniectomy for malignant middle cerebral artery infarction | DESTINY, DECIMAL and HAMLET pooled: mortality 22 against 71 per cent, with increased survival at severe disability | n/a | n/a | Surgical |

Secondary prevention is an antiplatelet — aspirin, or clopidogrel, or aspirin with dipyridamole — plus a statin and an antihypertensive, all on the Essential Medicines List, all

off-patent, together tens of euro a patient-year. Short-course dual antiplatelet therapy after minor stroke or transient ischaemic attack, in CHANCE and POINT, reduced recurrent stroke with hazard ratios around 0.68 to 0.75, with the benefit confined to the first three weeks. Anticoagulation replaces antiplatelet therapy where atrial fibrillation is present.

Stroke unit care is the intervention with the largest population-level benefit and the lowest technology requirement. It needs trained nursing, swallow assessment, early mobilisation and organised protocols, not a catheter laboratory. In most of the world it is the realistic intervention, and its effect applies to every stroke patient rather than to the 10 to 20 per cent who arrive inside a reperfusion window.

**Simple means.** Salt substitution is the cheapest proven stroke-prevention commodity in existence: SSaSS gave stroke of 29.14 against 33.65 per 1,000 person-years and total mortality of 39.28 against 44.61 in a population including prior-stroke patients. Physical activity gives an odds ratio of 0.60 and an attributable risk of 35.8 per cent, up to 59.9 per cent in China, and the activity is walking. Smoking cessation gives 12.4 per cent. Weight and waist reduction gives 18.6 per cent. A diet shifted to fruit, vegetables, fish and legumes gives 23.2 per cent. Cutting heavy drinking gives 5.8 per cent. Pulse palpation to find atrial fibrillation needs no equipment and is about 87 to 97 per cent sensitive; finding atrial fibrillation and anticoagulating prevents about 64 per cent of the strokes it would cause. Blood pressure measurement with a mechanical cuff is the single most useful piece of low-technology equipment in stroke prevention, by way of the 47.9 per cent attributable risk.

Aspirin within 48 hours of an ischaemic stroke gives about 9 fewer deaths or recurrent strokes per 1,000 treated, one tablet, under one euro. It must not be given before haemorrhage is excluded, and that needs a scanner. The scanner is the binding constraint, not the aspirin.

Positioning, swallow assessment and early mobilisation are nursing practice rather than equipment, and they are the core of stroke unit care. Withholding oral intake until swallow is assessed prevents aspiration pneumonia, a leading cause of post-stroke death. One qualification: AVERT, with 2,104 patients, found that very early and very high-dose mobilisation was worse than usual early care, odds ratio 0.73 for a favourable outcome, so earlier and more is not simply better. Rehabilitation by repetitive task practice with no devices improves function, with modest and dose-dependent effect sizes.

**Gaps.** About 25 per cent of ischaemic strokes are cryptogenic after full workup. Statins reduce ischaemic stroke and slightly increase haemorrhagic stroke, and the Cholesterol Treatment Trialists' meta-analysis found no reduction in stroke death at all, relative risk 0.96; this is routinely omitted when statins are described as stroke prevention, and it is printed here. Carotid intervention for asymptomatic stenosis is contested, since modern medical therapy may have erased the surgical benefit, and CREST-2 is designed to answer it and has not reported. Thrombolysis beyond 4.5 hours and in mild deficits remains debated, and the alteplase evidence has been publicly disputed over trial-level reanalysis. The INTERSTROKE diet reversal in south Asia is unexplained. Rising incidence under 55 is unexplained by measured risk factors. Global incidence figures depend on registries that barely exist across much of Africa and south Asia, and the 12 million figure carries wide model uncertainty. AVERT contradicts the instruction to mobilise as early and as much as possible. The number of stroke survivors is given as 101 million in one source and 93.8 million in another, and both stand. The ischaemic share of all strokes is given as 62 to 65 per cent globally, as about four in five, and as 70 to 85 per cent, in three different places; all three stand. A population attributable risk from a case-control design is not a demonstrated preventable fraction.

## Haemorrhagic stroke — intracerebral haemorrhage (ICD-11 8B00)

**What it is.** A small artery deep in the brain bursts and blood presses into the tissue. Headache, vomiting and loss of consciousness come on within minutes. It kills a much higher proportion of those affected than clot-caused stroke.

**Measured.** Intracerebral haemorrhage is the second leading cause of cardiovascular DALYs in GBD 2023, which ranks it above ischaemic stroke in third place, because it kills younger. GBD does not publish a separate death count for it in the retrieved tables; it falls within the 6.79 million GBD 2023 and 6.8 million WHO 2023 all-stroke deaths.

The haemorrhage share of all stroke is roughly 28 per cent of incident strokes globally, far higher in east and southeast Asia and sub-Saharan Africa, up to 35 to 40 per cent, and about

10 to 15 per cent in high-income western countries. Case fatality at 30 days is 35 to 52 per cent, with roughly half of deaths in the first two days — three to four times the case fatality of ischaemic stroke. The mean age at onset is younger than for ischaemic stroke, and the burden in people aged 40 to 60 is substantial, which is why the DALY rank exceeds the share of deaths. More than 80 per cent of cases occur in low- and middle-income countries, and incidence in east Asia is roughly double that in western Europe. Age-standardised incidence has fallen in high-income countries and risen or stayed flat elsewhere.

**Where it starts.** INTERSTROKE gives a combined attributable risk for intracerebral haemorrhage of 87.1 per cent (95 per cent CI 82.2–90.8). The factors associated with haemorrhage specifically are hypertension, physical activity, diet, waist-to-hip ratio, psychosocial factors, cardiac causes and alcohol. The ApoB/ApoA1 ratio and atrial fibrillation were not associated with haemorrhage; they were specific to ischaemic stroke. That is a measured difference between the subtypes and it matters: the lipid pathway is not the haemorrhage pathway.

Hypertension is the dominant cause, with an INTERSTROKE odds ratio of 2.98 for all stroke and an attributable risk of 47.9 per cent, and the hypertension odds ratio for haemorrhage specifically is higher than for ischaemic stroke in the published subtype analysis. Alcohol has a stronger association with haemorrhage than with ischaemic stroke; heavy or heavy episodic drinking carries an odds ratio of 2.09 for all stroke and higher for haemorrhage. Cerebral amyloid angiopathy causes most lobar haemorrhage in people over 70 and is the second major pathology after hypertensive small-vessel disease. Anticoagulation raises haemorrhage risk roughly seven- to tenfold with warfarin, and the direct oral anticoagulants roughly halve that against warfarin, with apixaban's intracranial haemorrhage hazard ratio of 0.42 in ARISTOTLE. Antiplatelet therapy raises the risk modestly. Statins are associated with a small increase, which is part of why the Cholesterol Treatment Trialists' meta-analysis found no reduction in stroke death. Arteriovenous malformations, cavernous malformations, moyamoya, cocaine and sympathomimetics, thrombocytopenia, haemophilia and sickle cell disease all contribute. Low LDL and low total cholesterol are associated with higher haemorrhage risk in observational data, the inverse of the ischaemic relation.

Which hypertensive person's deep perforating artery will rupture, and when, is not predictable. Why the haemorrhage-to-ischaemic ratio is so much higher in east Asia and sub-Saharan Africa than in western Europe is not explained by measured risk-factor differences alone. Whether the observational association between low cholesterol and haemorrhage is causal or confounded is unresolved, and it has direct consequences for intensive lipid lowering. Cerebral amyloid angiopathy cannot be diagnosed definitively without pathology.

**Cure status.** The acute haemorrhage: RELIEF ONLY. The underlying predisposition: CONTROLLABLE. An arteriovenous malformation, an aneurysm or a cavernous malformation as the bleeding source: CURABLE by obliteration or resection.

No treatment has been shown to improve functional outcome after intracerebral haemorrhage, and the major trials are negative or equivocal. STICH and STICH II found no benefit of early surgical evacuation of supratentorial haemorrhage over initial conservative treatment. INTERACT2, with 2,839 patients randomised to intensive blood-pressure lowering to below 140 systolic, did not significantly reduce death or major disability, odds ratio 0.87, p=0.06, with a favourable ordinal shift on secondary analysis. ATACH-2, with 1,000 patients and more intensive lowering, found no benefit and more renal adverse events. Recombinant factor VIIa reduced haematoma growth and did not improve outcome in the FAST trial. TICH-2, with 2,325 patients on tranexamic acid, found no difference in functional outcome, adjusted odds ratio 0.88, p=0.11, though haematoma expansion and early death were reduced. INTERACT3, in 2023, tested a care bundle of blood-pressure lowering with glucose, temperature and coagulation management across 7,036 patients and improved functional outcome, odds ratio 0.86 (0.76–0.97) — the first positive trial, and a bundle of basic care rather than a drug or a device.

Surgical or endovascular obliteration of an arteriovenous malformation or an aneurysm removes that source permanently, as does resection of a cavernous malformation. ARUBA, with 223 patients, found that for unruptured arteriovenous malformations intervention was worse than medical management, hazard ratio 0.27 favouring medical management. Posterior fossa or cerebellar haematoma evacuation is life-saving where brainstem compression is developing, on consensus rather than trial evidence.

**Prevention.**

*Blood pressure lowering — STRONG, and overwhelmingly the main measure.* Per 10 mmHg systolic reduction, stroke of all types carries a relative risk of 0.73; the effect on haemorrhage specifically is at least as large as on ischaemic stroke, and hypertension's attributable risk is the largest in INTERSTROKE at 47.9 per cent.

*Salt reduction and salt substitution — STRONG.* SSaSS reduced total stroke and total mortality in a rural Chinese population where haemorrhage makes up a large share of strokes. That matters: the trial was conducted in exactly the population where haemorrhage is proportionally common.

*Alcohol reduction — MODERATE*, and relatively more important for haemorrhage than for ischaemic stroke.

*Avoiding unnecessary anticoagulation and antiplatelet therapy — STRONG.* The absolute increase in haemorrhage risk is the main harm of these drugs, and using a direct oral anticoagulant rather than warfarin where anticoagulation is needed roughly halves it, with an intracranial haemorrhage hazard ratio of 0.42 for apixaban.

*Blood pressure lowering after a first haemorrhage — STRONG for recurrence.* Recurrence risk is roughly 2 to 4 per cent a year and higher with lobar amyloid haemorrhage, and blood-pressure control reduces it.

*Physical activity and diet — MODERATE*, both associated with haemorrhage in INTERSTROKE. *Smoking cessation — MODERATE*.

*Statins after haemorrhage — CONTESTED.* The observational low-cholesterol association and the small trial-level excess make the decision genuinely unresolved, and practice varies.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| INTERACT3 care bundle: blood-pressure lowering with glucose and temperature control and coagulation reversal | Functional outcome improved, odds ratio 0.86 (0.76–0.97) — the only positive trial, and a protocol rather than a product | Components yes | yes | Organisational |
| Blood pressure lowering: labetalol, nicardipine, urapidil | INTERACT2 odds ratio 0.87, p=0.06, not significant; ATACH-2 null; haematoma expansion reduced | yes, labetalol | yes | a few to tens of euro a dose |
| Reversal of anticoagulation: vitamin K with prothrombin complex concentrate for warfarin, idarucizumab for dabigatran, andexanet alfa for factor Xa inhibitors | Haematoma expansion reduced; ANNEXA-I showed andexanet reduced expansion with more thrombotic events | Vitamin K yes; prothrombin complex yes; idarucizumab and andexanet no | Vitamin K yes | Vitamin K a few euro; prothrombin complex hundreds to thousands of euro; andexanet tens of thousands of euro a course |
| Tranexamic acid | TICH-2: no functional benefit, odds ratio 0.88, p=0.11; expansion and early death reduced | yes, sections 10.2 and 22 | yes | a few to tens of euro a course |
| Surgical evacuation | STICH and STICH II: no benefit in supratentorial haemorrhage. Cerebellar haematoma evacuation life-saving on consensus. Minimally invasive evacuation in MISTIE III missed its primary endpoint and suggested benefit with good haematoma clearance | n/a | n/a | Surgical |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| External ventricular drain for hydrocephalus | Life-saving for obstructive hydrocephalus | n/a | n/a | hundreds to thousands of euro plus neurosurgical care |
| Stroke unit and neurocritical care | Organised care reduces death or dependency by about 20 per cent across stroke types | n/a | n/a | Organisational |

The important point for a reference work: in intracerebral haemorrhage the only positive randomised trial tested a bundle of cheap, basic care. Every expensive product — factor VIIa, surgery in the main trials, andexanet — either failed its functional endpoint or carried offsetting harm. The off-patent components, labetalol, vitamin K, tranexamic acid and prothrombin complex, plus organised nursing, are the therapy.

**Simple means.** Blood pressure control is the entire prevention programme and is achievable with thiazides, amlodipine and ACE inhibitors at tens of euro a patient-year, plus salt reduction, weight loss and exercise at no cost. Salt substitution, in exactly this population, gave total mortality of 39.28 against 44.61 per 1,000 person-years. Alcohol reduction matters relatively more here than for ischaemic stroke. Head elevation to 30 degrees, airway positioning and withholding oral intake until swallow is assessed are nursing actions requiring no equipment, and they prevent aspiration, a leading cause of death after haemorrhage. Stroke unit organisation gives an odds ratio of about 0.79 for death or dependency from trained nursing and protocol rather than technology. Vitamin K for warfarin-associated haemorrhage costs a few euro is on the Essential Medicines List, is off-patent, and reverses the coagulopathy slowly but effectively. Tranexamic acid costs a few to tens of euro is listed and off-patent, and reduces haematoma expansion with no proven functional benefit.

One negative is critical. Aspirin is beneficial in ischaemic stroke and harmful in haemorrhage, and without imaging the two are not reliably distinguishable at the bedside. That is the hard limit on simple means in stroke care: the single most consequential decision requires a scanner. The clinical scores — Siriraj, Guy's — have insufficient accuracy to substitute.

**Gaps.** No treatment improves functional outcome after intracerebral haemorrhage except the INTERACT3 care bundle, and that single positive trial has not been replicated. INTERACT2 at p=0.06 and ATACH-2 null disagree with guideline enthusiasm for intensive acute blood-pressure lowering, and both are printed. TICH-2 reduced early death and not disability, and how to report tranexamic acid is genuinely unclear. The low-cholesterol and haemorrhage association is unresolved and affects whether to give statins after a haemorrhage; practice varies between countries, and SATURN is running. ARUBA found intervention worse than medical management for unruptured arteriovenous malformations and remains disputed on generalisability. GBD publishes no separate death count for intracerebral haemorrhage in the retrieved tables despite ranking it second in cardiovascular DALYs; the burden figure and the death figure come from different granularities. The roughly twofold difference in the haemorrhage proportion between east Asia and western Europe is not explained. Cerebral amyloid angiopathy prevalence is unknown without pathology, and the Boston criteria are imaging proxies.

## Subarachnoid haemorrhage (ICD-11 8B01)

**What it is.** An aneurysm on an artery at the base of the brain bursts and blood spreads into the fluid around the brain. The person reports the worst headache of their life, starting in an instant. About a third die before reaching hospital.

**Measured.** Global incidence is roughly 7.9 per 100,000 person-years, with a meta-analysis range of 6.9 to 9.0 and large regional variation, from a pooled worldwide analysis in JAMA Neurology in 2019. Finland and Japan have incidence roughly twice the global average — Finland historically 15 to 20 per 100,000 and Japan above 20 — and central and south America are among the lowest at about 4. Subarachnoid haemorrhage is roughly 5 per cent of all stroke. Between 8 and 15 per cent die before medical contact, and overall 30-day case fatality is roughly 30 to 40 per cent, falling over recent decades. The mean age at onset is

roughly 55, substantially younger than ischaemic stroke, and it is the stroke type with the greatest loss of productive years per case. Incidence is roughly 1.3 to 1.6 times higher in women. Unruptured intracranial aneurysm prevalence in the general population is about 3.2 per cent (95 per cent CI 1.9–5.2), and most never rupture. Age-standardised incidence has fallen roughly 1.7 per cent a year worldwide since 1980, largely tracking falls in smoking and blood pressure. GBD counts subarachnoid haemorrhage within the all-stroke figures and the retrieved tables publish no separate count.

**Where it starts.** Smoking is the strongest modifiable risk factor, with a relative risk of roughly 2.2 to 3.1. Hypertension carries a relative risk of roughly 2.5. Heavy alcohol use carries roughly 1.5 to 2.1. Female sex and family history contribute, with a first-degree relative raising risk roughly three- to sevenfold. Autosomal dominant polycystic kidney disease carries an aneurysm prevalence of roughly 10 per cent. Connective tissue disorders — vascular Ehlers-Danlos, Marfan syndrome, fibromuscular dysplasia — contribute, as do cocaine and sympathomimetics as acute triggers. Rupture risk depends on size, site and population: the ISUIA and UCAS Japan studies give five-year rupture risks from under 1 per cent for small anterior-circulation aneurysms to over 40 per cent for large posterior-circulation ones.

Why most of the roughly 3.2 per cent of people carrying an aneurysm never bleed, and which will, is not predictable at the individual level; the PHASES score stratifies populations and performs poorly for individuals. Why Finland and Japan have roughly double the global incidence is not explained by known risk factors. Delayed cerebral ischaemia, which causes much of the disability in survivors, was long attributed to large-artery vasospasm, and drugs that relieve angiographic vasospasm, clazosentan among them, have not reliably improved outcome, so the causal account is now in doubt. The mechanism of nimodipine's benefit is therefore also unclear.

**Cure status.** The ruptured aneurysm: CURABLE — securing it permanently removes the source of bleeding. The brain injury already sustained: RELIEF ONLY. An unruptured aneurysm: intervention is not automatically beneficial, and the status is CONTROLLABLE by surveillance and risk-factor treatment.

ISAT randomised 2,143 patients to endovascular coiling or neurosurgical clipping: dependency or death at one year was 23.5 per cent with coiling against 30.9 per cent with clipping, an absolute reduction of 7.4 percentage points and a number needed to treat of 14. The survival advantage persisted at ten years, and rebleeding and retreatment were more common after coiling. Securing the aneurysm reduces the rebleed risk from roughly 20 to 30 per cent in the first two weeks, with case fatality around 50 per cent for a rebleed, to very low.

Before rupture the calculation changes. ISUIA and ARUBA caution that treating unruptured lesions can do net harm: ARUBA found medical management superior for unruptured arteriovenous malformations, hazard ratio 0.27, and for small unruptured aneurysms the procedural risk can exceed the natural rupture risk. Both statements belong together: after rupture, securing the aneurysm is curative of the lesion; before rupture, intervention is not automatically beneficial.

**Prevention.**

*Smoking cessation — STRONG, and the single largest modifiable factor.* Relative risk 2.2 to 3.1 for current smoking, with risk falling substantially after cessation. The worldwide decline of about 1.7 per cent a year in incidence is attributed chiefly to falling smoking prevalence.

*Blood pressure control — STRONG.* Relative risk about 2.5 for hypertension; per 10 mmHg systolic reduction, all stroke relative risk 0.73.

*Heavy alcohol reduction — MODERATE*.

*Screening in high-risk groups — MODERATE.* Screening first-degree relatives where two or more family members have had a subarachnoid haemorrhage, and screening in polycystic kidney disease, is cost-effective in modelling. Screening with only one affected relative is CONTESTED.

*Preventive treatment of an incidentally found aneurysm — CONTESTED.* It depends on size, site and age; the procedural risk is real, roughly 3 to 5 per cent morbidity for coiling and higher for clipping, and for small anterior aneurysms in older patients the natural risk may be lower.

*Population screening — not recommended*, and no body recommends it: a prevalence of 3.2 per cent with low rupture rates means screening would generate large numbers of harmful interventions.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Endovascular coiling | ISAT: death or dependency 23.5 against 30.9 per cent for clipping, NNT 14; more rebleeding and retreatment | n/a | n/a | tens of thousands of euro |
| Neurosurgical clipping | More durable occlusion; worse one-year functional outcome in ISAT | n/a | n/a | tens of thousands of euro |
| Nimodipine 60 mg four-hourly for 21 days | The only drug with a proven outcome benefit: poor outcome reduced, relative risk about 0.67, NNT about 13 to prevent one poor outcome, from the Cochrane review and the original Allen and Pickard trials | yes | yes | tens to hundreds of euro for the 21-day course |
| Tranexamic acid, short course before securing | Rebleeding reduced; the ULTRA trial, 955 patients, found no improvement in functional outcome, odds ratio 0.86 | yes | yes | a few to tens of euro |
| Clazosentan | Relieves angiographic vasospasm; CONSCIOUS-2 and CONSCIOUS-3 did not improve functional outcome | no | no | High; not standard |
| External ventricular drain for hydrocephalus | Life-saving for acute hydrocephalus, present in about 20 to 30 per cent | n/a | n/a | hundreds to thousands of euro plus care |
| Neurocritical care, euvolaemia, blood-pressure management | Organisational; part of standard care | n/a | n/a | Organisational |

Nimodipine is the key fact. The only drug shown to improve outcome in subarachnoid haemorrhage is a cheap, off-patent, Essential Medicines List calcium channel blocker at tens to hundreds of euro for the full 21-day course, with a number needed to treat of about 13. Every expensive agent aimed at vasospasm has failed on functional outcome.

**Simple means.** Smoking cessation carries a relative risk of 2.2 to 3.1, is the largest modifiable factor, drives the falling worldwide incidence, and costs nothing. Blood pressure control carries a relative risk of about 2.5 and is achievable with tens of euro a year of generic drugs plus salt reduction, weight loss and exercise. Heavy alcohol reduction carries 1.5 to 2.1. Recognition is free and it is the rate-limiting step: a sudden worst-ever headache, often with neck stiffness, vomiting or brief loss of consciousness, warrants immediate transfer. A substantial proportion of cases are missed at first contact, and the warning or sentinel headache that precedes a major bleed in perhaps 10 to 40 per cent of cases is the single best opportunity to intervene. Nimodipine is cheap, listed, off-patent and oral, with a number needed to treat of about 13; it needs a pharmaceutical chain and no technology. Nursing care — airway positioning, euvolaemia, bowel care, avoiding hypotension — is organisational.

The hard limit is severe. Securing an aneurysm requires either neurosurgery or an endovascular suite, and there is no simple-means substitute. Without one, the rebleed risk of 20 to 30 per cent in the first two weeks stands, with roughly 50 per cent case fatality per rebleed. Diagnosis also requires computed tomography, or lumbar puncture where the scan is negative. In subarachnoid haemorrhage the whole of definitive care depends on an industrial chain, and the only measures that need no chain are prevention and recognition.

**Gaps.** GBD publishes no separate burden figure for subarachnoid haemorrhage in the retrieved tables. Incidence estimates rest on registries concentrated in Europe, Japan and North America, and the 7.9 per 100,000 global figure extrapolates heavily. The Finland and Japan excess, roughly twofold, is unexplained. The vasospasm theory of delayed cerebral ischaemia is in doubt: drugs that relieve vasospasm do not improve outcome, while nimodipine improves outcome possibly without acting mainly on vasospasm, so the mechanism of the only effective drug is unclear. Individual rupture prediction is not possible, and PHASES stratifies

groups rather than people. Whether to treat small unruptured aneurysms is unresolved, and the two large natural-history studies, ISUIA and UCAS Japan, give different rupture rates for comparable lesions. Screening thresholds for family history differ between guidelines on one against two affected relatives. Pre-hospital deaths, 8 to 15 per cent, are poorly captured, so case fatality depends on whether the denominator includes them, and that alone explains much of the 30 to 50 per cent range in the literature†.

# The peripheral arteries and the veins

## Peripheral arterial disease (ICD-11 BD40–BD4Z)

**What it is.** The arteries to the legs narrow, so walking causes cramping pain in the calves that stops with rest. In advanced cases the tissue dies and the limb is lost. It marks the same disease as in the heart arteries.

**Measured.** About 122 million people worldwide were affected in 2023, from the GBD 2023 cardiovascular collaborators, and that figure is specifically for lower-extremity disease. No global death count and no DALY figure for peripheral arterial disease is published in the retrieved GBD 2023 tables.

An earlier estimate gives 236 million people aged 25 and over in 2015, of whom roughly two-thirds in low- and middle-income countries. That is nearly double the 2023 GBD figure, because it used a different case definition — an ankle-brachial index of 0.90 or below, including asymptomatic disease — rather than GBD's symptomatic definition. Both are printed with their definitions, because they are not measuring the same thing.

Prevalence rises from under 5 per cent at age 50 to over 20 per cent above 80. Roughly 1 to 3 per cent of patients a year progress to critical limb ischaemia, and one-year mortality after a major amputation is 20 to 50 per cent. Cardiovascular mortality runs roughly two to three times that of people without the condition, and most people with it die of coronary or cerebrovascular disease rather than of their legs. The highest absolute numbers are in south and east Asia, and the strongest risk-factor gradient is smoking. Absolute numbers are rising with ageing and diabetes.

**Where it starts.** Smoking is the dominant risk factor, with an odds ratio of roughly 2 to 4, stronger here than for coronary disease, and roughly 80 per cent of patients are current or former smokers. Diabetes carries an odds ratio of roughly 2 to 4 and also shifts the disease distally and multiplies amputation risk. Hypertension, dyslipidaemia, chronic kidney disease, age and male sex all contribute, as do homocysteine, C-reactive protein and lipoprotein(a). The INTERHEART and INTERSTROKE factors apply as the same atherosclerotic substrate, and neither study used peripheral arterial disease as an endpoint, so there is no INTERHEART-equivalent attributable-risk table for it.

Why atherosclerosis is distributed to the legs in one person and to the coronaries in another is not explained, though smoking and diabetes shift it toward the limbs. Most of the disease is asymptomatic or atypical: in population screening only about 10 to 30 per cent of people with an abnormal ankle-brachial index have classical claudication, and the natural history of the asymptomatic majority is poorly characterised. Why some patients with severe stenosis walk normally through collateral development while others with less disease lose a limb is not predictable.

**Cure status.** CONTROLLABLE.

No treatment removes the atherosclerosis. Revascularisation restores flow and relieves symptoms, restenosis is common, and the underlying disease progresses. In claudication, supervised exercise therapy matches or exceeds endovascular revascularisation for walking distance at one year — the CLEVER trial found supervised exercise improved peak walking time more than stenting — which is direct evidence that the procedure is not curing anything. For critical limb ischaemia revascularisation is limb-saving, and BEST-CLI, with 1,830 patients, found surgical bypass with a vein graft superior to endovascular therapy for the primary composite in the subgroup with adequate vein. Amputation removes the affected part; it does not cure the disease.

**Prevention.**

*Smoking cessation — STRONG, and the single most important measure for both incidence and limb outcomes.* Continued smoking after diagnosis is associated with far higher amputation and graft-failure rates, and cessation improves graft patency and walking distance. In coronary disease, cessation gave a 44 per cent reduction in major adverse cardiovascular events while reduction short of cessation gave nothing.

*Foot care and footwear in diabetes — STRONG for amputation prevention.* Structured foot care programmes reduce amputation rates by roughly 50 to 85 per cent in before-and-after and cohort studies.

*Diabetes prevention and control — STRONG* for limb outcomes; glycaemic control reduces amputation risk, though its effect on incidence of the arterial disease itself is more modest.

*Statins — STRONG.* In the Heart Protection Study subgroup, simvastatin reduced major vascular events by about 24 per cent; the Cholesterol Treatment Trialists' figure is a relative risk of 0.78 per 1 mmol/L of LDL reduction overall.

*Blood pressure lowering — STRONG* for cardiovascular events. *Physical activity — MODERATE* .

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Supervised exercise therapy | The first-line treatment for claudication: maximal walking distance increased by roughly 50 to 200 per cent, with Cochrane giving about a five-minute increase in treadmill walking time; CLEVER found it superior to stenting for peak walking time | n/a | n/a | Supervision cost only |
| Statin | Heart Protection Study subgroup: major vascular events down about 24 per cent; walking distance also improves | yes | yes | a few to tens of euro |
| Antiplatelet, aspirin or clopidogrel | CAPRIE subgroup: clopidogrel better than aspirin, relative risk reduction about 24 per cent in that subgroup. Aspirin's benefit in asymptomatic disease is not established; the AAA and POPADAD trials were null | yes, both | yes, both | a few to tens of euro |
| ACE inhibitor | HOPE subgroup: event reduction consistent with the main trial | yes | yes | a few to tens of euro |
| Cilostazol | Walking distance increased by roughly 40 to 50 per cent against placebo, per Cochrane; contraindicated in heart failure | no | yes | tens to hundreds of euro |
| Rivaroxaban 2.5 mg twice daily with aspirin | VOYAGER PAD, 6,564 patients after revascularisation: composite hazard ratio 0.85, with more major bleeding; the COMPASS subgroup was similar | yes, rivaroxaban | generics available | hundreds to thousands of euro branded; tens to hundreds of euro generic |
| Endovascular revascularisation | Relieves symptoms; no better than supervised exercise for claudication walking distance at one year, per CLEVER | n/a | n/a | thousands to tens of thousands of euro |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Surgical bypass | BEST-CLI: superior to endovascular therapy in critical limb ischaemia with adequate vein conduit | n/a | n/a | tens of thousands of euro |
| Amputation | Limb removal where revascularisation fails; one-year mortality after major amputation 20 to 50 per cent | n/a | n/a | Surgical |

**Simple means.** Walking is the first-line treatment for the commonest presentation. Structured walking — walk until claudication pain is moderate, rest, repeat, for 30 to 45 minutes three times a week — increases maximal walking distance by roughly 50 to 200 per cent and matches stenting at one year. It requires nothing but a programme and supervision. Home-based programmes with structured coaching also work, less well than supervised ones.

Foot inspection and footwear is the highest-yield no-technology intervention here. Daily foot inspection, properly fitted shoes and prompt treatment of ulcers reduce amputation by roughly 50 to 85 per cent in structured programmes. It needs eyes, a mirror, and shoes that fit.

Smoking cessation has the largest single effect on limb outcomes and costs nothing. Ankle-brachial index measurement needs only a blood-pressure cuff and a Doppler probe; with a cuff alone, palpation of foot pulses gives a rough screen with poor sensitivity, roughly 70 per cent. Weight loss, blood pressure control and diet act as in the hypertension and ischaemic heart disease entries. Keeping the limb warm, avoiding trauma and positioning the leg dependent at night reduces rest pain in critical ischaemia; symptomatic and unquantified.

The hard limit: critical limb ischaemia needs revascularisation or amputation. There is no simple-means substitute, and untreated critical limb ischaemia leads to limb loss or death.

**Gaps.** The two prevalence figures differ nearly twofold — 122 million in GBD 2023 against 236 million in the 2019 Lancet Global Health analysis — because of different case definitions, symptomatic against ankle-brachial index. Neither is wrong and they are not comparable; both are printed with their definitions. No global death or DALY figure for peripheral arterial disease exists in the retrieved GBD 2023 tables. No INTERHEART- or INTERSTROKE-equivalent attributable-risk study exists for this condition; risk factors are inferred from coronary studies and from disease-specific cohorts. The natural history of asymptomatic disease, which is most of it, is poorly characterised. Aspirin in asymptomatic disease: the AAA and POPADAD trials were null, against widespread practice. Revascularisation against exercise for claudication: CLEVER favours exercise, and revascularisation rates remain high and rising, so evidence and practice disagree. Amputation rates vary several-fold between countries and between regions within countries at similar disease prevalence, which is an access and practice signal rather than a disease signal.

## Aortic aneurysm (ICD-11 BD50–BD5Z)

**What it is.** The wall of the body's main artery stretches and balloons out. It gives no symptoms while it grows. If it tears or bursts, most people die within minutes to hours.

**Measured.** No global prevalence, death or DALY figure for aortic aneurysm is published in the retrieved GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all. GBD 2019 reported roughly 172,000 deaths worldwide, with an age-standardised death rate of about 2.2 per 100,000, and that is an earlier round.

Abdominal aortic aneurysm prevalence in men aged 65 to 74 is 1.3 to 3.3 per cent in modern screening programmes, down from 4 to 8 per cent in the screening trials of the 1990s. The prevalence has fallen by roughly half in two decades, tracking the fall in smoking. Prevalence in women is roughly one-sixth to one-quarter that in men. Rupture case fatality is roughly 80 to 90 per cent overall including pre-hospital deaths, and 30-day mortality after emergency repair of a ruptured aneurysm is roughly 30 to 50 per cent against 1 to 5 per cent for elective repair. Annual rupture risk by diameter: under 1 per cent at 4.0 to 4.9 cm, about 1 to 3 per

cent at 5.0 to 5.9 cm, about 10 to 20 per cent above 6.0 cm, and over 30 per cent above 7 cm. Acute aortic dissection has an incidence of roughly 3 to 6 per 100,000 person-years, and untreated type A dissection mortality rises about 1 to 2 per cent an hour in the first 48 hours. The condition is rare before 55 and incidence rises steeply with age. Incidence and mortality are falling in high-income countries, attributed mainly to reduced smoking.

**Where it starts.** Smoking is the overwhelming risk factor for abdominal aortic aneurysm, with an odds ratio of roughly 5 and a strong dose and duration relation; it is the strongest smoking association of any cardiovascular condition. Male sex gives four- to sixfold higher prevalence. Age, hypertension — strongest for thoracic aneurysm and dissection — and family history, with a first-degree relative raising risk roughly two- to fourfold, all contribute. Atherosclerosis and dyslipidaemia contribute, with a weaker relation than for coronary disease, and statins do not reliably slow aneurysm growth. Diabetes is inversely associated with abdominal aortic aneurysm, a consistent and unexplained finding with an odds ratio of roughly 0.7 to 0.8. Connective tissue disease dominates thoracic aneurysm in the young: Marfan syndrome and FBN1, Loeys-Dietz and TGFBR1 or TGFBR2, vascular Ehlers-Danlos and COL3A1, bicuspid aortic valve, Turner syndrome. Inflammatory and infective causes include Takayasu arteritis, giant cell arteritis, syphilitic aortitis and mycotic aneurysm.

Why aneurysms grow in bursts rather than steadily is not explained, and growth is not reliably predictable from diameter or risk factors. No drug has been shown to slow aneurysm growth: beta blockers in the propranolol trial, doxycycline in N-TA³CT, ACE inhibitors, statins and macrolides have all failed or given inconsistent results. The inverse association with diabetes is reproducible and unexplained. Why women have fewer aneurysms but rupture at smaller diameters is not understood, and the current size thresholds for repair were derived largely in men.

**Cure status.** An aneurysm above the repair threshold: CURABLE by repair. An aneurysm below the repair threshold: RELIEF ONLY — no medical treatment exists at all, and the only management is surveillance. The underlying aortopathy: RELIEF ONLY — the risk of a further aneurysm elsewhere remains.

Open surgical repair replaces the segment with a graft and is durable, with low reintervention rates. Endovascular repair carries a trade-off that must be stated honestly: EVAR-1, with 1,252 patients, found lower 30-day mortality, 1.8 against 4.3 per cent, and no long-term survival advantage, with higher aneurysm-related and all-cause mortality than open repair by eight years, driven by late rupture and endograft failure. The less invasive procedure traded early survival for late failure, and lifelong imaging surveillance is required after it.

Elective repair below 5.5 cm gives no benefit. The UK Small Aneurysm Trial, with 1,090 patients at 4.0 to 5.5 cm, and ADAM, with 1,136 patients, both found no survival advantage from early repair against surveillance. That is why the threshold is 5.5 cm in men, and it is trial-derived rather than arbitrary. Acute type A aortic dissection requires emergency surgery; mortality without it is roughly 50 per cent at 48 hours.

**Prevention.**

*Smoking cessation — STRONG, and by far the dominant measure.* An odds ratio of about 5 for current smoking; the roughly 50 per cent fall in screened prevalence over two decades tracks the fall in smoking, and continued smoking accelerates growth of an existing aneurysm.

*Screening men aged 65 for abdominal aortic aneurysm — STRONG, with randomised mortality evidence.* Four randomised trials — MASS, Viborg, Chichester and Western Australia — pooled give aneurysm- related mortality reduced by roughly 35 to 45 per cent, odds ratio about 0.60, in men invited to a single ultrasound scan. MASS showed persistent benefit at thirteen years. The number needed to screen is roughly 200 to 700 men to prevent one aneurysm death, depending on prevalence. Screening women is not recommended: prevalence is too low for net benefit and no trial shows benefit.

*Blood pressure control — STRONG for thoracic aneurysm and dissection*, where hypertension is the leading modifiable factor; per 10 mmHg systolic reduction, major cardiovascular events relative risk 0.80.

*Screening first-degree relatives — MODERATE*.

*Beta blockade in Marfan syndrome — MODERATE.* Losartan against atenolol trials showed similar aortic root growth rates, and a meta-analysis suggested both slow it.

*No drug prevents or slows sporadic aneurysm growth.* This is a genuine therapeutic void. Doxycycline, in N-TA³CT with 261 patients, did not slow growth and if anything growth was slightly faster.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Surveillance ultrasound | The entire management below threshold, because no treatment exists | n/a | n/a | tens to hundreds of euro a scan |
| Open surgical repair | Durable; elective 30-day mortality 4.3 per cent in EVAR-1; better long-term survival than endovascular repair beyond eight years | n/a | n/a | tens of thousands of euro |
| Endovascular repair | 30-day mortality 1.8 against 4.3 per cent for open repair; no long-term survival advantage and worse beyond eight years; lifelong surveillance required | n/a | n/a | tens of thousands of euro graft cost dominating |
| Emergency repair of rupture | 30-day mortality 30 to 50 per cent, against 80 to 90 per cent overall case fatality without repair | n/a | n/a | Surgical |
| Blood pressure and heart rate control in dissection: labetalol, esmolol, then oral agents | Reduces propagation; standard care | yes, labetalol | yes | a few to tens of euro |
| Beta blocker or losartan in Marfan syndrome | Slows aortic root growth; similar between agents | yes, both | yes, both | a few to tens of euro a year |
| Statins, doxycycline, ACE inhibitors, macrolides for growth | All failed to slow growth | — | — | — |

**Simple means.** Smoking cessation has a dominant effect, with an odds ratio of about 5, costs nothing, and also slows growth of an existing aneurysm. Blood pressure control is dominant for thoracic disease, with generic drugs at tens of euro a year plus salt reduction, weight loss and exercise. Abdominal palpation can feel a pulsatile mass in thinner patients, with poor sensitivity, roughly 30 to 40 per cent for aneurysms under 5 cm and better above, and it cannot be relied on to exclude an aneurysm. It costs nothing and occasionally finds one. Ultrasound screening requires a machine and an operator, and that is a modest chain: a single scan in a 65-year-old man reduces aneurysm mortality by roughly 35 to 45 per cent, and portable handheld ultrasound now brings this within reach of primary care in many settings.

The hard limit, stated plainly: there is no medical treatment for an aortic aneurysm at all, cheap or expensive. Below the threshold the management is watching; above it, major vascular surgery or an endograft. No simple means exists for the aneurysm itself, and the chain minimally requires ultrasound for detection and a vascular surgical service with anaesthesia, blood transfusion and intensive care for repair. Rupture without that chain is almost always fatal.

**Gaps.** No GBD 2023 global burden figure for aortic aneurysm exists in the retrieved tables, and the roughly 172,000 deaths figure comes from an earlier round; this entry is part of the seventeen-condition gap set out in this chapter’s introduction. No drug slows aneurysm growth, and multiple trials have failed; that is a complete therapeutic void. Endovascular against open repair: early survival favours endovascular and long-term survival favours open, guidelines and practice have not fully resolved it, and practice has shifted heavily toward endovascular repair on the early figures. Repair thresholds in women are not evidence-based: the 5.5 cm threshold was derived in male cohorts, women rupture at smaller diameters, and the correct threshold is unknown. The inverse diabetes association is reproducible and unexplained. Screening is cost-effective in high-smoking-prevalence populations, and as smoking falls so does screening yield and so does cost-effectiveness; several programmes are reconsidering thresholds, and that is an active policy disagreement. Pre-hospital rupture deaths

are inconsistently captured, so case fatality figures range from 65 to 90 per cent depending on the denominator†, and sources disagree for that reason.

## Deep vein thrombosis and pulmonary embolism — venous thromboembolism (ICD-11 BD71, BB00)

**What it is.** A clot forms in a deep vein, usually in the leg. A piece can break off and lodge in the lungs, blocking blood flow there. The leg clot causes pain and swelling; the lung clot can kill within hours.

**Measured.** No global prevalence, incidence, death or DALY figure for venous thromboembolism is published in the retrieved GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all, and it is consequential, because the figures that circulate instead are model outputs.

Incidence in high-income populations is 1 to 2 per 1,000 person-years for all venous thromboembolism, roughly two-thirds deep vein thrombosis and one-third pulmonary embolism, from the Worcester, Olmsted County and Tromsø population studies. Estimated annual events run at roughly 10 million worldwide, with 300,000 to 500,000 related deaths a year in Europe and roughly 100,000 in the United States, from the International Society on Thrombosis and Haemostasis and modelling estimates. Those are model-based and not measured, and they should never be presented as measured counts. Case fatality of untreated pulmonary embolism is roughly 25 to 30 per cent; with anticoagulation, roughly 2 to 8 per cent at 30 days. Hospital-acquired venous thromboembolism accounts for roughly 50 to 60 per cent of all cases, a large and partly preventable fraction. Recurrence after an unprovoked event off anticoagulation is roughly 10 per cent in the first year and 30 per cent at ten years, and much lower after a provoked event with a transient cause removed. Post-thrombotic syndrome develops in 20 to 50 per cent after a proximal deep vein thrombosis, and severe forms in roughly 5 to 10 per cent. Incidence rises sharply with age, from about 1 per 10,000 under 40 to about 1 per 100 above 80. Reported incidence is substantially lower in east Asian and African populations, partly genuine through lower factor V Leiden prevalence and partly under-detection.

**Where it starts.** Virchow's triad — stasis, endothelial injury, hypercoagulability. Measured contributions: major orthopaedic surgery without prophylaxis carries deep vein thrombosis rates of 40 to 60 per cent on screening venography, from the historical trials that established prophylaxis. Active cancer raises risk roughly four- to sevenfold, with pancreatic, brain, gastric and lung cancers highest. Pregnancy and the puerperium raise it roughly four- to fivefold, highest in the first six weeks postpartum. Combined oral contraceptives raise it roughly two- to fourfold, with the absolute risk remaining low at about 1 per 1,000 a year, and third-generation progestins somewhat higher than second. Oral hormone replacement therapy raises it roughly twofold, transdermal much less. Factor V Leiden raises it three- to eightfold heterozygous and roughly 50- to 80-fold homozygous, with a prevalence of about 5 per cent in European-ancestry populations and near zero in African and east Asian. Prothrombin G20210A raises it roughly threefold heterozygous. Antiphospholipid syndrome and antithrombin, protein C and protein S deficiency carry higher relative risks and are much rarer. Obesity raises it roughly two- to threefold; long-haul travel over eight hours roughly two- to threefold; previous venous thromboembolism is the strongest single predictor; and hospitalisation itself, with or without surgery, contributes.

Why a given person with a given risk factor clots on a given day is not predictable, and most people with factor V Leiden never have an event. Roughly 30 to 50 per cent of cases are unprovoked with no identifiable trigger, and in that group the decision on how long to anticoagulate rests on recurrence models — DASH, HERDOO2, Vienna — that perform moderately and are not individually reliable. Whether thrombophilia testing changes outcomes is not established, and most guidelines now advise against routine testing. Why some patients develop post-thrombotic syndrome and others do not is unexplained.

**Cure status.** A provoked event with a removable cause: CURABLE. Unprovoked and recurrent disease: CONTROLLABLE. Chronic thromboembolic pulmonary hypertension in operable cases: CURABLE by pulmonary endarterectomy.

A clot treated with anticoagulation resolves or organises, and after a provoked event with the provocation removed, three months of anticoagulation is sufficient and recurrence risk

falls to roughly 1 to 3 per cent a year; the condition is gone. After an unprovoked event, recurrence after stopping is roughly 10 per cent in year one and 30 per cent at ten years, so anticoagulation holds the state rather than curing it, and extended therapy is often indefinite. EINSTEIN-CHOICE and AMPLIFY-EXT showed low-dose extended therapy with a direct oral anticoagulant reduces recurrence by roughly 80 per cent with little excess bleeding.

Chronic thromboembolic pulmonary hypertension develops in roughly 3 per cent after a pulmonary embolism, and pulmonary endarterectomy is genuinely curative in operable cases, with large and durable falls in pulmonary vascular resistance and normalisation of function in many patients. That is one of the real surgical cures in this chapter.

**Prevention.**

*Pharmacological thromboprophylaxis in hospital — STRONG, and the single largest preventable fraction.* Low-molecular-weight heparin reduces deep vein thrombosis after major orthopaedic surgery from 40 to 60 per cent down to roughly 10 to 20 per cent on screening. It reduces symptomatic events by roughly 50 to 70 per cent across surgical and medical populations. Hospital-acquired cases are 50 to 60 per cent of the total, so this is a very large lever.

*Early mobilisation after surgery and illness — MODERATE*, and it costs nothing.

*Graduated compression stockings — the grade splits by population, and all three results must be printed.* MODERATE in surgical prophylaxis: Cochrane gives roughly a two-thirds reduction in deep vein thrombosis risk when added to other measures in surgical patients, odds ratio about 0.35. CONTESTED to negative after stroke: CLOTS-1, with 2,518 stroke patients, found no benefit from thigh-length stockings and increased skin breaks, 5 against 1 per cent. Null for post-thrombotic syndrome after deep vein thrombosis: the SOX trial, 806 patients, found no reduction, 14.2 against 12.7 per cent, against earlier smaller trials that had reported roughly a 50 per cent reduction. The same garment, three different answers in three different populations.

*Intermittent pneumatic compression — MODERATE* where anticoagulation is contraindicated; CLOTS-3, with 2,876 stroke patients, found it reduced deep vein thrombosis, 8.5 against 12.1 per cent, odds ratio 0.65, and showed a survival signal.

*Mechanical plus pharmacological prophylaxis — STRONG* in high-risk surgery. *Avoiding unnecessary immobility and central lines — MODERATE*.

*Calf exercises and hydration on long flights — WEAK.* Compression stockings on long flights reduce asymptomatic deep vein thrombosis substantially, Cochrane odds ratio about 0.10, and symptomatic events are too rare in the trials to measure.

*Extended thromboprophylaxis after cancer surgery and in high-risk ambulatory cancer — MODERATE*, from AVERT and CASSINI.

**Treatment.**

| Drug or procedure | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Low-molecular-weight heparin, enoxaparin or dalteparin | Initial treatment and prophylaxis; symptomatic events reduced about 50 to 70 per cent as prophylaxis | yes, enoxaparin | yes | tens to hundreds of euro a prophylaxis course; hundreds of euro a treatment course |
| Unfractionated heparin | Where renal failure or reversal matters | yes | yes | a few to tens of euro a course |
| Warfarin | Long-standing standard; recurrence reduced about 80 to 90 per cent against no treatment | yes | yes | a few to tens of euro a year plus tens to hundreds of euro a year for INR monitoring |

| Drug or procedure | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Apixaban | AMPLIFY, 5,395 patients: recurrent venous thromboembolism or related death 2.3 against 2.7 per cent against warfarin, non-inferior; major bleeding 0.6 against 1.8 per cent, relative risk 0.31, a large bleeding advantage | yes | generics from 2026 in several markets | €500–3,000 branded; €30–150 generic |
| Rivaroxaban | EINSTEIN-DVT and EINSTEIN-PE: non-inferior to standard therapy, less major bleeding in pulmonary embolism | yes | generics available | hundreds to thousands of euro branded; tens to hundreds of euro generic |
| Thrombolysis for high-risk pulmonary embolism, alteplase | PEITHO, 1,005 intermediate-risk patients: death or haemodynamic decompensation 2.6 against 5.6 per cent, odds ratio 0.44, with major bleeding 11.5 against 2.4 per cent and stroke 2.4 against 0.2 per cent. Net benefit only in haemodynamically unstable embolism | yes | yes | hundreds of euro a dose |
| Catheter-directed thrombolysis or thrombectomy | Thrombus burden reduced; ATTRACT, 692 patients, did not reduce post-thrombotic syndrome, 47 against 48 per cent, and increased bleeding | n/a | n/a | thousands to tens of thousands of euro |
| Inferior vena cava filter | PREPIC: pulmonary embolism reduced and recurrent deep vein thrombosis increased, with no mortality benefit; PREPIC-2 found no benefit added to anticoagulation | n/a | n/a | thousands of euro |
| Pulmonary endarterectomy for chronic thromboembolic pulmonary hypertension | Curative in operable cases | n/a | n/a | tens of thousands of euro |
| Compression stockings after deep vein thrombosis | The SOX trial, 806 patients: did not prevent post-thrombotic syndrome, 14.2 against 12.7 per cent; earlier smaller trials by Brandjes and by Prandoni reported roughly a 50 per cent reduction. Both are printed — this is a genuine reversal | no | n/a | tens of euro a pair |

**Simple means.** Early mobilisation and walking cost nothing and reduce stasis; they are standard in all post-operative care. Graduated compression stockings cost tens of euro a pair and need no power and no supply chain beyond the garment. They carry three different answers. In surgical prophylaxis, roughly a two- thirds reduction in deep vein thrombosis, Cochrane odds ratio about 0.35. After stroke, no benefit and more skin breaks, in CLOTS-1. After deep vein thrombosis, no prevention of post-thrombotic syndrome, in SOX. All three are printed, and the common claim that stockings prevent post-thrombotic syndrome is contradicted by the largest trial. Calf and ankle exercises during immobility and long travel reduce stasis, with symptomatic event reduction not measurable in the trials. Leg elevation relieves swelling in acute deep vein thrombosis with no effect on outcome. Hydration during travel and illness is plausible and unquantified. Early recognition of pulmonary embolism — sudden breathlessness, chest pain, collapse — costs nothing and is the decisive step, because untreated embolism carries a case fatality of 25 to 30 per cent and treated embolism 2 to 8 per cent.

The hard limit. Venous thromboembolism cannot be treated without anticoagulation, and anticoagulation cannot be improvised. The minimum chain is heparin, warfarin or a direct oral anticoagulant, plus INR measurement for warfarin. Diagnosis also effectively requires D-dimer and either ultrasound for deep vein thrombosis or computed tomographic pulmonary angiography for embolism; the clinical scores, Wells and Geneva, rule out low-risk cases and cannot confirm. In this condition the simple means are all preventive and the treatment requires an industrial chain.

**Gaps.** No GBD global burden figure for venous thromboembolism exists, and this entry is part of the seventeen-condition gap in this chapter's introduction. The widely quoted 10 million events and 300,000 to 500,000 European deaths are model-based estimates rather than measurements and should never be presented as measured counts. Compression stockings after deep vein thrombosis: SOX null against earlier positive trials, the guidelines changed and much clinical practice did not. CLOTS-1 after stroke, no benefit and more harm, against the surgical prophylaxis evidence of benefit — the same device, opposite answers in different populations. ATTRACT: catheter-directed thrombolysis did not reduce post-thrombotic syndrome, against strong prior expectation. Duration of anticoagulation after an unprovoked event is unresolved, the risk-prediction models perform moderately, and practice varies widely. Thrombophilia testing has no evidence that it improves outcomes and is widely performed. Reported incidence in Asian and African populations is much lower, and how much of that is genuine and how much under-diagnosis is not resolved. Most incidence data come from a handful of North American and Scandinavian cohorts.

## Varicose veins and chronic venous insufficiency (ICD-11 BD74, BD72)

**What it is.** The valves in the leg veins fail, so blood falls back down and pools. The veins bulge and the lower leg aches, swells, darkens and eventually ulcerates. It is very common and rarely fatal.

**Measured.** No global prevalence, death or DALY figure for varicose veins or chronic venous insufficiency is published in the retrieved GBD 2023 tables. GBD does model varicose veins as a cause with years lived with disability, and no figure was retrieved. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all, and the burden is almost certainly substantially under-counted in global data.

Visible varicose veins affect roughly 20 to 35 per cent of western adults; the Edinburgh Vein Study found 40 per cent of men and 32 per cent of women with trunk varices, and the Bonn Vein Study was similar. Chronic venous insufficiency with skin changes, CEAP classes C4 to C6, affects roughly 3 to 7 per cent of adults. An active venous leg ulcer affects roughly 0.1 to 0.3 per cent of adults, rising to 1 to 3 per cent above age 70. Venous ulcers account for 60 to 80 per cent of all leg ulcers. With compression, roughly 60 to 70 per cent of venous ulcers heal within 24 weeks, and recurrence at twelve months is 25 to 50 per cent without continued compression. Prevalence rises steadily with age; incidence is higher in women for symptoms and roughly equal or male-predominant for trunk varices depending on the study. Reported prevalence is lower in African, Asian and rural populations, and whether that is genuine or a reporting artefact is not established. Venous ulcer care consumes roughly 1 to 3 per cent of total healthcare budgets in western European estimates, almost entirely nursing time and dressings.

**Where it starts.** Age and family history: a parent affected roughly doubles risk, and both parents higher. Female sex for symptomatic disease, and each pregnancy raises risk. Prolonged standing occupations carry an odds ratio of roughly 1.5 to 2. Obesity carries roughly 1.5 to 3, stronger for venous insufficiency and ulceration than for simple varices. A previous deep vein thrombosis causes post-thrombotic venous insufficiency in 20 to 50 per cent of proximal cases. Height and male sex contribute for trunk varices. FOXC2 mutations appear in rare syndromic cases, and genome-wide association studies have found common variants with small effects.

Whether valve failure causes vein wall dilatation or the reverse is unresolved — the descending and ascending theories have not been settled, and that is the central mechanistic question. Why some people with extensive varices never develop skin changes while others ulcerate from modest disease is not predictable. Whether standing occupations cause the condition or

select for it is confounded. The relation between visible varices and symptoms is weak: many symptomatic legs have no visible varices and many prominent varices are asymptomatic.

**Cure status.** Varicose veins: CURABLE by ablation of the refluxing vein. Established chronic venous insufficiency with skin damage: CONTROLLABLE. Post-thrombotic venous insufficiency: RELIEF ONLY.

Endovenous thermal ablation by laser or radiofrequency, ultrasound-guided foam sclerotherapy and surgical stripping all abolish the refluxing segment. Occlusion or abolition rates at five years are roughly 85 to 95 per cent for radiofrequency and laser, 70 to 80 per cent for foam sclerotherapy and about 85 per cent for surgical stripping, from the CLASS trial of 798 patients and the EVRA follow-up series. New varices form elsewhere over years, so the condition recurs in a substantial minority even though the treated vein stays closed.

The EVRA trial, with 450 patients carrying venous ulcers, found early endovenous ablation plus compression healed ulcers faster than compression alone, median 56 against 82 days, with more ulcer-free time over one year. That is the clearest evidence that correcting the reflux changes the disease course rather than just the appearance.

Established skin damage — lipodermatosclerosis, pigmentation — does not reverse. Compression prevents progression and ulceration and does not restore the skin. Post-thrombotic venous insufficiency has no curative treatment; deep venous valve reconstruction and stenting are used in selected cases with limited evidence.

**Prevention.**

*Preventing deep vein thrombosis — STRONG* for preventing post-thrombotic venous insufficiency, which affects 20 to 50 per cent after a proximal clot. Hospital thromboprophylaxis is the measure; see the venous thromboembolism entry.

*Compression to prevent ulcer recurrence after healing — STRONG.* Cochrane finds compression reduces recurrence substantially, against 25 to 50 per cent recurrence at twelve months without it.

*Compression after deep vein thrombosis to prevent post-thrombotic syndrome — CONTESTED.* The SOX trial, 806 patients, found no reduction, 14.2 against 12.7 per cent; earlier smaller trials reported roughly a 50 per cent reduction. Both are printed.

*Weight management — MODERATE*. *Exercise, calf muscle pump training — MODERATE* for symptoms and venous function. *Avoiding prolonged static standing, and moving and activating the calf muscles — WEAK*, mostly observational. *Compression during pregnancy — WEAK*: symptoms are reduced and prevention of varices is not established.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Graduated compression, stockings or bandaging | The foundation of all venous care. Cochrane: compression heals more venous ulcers than no compression, relative risk about 1.8; multi-component and elastic systems better than single-layer; 60 to 70 per cent healing by 24 weeks | no | n/a | tens of euro a pair, replaced every three to six months; bandages a few to tens of euro an application |
| Endovenous thermal ablation, laser or radiofrequency | Five-year occlusion 85 to 95 per cent; EVRA ulcer healing median 56 against 82 days with compression alone | n/a | n/a | hundreds to thousands of euro |
| Ultrasound-guided foam sclerotherapy | Five-year success 70 to 80 per cent; the cheapest ablative option | Polidocanol and sodium tetradecyl sulfate: no | yes | hundreds of euro |
| Surgical stripping and ligation | Five-year success about 85 per cent; more post-operative pain than endovenous methods | n/a | n/a | thousands of euro |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Pentoxifylline, adjunct for venous ulcers | Cochrane: ulcer healing improved, relative risk 1.70 (1.30–2.24), added to compression | no | yes | tens to hundreds of euro a year |
| Micronised purified flavonoid fraction or horse chestnut | Oedema and symptoms modestly reduced; Cochrane rates the evidence low to moderate | no | yes | hundreds of euro a year |
| Aspirin, adjunct for ulcer healing | Small trials positive; the larger ASPiVLU and AVURT trials null | yes | yes | a few euro a year |
| Antibiotics for venous ulcers | No benefit without clinical infection, per Cochrane; routine use is inappropriate | yes | yes | Varies |
| Skin grafting or bioengineered skin | For large non-healing ulcers; moderate evidence | n/a | n/a | thousands to tens of thousands of euro |

**Simple means.** This is the condition in the chapter where simple means do the most work.

Compression is the single most effective treatment for chronic venous disease, and it is a garment or a bandage. Cochrane finds compression heals substantially more venous ulcers than no compression, relative risk about 1.8, with 60 to 70 per cent healed by 24 weeks, and it reduces recurrence from 25 to 50 per cent at twelve months. It costs tens of euro a pair, or a few to tens of euro an application for bandaging. No electricity, no drug, no procedure. The binding constraints are correct application, since it must be graduated and firm; patient tolerance; and excluding arterial disease first, because full compression on an ischaemic leg causes necrosis, so an ankle-brachial index or at least palpable foot pulses are required before applying it.

Simple non-adherent dressings carry an important economic finding: Cochrane found no dressing type superior to simple low-adherent dressings beneath compression. The expensive advanced dressings have not been shown to outperform cheap ones, and compression is what heals the ulcer.

Leg elevation above heart level for thirty minutes several times daily reduces oedema; standard advice, with the effect on healing not well quantified. Calf-muscle pump exercise, heel raises and walking improve venous return and calf pump function, and small trials show improved healing and reduced symptoms. Weight loss reduces venous pressure and ulcer risk. Skin care and emollients prevent fissuring and cellulitis in lipodermatosclerosis at very little cost. Avoiding prolonged standing and taking movement breaks helps. Foam sclerotherapy is the cheapest ablative option at hundreds of euro and needs only ultrasound and a sclerosant, not a laser or a theatre.

**Gaps.** No GBD global figure was retrieved for varicose veins or chronic venous insufficiency despite a prevalence of 20 to 35 per cent, and this entry is part of the seventeen-condition gap in this chapter’s introduction. Compression after deep vein thrombosis to prevent post-thrombotic syndrome is unresolved: SOX null against earlier positive trials. The descending against ascending theory of valve failure is unsettled, so the basic mechanism is not agreed. Visible varices correlate poorly with symptoms, which makes prevalence figures of limited clinical meaning and treatment indications contested. Lower reported prevalence in African and Asian populations is unresolved as genuine or as detection. Advanced dressings have a large market and no demonstrated advantage over simple dressings under compression. Long-term comparative data beyond five years between endovenous methods and surgery are thin, and recurrence definitions differ between trials. Pentoxifylline has a positive Cochrane result, relative risk 1.70, and is barely used, and that gap between evidence and practice is unexplained.

# The valves, the muscle and the sac

## Rheumatic heart disease (ICD-11 BA00–BA0Z, 1B40–1B41)

**What it is.** A throat infection with group A streptococcus sets off an immune reaction that scars the heart valves. It happens in childhood and the damage shows up years later as a leaking or narrowed valve. It is almost entirely a disease of poverty.

**Measured.** WHO gives rheumatic heart disease as about 2 per cent of all cardiovascular deaths, which against the WHO total of 19.8 million is roughly 0.4 million deaths. Global prevalence at all ages was 54.8 million in 2021, up from 32.3 million in 1990, from GBD 2021 as cited in a 2025 analysis in Frontiers in Cardiovascular Medicine. More than 11.6 million children and young people aged 5 to 19 are affected.

In ages 5 to 19, from GBD 2021. Age-standardised incidence rose from 77.98 per 100,000 in 1990 to 93.96 in 2021 (95 per cent CI 62.05–134). Age-standardised prevalence rose from 498.49 to 588.46 per 100,000, estimated annual percentage change +0.42. Age-standardised mortality fell from 1.23 to 0.52 per 100,000, estimated annual percentage change −2.71. Prevalence rose most in the 10 to 14 group and mortality fell most in the 5 to 9 group. Women aged 15 to 19 had the highest incidence and prevalence; women have higher prevalence, men higher mortality.

Geography: prevalence is highest in sub-Saharan Africa and south Asia, and low and low-middle sociodemographic index countries carry the greatest burden. Eritrea has the highest incidence at 252.88 per 100,000; the Republic of the Congo the highest prevalence at 1,517.35; Niue the highest mortality at 5.38; Sweden the lowest prevalence at 2.79. Incidence and prevalence are rising and mortality is falling in nearly all regions, with south Asia showing the fastest rise in incidence and prevalence.

The source carries three internal inconsistencies, and they must travel with its figures. Its Discussion describes incidence rising from 1995 to 2015 and then falling from 2015 to 2021, which contradicts the abstract's overall 1990 to 2021 increase. Its Results say incidence was higher in men while its Discussion says significantly higher in females. And its abstract gives a 1990 mortality upper confidence limit of 19.89 where Table 1 gives 1.48.

**Where it starts.** Untreated group A streptococcal pharyngitis. Roughly 0.3 to 3 per cent of untreated streptococcal sore throats lead to acute rheumatic fever in susceptible populations, and roughly 30 to 50 per cent of acute rheumatic fever episodes leave valve damage. Recurrent streptococcal infection is the main driver of progressive valve damage, each recurrence adding injury. Household crowding, poor housing and limited access to primary care are the dominant determinants, and this is the clearest social-gradient disease in the chapter. Acute rheumatic fever is concentrated in ages 5 to 15. Genetic susceptibility shows HLA class II associations with DR7 and DR4, familial clustering, and monozygotic twin concordance of roughly 44 per cent against 12 per cent dizygotic. Differences between group A streptococcal emm types exist and the relation to rheumatogenicity is disputed. Skin infection, impetigo, as an alternative route to rheumatic fever is proposed in high-burden Indigenous populations and is not established.

Why only a small minority of people with streptococcal pharyngitis develop rheumatic fever is not explained. The autoimmune account — molecular mimicry between streptococcal M protein and cardiac myosin — is well supported and does not predict who will react. Whether specific rheumatogenic strains exist is contested. There is no vaccine, and the historical concern that a vaccine might itself provoke rheumatic autoimmunity has slowed development; several candidates are now in early trials. Why incidence is rising in ages 5 to 19 while mortality falls is not explained in the source.

**Cure status.** Acute rheumatic fever and streptococcal pharyngitis: CURABLE. Established rheumatic valve disease: CONTROLLABLE.

Penicillin eradicates the infection and, given within nine days of symptom onset, prevents the first episode of rheumatic fever; the original United States military trials showed roughly a 70 to 80 per cent reduction.

For established valve disease, percutaneous balloon mitral valvuloplasty for rheumatic mitral stenosis with suitable anatomy has a procedural success of 80 to 95 per cent, with immediate doubling of valve area and restenosis-free survival of roughly 50 to 70 per cent at ten years.

In suitable anatomy it is as effective as open surgery, far cheaper, and performed by catheter. Mitral valve repair in rheumatic disease is less durable than in degenerative disease because the leaflets themselves are scarred, and replacement is often required. Valve replacement relieves the lesion permanently; a mechanical valve commits the patient to lifelong warfarin, and a bioprosthesis to re-operation in ten to fifteen years. The rheumatic process itself is not cured by surgery, and secondary prophylaxis must continue.

**Prevention.** This is the condition in the chapter with the clearest, cheapest and most neglected prevention.

*Secondary prophylaxis with benzathine benzylpenicillin intramuscularly every three to four weeks — STRONG, and the single highest-value intervention here.* Cochrane and cohort evidence give a reduction in recurrence of acute rheumatic fever of roughly 80 to 90 per cent against no prophylaxis, with reduced progression of valve disease. Intramuscular administration is clearly superior to oral. Cost: a fraction of a euro per injection and a few euro per patient-year. The UNICEF indicative price in October 2026 for benzathine benzylpenicillin powder for injection, 2.4 million IU, was US$29.49 per box of 50 vials on one page of the catalogue and US$29.12 on another, which works out at about US$0.59 a vial; the single-vial pack with solvent was US$3.01, five times as much per dose. Benzathine benzylpenicillin is on the 24th Model List, in section 6.2.1, the Access group antibiotics, with syphilis as its listed first-choice indication. This is arguably the largest measured mortality and disability benefit per euro in this entire chapter.

*Primary prophylaxis: penicillin for streptococcal pharyngitis — STRONG.* Treatment within nine days of onset reduces first-episode rheumatic fever by roughly 70 to 80 per cent, and Cochrane confirms that antibiotic treatment of sore throat reduces acute rheumatic fever, relative risk about 0.27.

*Housing, crowding reduction and access to primary care — STRONG historically.* Rheumatic fever disappeared from western Europe and North America largely before widespread penicillin use, as housing and nutrition improved: the decline began in the 1900s and antibiotics arrived in the 1940s. This is the strongest historical evidence in the chapter that a non-medical measure eliminated a major disease.

*Oral penicillin for secondary prophylaxis — MODERATE*, clearly inferior to intramuscular, used where injections are refused or unavailable.

*Echocardiographic screening of schoolchildren — CONTESTED.* It detects large amounts of subclinical borderline disease whose natural history and treatment benefit are not established, and WHO has not recommended population echocardiographic screening.

*Vaccine — none exists.* Candidates are in early trials.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Benzathine benzylpenicillin intramuscularly, three- to four-weekly, secondary prophylaxis | Recurrence reduced about 80 to 90 per cent; valve progression prevented | yes, section 6.2.1 | yes | Under one euro an injection; a few euro a patient-year. UNICEF indicative price October 2026 about US$0.59 a vial in a box of 50 |
| Phenoxymethylpenicillin or benzylpenicillin, acute pharyngitis | First-episode rheumatic fever reduced about 70 to 80 per cent | yes | yes | a few to a few euro a course |
| Aspirin or naproxen, acute rheumatic fever arthritis | Symptom control; does not alter cardiac outcome | yes | yes | a few to tens of euro a course |
| Corticosteroids, severe carditis | Cochrane: no clear reduction in cardiac valve damage at one year, relative risk 0.87 — a negative result against long practice | yes | yes | a few to tens of euro a course |
| Diuretics, ACE inhibitors, beta blockers, for heart failure from valve disease | Symptom and afterload management | yes | yes | tens of euro a year |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Warfarin, mechanical valve or atrial fibrillation with mitral stenosis | Essential; stroke prevention | yes | yes | a few to tens of euro a year plus tens to hundreds of euro for INR monitoring |
| Percutaneous balloon mitral valvuloplasty | Success 80 to 95 per cent; restenosis-free survival 50 to 70 per cent at ten years | n/a | n/a | thousands of euro far cheaper than surgery |
| Valve repair | Less durable in rheumatic than degenerative disease | n/a | n/a | thousands to tens of thousands of euro |
| Valve replacement, mechanical or bioprosthetic | Relieves the lesion; mechanical commits the patient to lifelong warfarin | n/a | n/a | thousands to tens of thousands of euro; mechanical valve thousands of euro |

The central economic fact. A disease affecting 54.8 million people and killing roughly 0.4 million a year is prevented by an injection costing under one euro, given every three to four weeks, reducing recurrence by 80 to 90 per cent. Benzathine penicillin has been on the market since the 1950s, is on the Essential Medicines List†, is off-patent, and has suffered repeated global supply shortages because its margins are too low to attract manufacturers.

**Simple means.** Benzathine penicillin injections are the model case of a no-industrial-chain intervention with a large mortality benefit. US$0.59 a vial at UNICEF indicative prices, October 2026, an 80 to 90 per cent recurrence reduction, and a requirement of a needle, a syringe and someone trained to inject. No electricity, no laboratory, no refrigeration beyond basic. Treating sore throats with oral penicillin costs a few to a few euro a course and prevents 70 to 80 per cent of first rheumatic fever episodes; the constraint is access to a health worker within nine days, not the drug.

Reducing household crowding and improving housing eliminated rheumatic fever in western Europe and North America before antibiotics, with no medical chain at all. Hand hygiene and respiratory hygiene to reduce streptococcal transmission are plausible and unquantified for this endpoint. Register-based recall for injections is organisational rather than technological: the main cause of secondary prophylaxis failure is missed doses, and a paper register with community health workers raises adherence substantially in programme reports. Auscultation with a stethoscope detects most significant valve lesions, with moderate sensitivity against echocardiography, roughly 40 to 60 per cent for mild disease and better for severe; a stethoscope costs a few euro and needs nothing.

The hard limit: severe valve disease needs valvuloplasty or surgery. Balloon valvuloplasty is the cheap end of that chain at thousands of euro and needs a catheter laboratory, and nothing below that treats a tight mitral valve.

**Gaps.** The main source carries three internal contradictions — the direction of the incidence trend, the sex difference in incidence, and the 1990 mortality confidence limit — and any figure taken from it must carry them. WHO gives rheumatic heart disease as about 2 per cent of cardiovascular deaths, roughly 0.4 million, and GBD-based analyses give varying counts; no precise global death count was retrieved. Why incidence is rising in ages 5 to 19 while mortality falls is not explained. Echocardiographic screening is contested: it finds large amounts of borderline disease of unknown significance, and no trial shows that treating it helps. Corticosteroids for acute carditis: Cochrane found no benefit, relative risk 0.87, against long-standing practice. There is no vaccine, and the historical safety concern has never been formally resolved. Benzathine penicillin supply shortages recur globally for a sub-euro off-patent drug; that is a market failure rather than a scientific gap, and it is the binding constraint on prevention. Whether skin infection can trigger rheumatic fever is unresolved and matters for prevention strategy in high-burden Indigenous populations. Surveillance in the highest-burden countries is weakest, and the GBD figures for sub-Saharan Africa rest on sparse primary data.

## Cardiomyopathies (ICD-11 BC43)

**What it is.** The heart muscle itself is diseased — stretched thin and weak, abnormally thickened, or stiff and infiltrated. The valves and arteries may be normal. Many forms run in families.

**Measured.** No global prevalence, death or DALY figure for cardiomyopathy and myocarditis was retrieved from the GBD 2023 tables. GBD groups cardiomyopathy and myocarditis as a cause, and GBD 2019 estimates gave roughly 354,000 deaths globally, which is an earlier round.

Hypertrophic cardiomyopathy has a prevalence of 1 in 500 by classical echocardiographic series, revised to roughly 1 in 200 when genetic carriers are included; it is the commonest inherited cardiac condition. Dilated cardiomyopathy has a prevalence of roughly 1 in 250 to 1 in 2,500 depending on definition, with an incidence of roughly 5 to 7 per 100,000 a year. Arrhythmogenic right ventricular cardiomyopathy runs at roughly 1 in 1,000 to 1 in 5,000. Transthyretin cardiac amyloidosis is present in roughly 10 to 15 per cent of men over 60 with heart failure with preserved ejection fraction and left ventricular hypertrophy, and the wild-type form is far commoner than previously thought. Peripartum cardiomyopathy incidence varies from 1 in 100 pregnancies in Nigeria and 1 in 300 in Haiti to 1 in 1,000 to 4,000 in Europe and North America, a ten- to fortyfold geographic range. Chagas cardiomyopathy: roughly 6 to 7 million people are infected with Trypanosoma cruzi, predominantly in Latin America, of whom 20 to 30 per cent develop cardiomyopathy over decades. Endemic restrictive cardiomyopathy, endomyocardial fibrosis, is a leading cause of heart failure in parts of equatorial Africa and is almost absent from global datasets. Hypertrophic cardiomyopathy is the commonest cause of sudden cardiac death in young athletes in United States series, roughly a third of cases, while in UK and Italian series arrhythmogenic cardiomyopathy and normal-heart sudden death are relatively more prominent. Hypertrophic cardiomyopathy presents from adolescence onward, transthyretin amyloidosis after 60, and peripartum cardiomyopathy in the weeks around delivery.

**Where it starts.** Hypertrophic cardiomyopathy: autosomal dominant sarcomere gene mutations, with MYH7 and MYBPC3 accounting for roughly 70 per cent of genotype-positive cases, and a pathogenic variant found in roughly 30 to 60 per cent of probands. Dilated cardiomyopathy: 30 to 40 per cent familial, with truncating titin variants the commonest single finding at roughly 15 to 25 per cent of familial cases, and also LMNA with its high arrhythmic risk, MYH7, RBM20, FLNC and DSP. Arrhythmogenic cardiomyopathy: desmosomal genes PKP2, DSG2, DSC2, DSP and JUP. Acquired dilated cardiomyopathy: alcohol, with a threshold of roughly 80 g a day for years; anthracycline and trastuzumab chemotherapy, dose-dependent; viral myocarditis; iron overload from haemochromatosis or transfusion; thyroid disease; cocaine and methamphetamine; uncontrolled tachyarrhythmia; and the peripartum state. Cardiac amyloidosis: wild-type transthyretin misfolding with age, or hereditary TTR variants, of which V122I is carried by roughly 3 to 4 per cent of people of West African ancestry. Chagas disease: vector-borne T. cruzi infection. Endomyocardial fibrosis: cause unknown, with hypotheses including eosinophilia, helminth infection, cerium and magnesium soil content and dietary factors, none established.

Penetrance and expressivity in hypertrophic cardiomyopathy vary widely within the same family carrying the same variant and are not predictable, which is the central unsolved problem for genetic counselling. In 40 to 70 per cent of hypertrophic cardiomyopathy probands no causal variant is found. Risk stratification for sudden death is imperfect: the HCM Risk-SCD model and the United States criteria disagree on a substantial minority of patients, and most sudden deaths occur in people not identified as high risk. The cause of endomyocardial fibrosis, a leading cause of heart failure in parts of Africa, is entirely unknown. Why peripartum cardiomyopathy incidence varies ten- to fortyfold geographically is unexplained. Whether viral myocarditis commonly progresses to dilated cardiomyopathy, and in whom, is not established.

**Cure status.** Genetic cardiomyopathies — hypertrophic, dilated, arrhythmogenic: CONTROLLABLE. Tachycardia-induced cardiomyopathy: CURABLE. Alcoholic cardiomyopathy: CONTROLLABLE. Iron-overload and thyrotoxic cardiomyopathy: CURABLE on treating the cause. Chagas cardiomyopathy once established: RELIEF ONLY. Cardiac transthyretin amyloidosis: CONTROLLABLE, newly so.

For the genetic forms, no treatment removes the mutation, and treatment reduces symptoms and sudden-death risk. Septal myectomy or alcohol septal ablation for obstructive hypertrophic cardiomyopathy permanently abolishes the outflow gradient; myectomy in experienced centres gives operative mortality under 1 per cent and long-term survival equal to the general population. That is relief of the obstruction rather than cure of the cardiomyopathy, and it is one of the most effective operations in cardiology.

Tachycardia-induced cardiomyopathy: ablation or rate control of the driving arrhythmia normalises ejection fraction in the majority. Alcoholic cardiomyopathy: substantial recovery in a large minority with sustained abstinence. Peripartum cardiomyopathy: ejection fraction recovers in roughly 50 to 70 per cent, the most reversible of the dilated cardiomyopathies.

Chagas cardiomyopathy once established is RELIEF ONLY. The BENEFIT trial, with 2,854 patients, found benznidazole reduced parasite detection and did not reduce cardiac clinical progression, hazard ratio 0.93. Antiparasitic treatment is effective in acute and early chronic infection and does not reverse established cardiomyopathy.

Cardiac transthyretin amyloidosis has become CONTROLLABLE. Tafamidis reduced all-cause mortality from 42.9 to 29.5 per cent, hazard ratio 0.70, in ATTR-ACT; patisiran, vutrisiran and eplontersen reduce transthyretin production, and HELIOS-B with vutrisiran showed reduced death and cardiovascular events. CRISPR-based TTR knockout is in trials and is the first plausible one-time cure in this group; outcome data are not yet available and no cure should be claimed. Heart transplantation removes the organ, with median post-transplant survival of roughly 12 to 13 years.

**Prevention.**

*Family screening in genetic cardiomyopathy — STRONG for case-finding.* Cascade genetic and echocardiographic screening of first-degree relatives identifies affected relatives in roughly 20 to 50 per cent. It prevents sudden death by enabling defibrillator placement and activity modification; it does not prevent the cardiomyopathy.

*Alcohol limitation — STRONG* for alcoholic cardiomyopathy. For scale: alcohol-attributable deaths worldwide were 2.6 million in 2019, including 474,000 cardiovascular deaths, and alcohol-attributable death rates per 100,000 fell 20.2 per cent globally between 2010 and 2019.

*Iron chelation in transfusion-dependent thalassaemia — STRONG*; it transformed survival in thalassaemia major, where cardiac iron overload was the leading cause of death.

*Chagas vector control, blood-donor screening and treatment of early infection — STRONG.* Vector-control programmes in the Southern Cone reduced transmission by over 90 per cent.

*Anthracycline dose limitation, dexrazoxane and cardiac monitoring during chemotherapy — MODERATE.* Dexrazoxane reduces clinical heart failure, Cochrane relative risk about 0.29.

*Avoiding cocaine and methamphetamine — MODERATE*.

*Pre-participation athletic screening — CONTESTED.* The Italian programme with electrocardiography reported reduced sudden death in athletes; United States and Israeli analyses found no benefit, and false-positive rates and costs are substantial. Guidelines differ between countries and the disagreement is unresolved.

*Nothing prevents hypertrophic, arrhythmogenic or familial dilated cardiomyopathy.*

**Treatment.** The proportion of alcoholic cardiomyopathy that recovers with sustained abstinence is not given by the sources used here, which describe recovery only as substantial in a large minority.

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Beta blocker, for hypertrophic cardiomyopathy symptoms and for dilated cardiomyopathy | Reduces outflow gradient and symptoms in hypertrophic disease; mortality benefit in dilated disease per the heart failure trials, CIBIS-II hazard ratio 0.66 | yes | yes | a few to tens of euro |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Verapamil or disopyramide, hypertrophic cardiomyopathy | Gradient and symptoms reduced | yes, verapamil | yes | a few to tens of euro |
| Four-pillar heart failure therapy for dilated cardiomyopathy | As in the heart failure entry: RALES number needed to treat 9, CIBIS-II 18, DAPA-HF 21 | First three yes | First three yes | tens of euro for the three cheap pillars |
| Septal myectomy, obstructive hypertrophic cardiomyopathy | Abolishes the gradient; operative mortality under 1 per cent in expert centres; long-term survival equal to the general population | n/a | n/a | tens of thousands of euro |
| Alcohol septal ablation, obstructive hypertrophic cardiomyopathy | Comparable gradient reduction; 10 to 20 per cent need a pacemaker for heart block | n/a | n/a | thousands to tens of thousands of euro |
| Mavacamten, obstructive hypertrophic cardiomyopathy | EXPLORER-HCM, 251 patients: primary functional endpoint met in 37 against 17 per cent; gradient and symptoms improved; no mortality data | no | no | tens of thousands of euro |
| Implantable defibrillator | Terminates ventricular arrhythmia; SCD-HeFT hazard ratio 0.77, number needed to treat 14 over five years; DANISH null in non-ischaemic cardiomyopathy | n/a | n/a | tens of thousands of euro |
| Tafamidis, transthyretin amyloidosis | All-cause mortality 29.5 against 42.9 per cent, hazard ratio 0.70, ATTR-ACT | no | no | hundreds of thousands of euro |
| Patisiran, vutrisiran, eplontersen, transthyretin amyloidosis | Transthyretin reduced; HELIOS-B reduced death and cardiovascular events | no | no | hundreds of thousands of euro |
| Benznidazole or nifurtimox, Chagas disease | Effective in acute and early chronic infection; BENEFIT found no reduction in cardiac progression once cardiomyopathy is established, hazard ratio 0.93 | yes, both | yes | tens to hundreds of euro a course |
| Iron chelation, deferoxamine or deferasirox | Transformed survival in thalassaemia major | yes; deferiprone is on the 24th List only as a therapeutic equivalent to deferasirox, not as a selected medicine | Deferoxamine yes | hundreds to tens of thousands of euro |
| Heart transplantation | Median survival 12 to 13 years | n/a | n/a | hundreds of thousands of euro in the first year |

The price range inside this one entry runs from a few euro for a beta blocker to hundreds of thousands of euro for an amyloidosis drug. Both are standing treatments in cardiomyopathy.

**Simple means.** Alcohol abstinence is curative in a large minority of alcoholic cardiomyopathy and costs nothing. Avoiding competitive high-intensity exertion matters in hypertrophic and arrhythmogenic cardiomyopathy, and the advice now differs by disease, so both results are printed. In arrhythmogenic cardiomyopathy exercise restriction is disease-modifying: endurance exercise accelerates structural progression and arrhythmic events in cohort studies — a behavioural measure with a structural effect and no cost. In hypertrophic cardiomyopathy the blanket restriction has loosened: the LIVE-HCM study found no excess event rate in vigorous exercisers.

Family history taking and cascade screening is the highest-yield no-technology action in genetic cardiomyopathy: a pedigree costs nothing and identifies at-risk relatives. Confirming disease requires echocardiography. Auscultation detects the dynamic systolic murmur of obstructive hypertrophic cardiomyopathy — louder on Valsalva and standing, softer on squatting — with a stethoscope, and the manoeuvres cost nothing. Salt and fluid management and weight monitoring act as in the heart failure entry, with SODIUM-HF null on sodium restriction. Vector control for Chagas disease is largely housing and community work: house improvement, wall plastering, roof replacement and insecticide reduced transmission by over 90 per cent in the Southern Cone programmes. The four cheap heart failure pillars — an ACE inhibitor with a beta blocker and spironolactone at tens of euro a patient-year — carry most of the mortality benefit in dilated cardiomyopathy, and they need a pharmaceutical chain, but a very cheap one.

The hard limit. Hypertrophic obstruction, arrhythmic risk and amyloidosis need surgery, devices or very expensive drugs. For a young person at risk of sudden death from cardiomyopathy the only effective intervention is an implantable defibrillator, and there is no simple-means substitute. Bystander CPR and a public defibrillator are the fallback.

**Gaps.** No GBD 2023 global burden figure for cardiomyopathy was retrieved, and the roughly 354,000 deaths figure comes from an earlier round. Penetrance in genetic cardiomyopathy is unpredictable, and in 40 to 70 per cent of hypertrophic cardiomyopathy probands no variant is found; genetic counselling operates with that uncertainty. Sudden-death risk stratification is imperfect and the European and American criteria disagree for a substantial minority. Athletic pre-participation electrocardiographic screening is unresolved, with Italian data positive and United States and Israeli analyses negative, and large policy consequences. Exercise advice has reversed in hypertrophic cardiomyopathy with LIVE-HCM while remaining restrictive in arrhythmogenic cardiomyopathy; both are printed. The cause of endomyocardial fibrosis is unknown, and it is a leading cause of heart failure in parts of Africa with almost no representation in global data. Peripartum cardiomyopathy incidence varies ten- to forty-fold geographically, unexplained. Defibrillator benefit in non-ischaemic cardiomyopathy is unresolved. BENEFIT was negative for benznidazole in established Chagas cardiomyopathy, against prior expectation. Amyloidosis drug prices of hundreds of thousands of euro a year make the measured mortality benefit inaccessible to the large majority of affected people worldwide, and no generic pathway exists.

## Congenital heart disease (ICD-11 LA80–LA8Z)

**What it is.** The heart is formed wrongly before birth — a hole between chambers, a narrowed valve, vessels joined in the wrong place. Some kinds cause no trouble; others are fatal within days unless corrected. It is the commonest serious birth defect.

**Measured.** Birth prevalence is roughly 9 per 1,000 live births worldwide, with a meta-analysis range of 8 to 9.4, which is roughly 1.35 million affected births a year. Congenital anomalies of all types carried 54.8 million DALYs in 2023, rank 13 of all causes, and congenital heart anomalies are the largest single component; no separate GBD 2023 figure for congenital heart disease was retrieved. Deaths run at roughly 217,000 to 261,000 a year from congenital heart anomalies in GBD 2017 to 2019 estimates, of which about 70 per cent in the first year of life. WHO’s own congenital disorders fact sheet gives 240,000 newborn deaths within 28 days of birth each year from congenital disorders of all types, plus 170,000 deaths of children aged one month to five years. It gives no prevalence figure for cardiac defects. That page also contradicts itself on the low- and middle-income share: Key Facts gives nine in ten and the body gives about 94 per cent.

Severe or critical disease requiring intervention in the first year affects roughly 2 to 3 per 1,000 live births. Reported birth prevalence has risen from about 0.6 per 1,000 in the 1930s to 1950s to about 9 per 1,000 now, almost entirely from improved echocardiographic detection of mild lesions rather than a true increase. In high-income countries over 90 per cent of children now reach adulthood and adults with congenital heart disease outnumber children with it; in low-income countries a large share still die in infancy, and mortality is roughly ten to twenty times higher in low-income than high-income settings. Roughly 90 per cent of children with congenital heart disease are born in regions without adequate access to cardiac surgical care. The commonest lesions are ventricular septal defect at about 30 per cent of all cases, atrial septal defect, patent ductus arteriosus, pulmonary stenosis, tetralogy of Fallot, coarctation and transposition of the great arteries.

**Where it starts.** Roughly 20 to 30 per cent has an identified genetic cause. Trisomy 21, of which 40 to 50 per cent have a cardiac defect, typically an atrioventricular septal defect. The 22q11.2 deletion, with conotruncal defects. Turner syndrome, with coarctation and bicuspid aortic valve. Noonan, Williams, trisomy 13 and trisomy 18. Pre-gestational maternal diabetes raises risk roughly three- to fivefold and is one of the strongest and most modifiable factors. Maternal rubella infection in the first trimester causes congenital rubella syndrome with patent ductus arteriosus and pulmonary artery stenosis, and is essentially eliminated by vaccination where coverage is high. Uncontrolled maternal phenylketonuria carries high risk. Teratogenic drugs: retinoids, thalidomide, lithium, some anticonvulsants including valproate, and ACE inhibitors and angiotensin receptor blockers in pregnancy. Maternal alcohol, with septal defects in the fetal alcohol spectrum; smoking, a modest increase; obesity, roughly 1.15- to 1.4-fold. Folate deficiency: folic acid fortification is associated with roughly 20 to 40 per cent reductions in some conotruncal and septal defects in before-and-after national studies from Canada and Quebec — ecological, and smaller than its effect on neural tube defects. Assisted reproduction gives a modest increase of roughly 1.3- to 1.5-fold, partly confounded. Consanguinity raises risk in populations with high rates, and WHO describes the risk as nearly doubling, without a figure.

In roughly 70 to 80 per cent of cases no cause is identified at all. Most congenital heart disease is sporadic, in families with no history and mothers with no identified exposure. Why a specific structure fails to form is not explained in the individual case. The large majority of the genetic contribution is not single-gene: de novo variants, copy number variation and oligogenic models account for part of it, and much remains unassigned. Whether the rise in reported birth prevalence contains any true increase alongside the detection effect is not resolved.

**Cure status.** Patent ductus arteriosus, secundum atrial septal defect, ventricular septal defect, coarctation, pulmonary valve stenosis and transposition of the great arteries after an arterial switch: CURABLE. Small ventricular septal defects, roughly 70 to 80 per cent of which close by school age: SELF-LIMITING. Tetralogy of Fallot after repair: CONTROLLABLE. Single-ventricle lesions palliated to a Fontan circulation: CONTROLLABLE. Eisenmenger syndrome: RELIEF ONLY.

This is the chapter’s clearest set of procedural cures. Patent ductus arteriosus closure, by transcatheter device or surgical ligation, has a success rate of roughly 95 to 99 per cent with complete closure and normal life expectancy afterwards, and transcatheter closure in infants and children has largely replaced surgery. That is a complete cure of a potentially fatal lesion by one procedure. Secundum atrial septal defect closure by transcatheter device has a procedural success of 95 to 98 per cent, with normalisation of right heart loading and normal life expectancy if done in childhood or early adulthood. Ventricular septal defect closure, surgical or transcatheter in selected anatomy, has high success, and small defects close spontaneously in roughly 70 to 80 per cent by school age, so many need no treatment at all. Coarctation repair, by surgery in infancy or balloon and stent in older children and adults, relieves the obstruction, and long-term hypertension persists in 25 to 50 per cent, so it is cure of the obstruction and not of the arteriopathy. Pulmonary valve stenosis: balloon valvuloplasty has a success of roughly 85 to 95 per cent and is usually durable and effectively curative. Tetralogy of Fallot repair has early mortality now under 2 per cent in high-income centres with over 90 per cent survival to thirty years, and pulmonary regurgitation leads to re-operation for valve replacement in a large proportion: repaired rather than cured. Transposition of the great arteries treated by arterial switch has operative survival over 95 per

cent with excellent long-term function, close to a cure, with lifelong surveillance needed for the coronary anastomoses and the neo-aortic valve.

Not curable: single-ventricle lesions — hypoplastic left heart, tricuspid atresia — are palliated by staged surgery to a Fontan circulation, with roughly 60 to 70 per cent surviving to twenty years and progressive Fontan-associated liver disease, protein-losing enteropathy, arrhythmia and eventual failure; transplantation is the endpoint for many. Eisenmenger syndrome, irreversible pulmonary hypertension from a late-closed shunt, is RELIEF ONLY, and closing the defect at that stage is harmful.

**Prevention.**

*Rubella vaccination — STRONG, and one of the clearest primary preventions of a structural birth defect in existence.* Congenital rubella syndrome with its cardiac lesions has been eliminated in the Americas and in much of Europe through vaccination. Rubella coverage in 2025 was 73 per cent globally.

*Pulse oximetry screening of newborns — STRONG for detection, not prevention, and it saves lives.* Adding pulse oximetry to clinical examination detects critical congenital heart disease with a sensitivity of roughly 76 per cent and a false-positive rate of roughly 0.14 per cent, from a meta-analysis of 229,421 newborns. United States states that mandated screening showed roughly a 33 per cent reduction in infant deaths from critical congenital heart disease. A pulse oximeter costs tens to hundreds of euro and this is the highest-value detection intervention in the entry.

*Pre-conception glycaemic control in maternal diabetes — STRONG.* Risk falls from the three- to fivefold excess toward baseline with good peri-conceptional control.

*Avoiding teratogens in pregnancy — STRONG*: retinoids, valproate, lithium, ACE inhibitors and angiotensin receptor blockers. *Alcohol avoidance in pregnancy — STRONG*. *Maternal phenylketonuria dietary control — STRONG*.

*Folic acid fortification — MODERATE.* Roughly 20 to 40 per cent reductions in some septal and conotruncal defects in national before-and-after studies; these are ecological and the effect is much less certain than for neural tube defects, so the grade is MODERATE rather than STRONG.

*Antenatal ultrasound screening — MODERATE* for detection; detection rates for major lesions range from under 30 per cent to over 80 per cent between programmes.

*Maternal weight management and smoking cessation — MODERATE*. *Genetic counselling in consanguineous populations and after an affected child — MODERATE*.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Prostaglandin E1, alprostadil, infusion | Keeps the ductus open in duct-dependent lesions; it is the drug that keeps a newborn alive until surgery and there is no substitute | yes | yes | tens to hundreds of euro a course |
| Ibuprofen, indomethacin or paracetamol, to close a patent ductus in preterm infants | Pharmacological closure in roughly 70 to 80 per cent of preterm cases; paracetamol comparably effective to ibuprofen in meta-analysis | yes, all three | yes | a few to tens of euro a course |
| Transcatheter patent ductus closure | Success 95 to 99 per cent, curative | n/a | n/a | thousands of euro device-dominated |
| Transcatheter atrial septal defect closure | Success 95 to 98 per cent, curative | n/a | n/a | thousands to tens of thousands of euro |
| Balloon pulmonary valvuloplasty | Success 85 to 95 per cent, usually curative | n/a | n/a | thousands of euro |
| Surgical closure of a septal defect | High success, curative | n/a | n/a | thousands to tens of thousands of euro depending on country |
| Tetralogy of Fallot repair | Early mortality under 2 per cent; over 90 per cent survival to thirty years | n/a | n/a | thousands to tens of thousands of euro |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Arterial switch for transposition | Operative survival over 95 per cent | n/a | n/a | tens of thousands of euro |
| Staged Fontan palliation | 60 to 70 per cent survival to twenty years, with progressive complications | n/a | n/a | tens of thousands to hundreds of thousands of euro across stages |
| Diuretics, ACE inhibitors, digoxin, for heart failure in congenital disease | Symptom management | yes | yes | a few to tens of euro a year |
| Endocarditis prophylaxis, amoxicillin before dental procedures in high-risk lesions | Indications narrowed sharply in the 2007 and 2008 guidelines; evidence of benefit is weak | yes | yes | a few to a few euro a dose |
| Pulmonary vasodilators in Eisenmenger syndrome, bosentan or sildenafil | Exercise capacity improved, per BREATHE-5 | **Neither bosentan nor sildenafil is on the 24th Model List in any form** | Sildenafil yes | hundreds to tens of thousands of euro a year |

**Simple means.** Pulse oximetry on every newborn is the single highest-value low-technology intervention in this entry and it requires no laboratory, no specialist and almost no training. A device costs tens to hundreds of euro and the measurement is one reading in each foot and hand at 24 hours of age. Sensitivity for critical congenital heart disease is roughly 76 per cent with false positives at 0.14 per cent, and mandated screening was followed by roughly 33 per cent fewer infant deaths from critical disease in United States states.

Clinical examination of the newborn costs nothing: auscultation for murmurs, femoral pulse palpation, where absent or weak femoral pulses indicate coarctation, and observation of colour, feeding and breathing. Its sensitivity alone is poor for critical lesions, which is exactly why pulse oximetry adds so much. Rubella vaccination eliminates congenital rubella syndrome and is on the Essential Medicines List, off-patent, and part of routine immunisation. Pre-conception folic acid costs €1 to €5 a year and is on the Essential Medicines List†; the UNICEF indicative price in October 2026 for folic acid 5 mg was US$5.41 per bottle of 1,000 tablets on one page and US$5.39 on another, about US$0.0054 a tablet. Avoiding alcohol and teratogenic drugs in pregnancy costs nothing. Breastfeeding support and high-calorie feeding for infants who fail to thrive from the work of breathing is nursing and nutritional support with no technology.

The knee-chest position in a tetralogy of Fallot hypoxic spell is a free manoeuvre that raises systemic vascular resistance and aborts the spell. That is a technique that saves lives with nothing but hands.

The hard limit, stated plainly. Most congenital heart disease requiring treatment needs cardiac surgery or interventional catheterisation: a theatre, cardiopulmonary bypass, paediatric anaesthesia, intensive care and trained surgeons. Roughly 90 per cent of affected children are born where that chain does not exist, and mortality is ten to twenty times higher as a result. Prostaglandin E1 keeps a duct-dependent newborn alive but only until surgery; it is a bridge to a chain that must exist. There is no simple-means substitute for cardiac surgery.

**Gaps.** No GBD 2023 figure for congenital heart disease specifically was retrieved; it sits inside congenital anomalies at 54.8 million DALYs, rank 13. In 70 to 80 per cent of cases no cause is identified. The rise in reported birth prevalence from 0.6 to 9 per 1,000 over eighty years† is attributed to detection, and how much if any is a true increase is unresolved. Antenatal detection rates range from under 30 per cent to over 80 per cent between programmes at similar resource levels, and the reasons are not well characterised. Folic acid's effect on cardiac defects is ecological and much weaker than for neural tube defects, and grades differ between sources. Endocarditis prophylaxis indications were narrowed on weak evidence and the change remains debated, with UK and United States and European guidance differing. Long-term outcome data for Fontan patients beyond thirty years barely exist, since the first cohorts are only now reaching that age. Mortality data from the regions carrying most of the burden are the weakest, so the global death count of roughly 217,000 to 261,000 is a

model output rather than a measurement. Surgical outcome figures come overwhelmingly from high-volume high-income centres, and population outcomes in low-income settings are largely unmeasured. WHO's congenital disorders fact sheet contradicts itself on the low- and middle-income share, nine in ten against 94 per cent, and is dated February 2023.

## Infective endocarditis (ICD-11 BB40)

**What it is.** Bacteria settle on a heart valve and build a crumbling mass of infected tissue. Fever drags on for weeks, fragments break off and travel to the brain or limbs, and the valve is destroyed. Untreated it is almost always fatal.

**Measured.** No global prevalence, death or DALY figure for endocarditis was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all. GBD 2019 estimates gave roughly 66,000 deaths a year globally with incidence up roughly 50 per cent since 1990, and that is an earlier round.

Incidence in high-income countries is roughly 3 to 15 per 100,000 person-years and rising. In-hospital mortality is 15 to 25 per cent and one-year mortality 25 to 40 per cent despite treatment, from the ICE-PCS and EURO-ENDO registries. Roughly 40 to 50 per cent of patients undergo valve surgery during the index admission in high-income series. The microbiology has shifted: Staphylococcus aureus is now the commonest cause in high-income countries at about 25 to 30 per cent, displacing the viridans streptococci, and enterococci are rising with age and healthcare exposure. In low- and middle-income countries rheumatic valve disease remains the dominant substrate and streptococci the dominant organisms, and patients are decades younger. The median age has risen from roughly 40 in the 1960s to 65 to 70 now in high-income countries, tracking the shift from rheumatic to degenerative and prosthetic valve substrate. Injecting drug use accounts for a rising share, with an incidence in that group of roughly 1 to 5 per cent a year, far higher than any other risk group. Prosthetic valve endocarditis runs at roughly 1 per cent in the first year after valve replacement and 0.3 to 0.6 per cent a year thereafter.

**Where it starts.** A damaged or prosthetic valve plus a bacteraemia; the two together are the requirement. A prosthetic heart valve is the highest single structural risk. Previous endocarditis strongly raises the risk of a further episode. Rheumatic valve disease dominates in low-income settings. Congenital heart disease, especially unrepaired cyanotic lesions and prosthetic material, contributes. Degenerative valve disease — calcific aortic stenosis, mitral annular calcification — is the dominant substrate in ageing high-income populations. Injecting drug use gives right-sided tricuspid endocarditis, usually with S. aureus. Intravascular catheters, haemodialysis and pacemaker and defibrillator leads make healthcare-associated endocarditis roughly 25 to 30 per cent of cases in high-income series.

Poor dental health and dental procedures need care. Dental procedures were long assumed causal, and case-control studies by Strom and colleagues found no significant association between dental procedures and endocarditis, while chewing and tooth-brushing produce bacteraemia far more often than dental visits. That finding is why the prophylaxis guidance was narrowed.

Why a transient bacteraemia, which occurs routinely with chewing and brushing, settles on a valve on one occasion and not the thousands of others is not explained. Whether antibiotic prophylaxis before dental procedures prevents endocarditis has never been tested in a randomised trial and almost certainly never will be, because the event is too rare. The guidance change rests on case-control and ecological data, and the subsequent observation of rising endocarditis incidence after the restriction in some countries, notably England after the 2008 NICE guidance, has been read both as evidence of harm from the change and as part of a longer pre-existing trend. That disagreement is unresolved. The optimal timing of valve surgery is also not settled by adequate trial evidence.

**Cure status.** CURABLE.

A completed course of appropriate intravenous antibiotics, with valve surgery where indicated, eradicates the infection in the majority of survivors, and relapse rates are roughly 2 to 6 per cent. That is a cure of the infection. But in-hospital mortality is 15 to 25 per cent and one-year mortality 25 to 40 per cent; the valve damage is permanent, and many patients are left with a prosthetic valve that itself carries a renewed endocarditis risk of 0.3 to 0.6 per

cent a year. Treatment requires two to six weeks of intravenous antibiotics, which means prolonged hospital admission or an outpatient parenteral service.

The POET trial, with 400 patients, found that switching to oral antibiotics after an initial intravenous period was non-inferior to continued intravenous therapy, with a primary composite of 12.1 against 12.1 per cent — a significant finding for resource-limited settings and for shortening admission. On surgical timing, the EASE trial, with 76 patients, found early surgery reduced the composite of death and embolic events, 3 against 23 per cent, in a selected group, and the evidence base for timing is otherwise observational.

**Prevention.**

*Aseptic technique and prompt removal of intravascular catheters — STRONG* for healthcare-associated endocarditis, which is 25 to 30 per cent of cases. *Chlorhexidine skin preparation before vascular access — STRONG* for catheter-related bacteraemia generally. *Treating S. aureus bacteraemia promptly and adequately — STRONG*.

*Preventing rheumatic heart disease with benzathine penicillin — STRONG* where rheumatic disease is the substrate: a few euro a patient-year for an 80 to 90 per cent reduction in recurrence.

*Dental and oral hygiene — MODERATE, and probably more important than procedural prophylaxis* given that routine chewing and brushing cause more cumulative bacteraemia than dental visits.

*Needle and syringe programmes and opioid agonist therapy in injecting drug use — MODERATE* for reducing injection-related bacteraemia, by reducing injection frequency and sharing.

*Antibiotic prophylaxis before dental procedures in the highest-risk group — CONTESTED, and both readings must be printed.* No randomised trial exists and none is feasible. Indications were narrowed sharply in 2007 and 2008 by the American Heart Association and essentially withdrawn in England by NICE in 2008, then partly reinstated by NICE in 2016. Case-control data found no association between dental procedures and endocarditis; ecological data from England showed rising incidence after the restriction, and that has been interpreted both ways. Current guidance restricts prophylaxis to prosthetic valves, previous endocarditis and some congenital lesions, before dental procedures involving gingival manipulation. Cost: a few to a few euro a dose of amoxicillin.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Benzylpenicillin or amoxicillin with gentamicin, streptococcal and enterococcal disease | Cure in the majority; two- to six-week courses | yes, all | yes | €20–200 a course. UNICEF indicative price October 2026 for amoxicillin 250 mg dispersible: US$0.54 for ten tablets, about US$0.054 a tablet |
| Flucloxacillin or cloxacillin, methicillin-sensitive S. aureus | The drug of choice, and clearly better than vancomycin for sensitive strains | yes | yes | tens to hundreds of euro a course |
| Vancomycin, resistant strains or penicillin allergy | Standard for resistant S. aureus; requires level monitoring | yes | yes | hundreds of euro a course |
| Gentamicin, for synergy | Synergy in enterococcal disease; nephrotoxic, and its role in staphylococcal disease has been withdrawn | yes | yes | tens of euro a course |
| Ceftriaxone, outpatient streptococcal regimens | Once-daily, which enables outpatient therapy | yes | yes | tens to hundreds of euro a course |
| Rifampicin, prosthetic valve, with others | Biofilm penetration | yes | yes | tens of euro a course |
| Daptomycin | Alternative for resistant S. aureus and enterococci | no | yes, generics | hundreds to thousands of euro a course |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Oral step-down after initial intravenous therapy, the POET regimen | Non-inferior to continued intravenous therapy: 12.1 against 12.1 per cent composite | Component drugs yes | yes | Substantially cheaper; shortens admission |
| Valve surgery | Indicated for heart failure, uncontrolled infection and large vegetations with embolism; EASE gave a composite of 3 against 23 per cent in a selected group | n/a | n/a | tens of thousands of euro |

The antibiotics that cure endocarditis are old, off-patent and on the Essential Medicines List: penicillin, amoxicillin, flucloxacillin, gentamicin, ceftriaxone, vancomycin and rifampicin. A full curative course costs on the order of tens to hundreds of euro in drug terms. The expensive parts are the weeks of hospital admission, the blood cultures, the echocardiography and the surgery.

**Simple means.** Oral step-down antibiotic therapy is the single most important finding for treating endocarditis where hospital beds and intravenous services are scarce: non-inferior to intravenous therapy in POET, and it converts weeks of admission into oral tablets. Dental and oral hygiene — brushing, and access to basic dental care — is probably more important than procedural prophylaxis given the bacteraemia arithmetic, and costs very little. Benzathine penicillin for rheumatic heart disease prevention costs US$0.59 a vial at UNICEF indicative prices, October 2026 and prevents the valve damage that becomes the endocarditis substrate. Amoxicillin prophylaxis where indicated costs a few to a few euro a dose, is oral, listed and off-patent, with the grade of benefit CONTESTED. Hand hygiene and clean injection practice are free or nearly free and directly address the two fastest-growing risk groups.

The hard limit, stated plainly. Endocarditis cannot be diagnosed without blood cultures and echocardiography, and it cannot be treated without weeks of appropriate antibiotics. The modified Duke criteria depend on both. Clinical suspicion alone — fever with a new murmur, splinter haemorrhages, splenomegaly — identifies candidates and cannot confirm or guide therapy. The minimum chain is a microbiology laboratory able to culture blood, an echocardiography machine, and a reliable supply of intravenous and then oral antibiotics. Without blood cultures, therapy is blind and failure rates rise sharply. There is no simple-means substitute.

**Gaps.** No GBD 2023 global burden figure for endocarditis was retrieved, and the roughly 66,000 deaths figure comes from an earlier round; this entry is part of the seventeen-condition gap in this chapter’s introduction. Whether dental antibiotic prophylaxis works has never been and will never be tested in a randomised trial; the guidance rests on case-control and ecological data, England’s rising incidence after restriction is read both ways, and guidelines differ between countries. Optimal timing of valve surgery rests on one small trial of 76 patients and on observational data. Incidence is rising and the reasons are multiple and not apportioned: ageing, more prosthetic valves and devices, more injecting drug use, more healthcare exposure, better detection. Blood-culture-negative endocarditis is 5 to 20 per cent of cases depending on prior antibiotic exposure and on the availability of serology for Coxiella, Bartonella and Tropheryma, and in most of the world those tests do not exist, so the true share is unknown. Mortality figures come from referral centres in registries, and population-based case fatality, especially where surgery is unavailable, is largely unmeasured. The low- and middle-income disease — younger patients, rheumatic substrate, streptococcal organisms — is barely represented in a guideline evidence base built on high-income cohorts.

## Pericarditis (ICD-11 BB20)

**What it is.** The thin sac around the heart becomes inflamed. It causes sharp chest pain that is worse lying flat and better sitting forward. Most cases settle on their own; a few fill the sac with fluid and squeeze the heart.

**Measured.** No global prevalence, death or DALY figure for pericarditis was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Incidence is roughly 27.7 per 100,000 person-years in an Italian urban population study, and pericarditis accounts for roughly 0.1 per cent of hospital admissions and 5 per cent of emergency attendances for non-ischaemic chest pain. Recurrence after a first episode is 15 to 30 per cent without colchicine and 10 to 15 per cent with it. Constrictive pericarditis develops in roughly 0.5 to 1 per cent after idiopathic or viral pericarditis, roughly 2 to 5 per cent after immune-mediated causes, and 20 to 30 per cent after tuberculous or purulent pericarditis. In-hospital mortality for acute pericarditis in high-income series is roughly 1.1 per cent, concentrated in those with a bacterial cause or comorbidity. Idiopathic and viral pericarditis peaks in young and middle-aged adults with a male predominance of roughly 1.5 to 1.

Tuberculous pericarditis accounts for roughly 70 to 80 per cent of pericarditis in sub-Saharan Africa and is strongly associated with HIV, with six-month mortality of roughly 17 to 40 per cent; in high-income countries it is under 5 per cent of cases. That is the sharpest geographic divergence in the chapter: the same named condition is a self-limiting viral illness in Europe and a frequently fatal tuberculous one in southern Africa. For scale, tuberculosis caused 1.23 million deaths in 2024 with 10.7 million new cases, and people with HIV are twelve times more likely to develop tuberculosis.

**Where it starts.** Idiopathic or presumed viral accounts for roughly 80 to 90 per cent of cases in high-income countries: coxsackievirus, echovirus, adenovirus, influenza, Epstein-Barr virus, cytomegalovirus, parvovirus B19, human herpesvirus 6 and SARS-CoV-2. Tuberculosis dominates in sub-Saharan Africa and in HIV-positive populations. Bacterial purulent pericarditis, from S. aureus or S. pneumoniae, is rare and highly lethal, with untreated mortality near 100 per cent. Post-cardiac-injury causes: after myocardial infarction, now rare with reperfusion; after cardiac surgery, with post-pericardiotomy syndrome in 10 to 40 per cent; after catheter ablation or device implantation. Autoimmune causes: systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis, familial Mediterranean fever, Still disease. Uraemia in advanced kidney failure and in dialysis patients. Malignancy — lung and breast cancer, lymphoma, mesothelioma — is the commonest cause of a large haemorrhagic effusion. Chest radiotherapy and drugs, including hydralazine, isoniazid, procainamide and immune checkpoint inhibitors, contribute. Hypothyroidism causes effusion without much inflammation.

In the 80 to 90 per cent called idiopathic, no specific cause is ever identified. Viral aetiology is presumed on clinical grounds and rarely confirmed, because pericardial fluid and tissue are seldom sampled in uncomplicated cases, and when they are the yields are low. Why some patients recur repeatedly for years and others never do is not explained, and the recurrent form behaves like an autoinflammatory disease; the success of interleukin-1 blockade supports that, and the mechanism is not established. Why colchicine works is not fully explained. Which patients will progress to constriction cannot be predicted.

**Cure status.** Acute idiopathic and viral pericarditis, the large majority: SELF-LIMITING. Bacterial and tuberculous pericarditis: CURABLE with appropriate antimicrobial therapy and drainage, and fatal without it. Recurrent pericarditis: CONTROLLABLE. Constrictive pericarditis: CURABLE by pericardiectomy. Tamponade: CURABLE by drainage, for that episode.

Acute idiopathic and viral pericarditis resolves without specific treatment in roughly 70 to 85 per cent, and anti-inflammatory therapy shortens symptoms and reduces recurrence rather than being necessary for resolution. This is one of the few genuinely self-limiting conditions in the chapter.

Recurrent pericarditis is CONTROLLABLE rather than curable, and the interleukin-1 blockers make the point. Colchicine halves recurrence. Anakinra and rilonacept suppress it strongly and recurrence returns on withdrawal: RHAPSODY, with 61 patients on rilonacept, gave a recurrence hazard ratio of 0.04 on treatment, with flares after stopping. That is holding the state.

Constrictive pericarditis is CURABLE by pericardiectomy, with substantial perioperative mortality of 6 to 12 per cent in modern series and higher after radiation, and excellent long-term

relief in survivors. Tamponade is relieved immediately and definitively for that episode by pericardiocentesis.

**Prevention.**

*Colchicine to prevent recurrence — STRONG, and the central evidence of this entry.* The ICAP trial, 240 patients with a first episode: colchicine added to conventional therapy reduced incessant or recurrent pericarditis from 37.5 to 16.7 per cent, relative risk 0.45, number needed to treat about 5. CORP and CORP-2, in recurrent pericarditis, reduced recurrence from roughly 55 to 24 per cent and from 42 to 22 per cent respectively. Colchicine is off-patent, cheap at tens of euro a course, and on the Essential Medicines List.

*Colchicine to prevent post-pericardiotomy syndrome after cardiac surgery — STRONG.* The COPPS and COPPS-2 trials reduced the syndrome by roughly half, with COPPS-2 giving 19.4 against 29.4 per cent, relative risk 0.67, number needed to treat 10.

*Avoiding corticosteroids in a first episode — MODERATE, and important.* Corticosteroid use is associated with increased recurrence in cohort and trial-subgroup data, and steroids are reserved for specific indications. This is a case where a widely available cheap drug makes the condition worse and the evidence says to withhold it.

*Tuberculosis control and HIV treatment — STRONG* where tuberculous pericarditis dominates.

*Adjunctive corticosteroids in tuberculous pericarditis — CONTESTED, with three results to print.* The IMPI trial, 1,400 patients: prednisolone did not reduce the primary composite of death, tamponade or constriction; it did reduce constriction and hospitalisation; and it increased HIV-associated malignancy.

*Exercise restriction during acute inflammation — WEAK*, consensus-based. *Dialysis adequacy — MODERATE* for uraemic pericarditis.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| NSAID, ibuprofen or high-dose aspirin, with gastroprotection | First-line; relieves pain in the large majority within days | yes, both | yes | €2–20 a course. UNICEF indicative price October 2026 for ibuprofen 400 mg: US$2.23 on one page and US$1.43 on another |
| Colchicine 0.5 mg once or twice daily, three months for a first episode or six for recurrent disease | Recurrence 37.5 down to 16.7 per cent, number needed to treat about 5, ICAP; CORP and CORP-2 similar | yes | yes | tens of euro a course |
| Corticosteroids, prednisone, low dose | Effective for symptoms and associated with more recurrence; reserved for failure of NSAIDs and colchicine, autoimmune cause, or contraindication | yes | yes | a few to tens of euro a course |
| Anakinra, interleukin-1 receptor antagonist, recurrent disease | AIRTRIP, 21 patients: recurrence 18 against 90 per cent on placebo | no | no | tens of thousands of euro a year |
| Rilonacept, recurrent disease | RHAPSODY: recurrence hazard ratio 0.04 on treatment; flares after withdrawal | no | no | €200,000 and above a year, United States list price, year not stated in the source |
| Azathioprine or intravenous immunoglobulin, recurrent, steroid-sparing | Observational support | Azathioprine yes | Azathioprine yes | Azathioprine tens to hundreds of euro a year; immunoglobulin thousands to tens of thousands of euro a course |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Antituberculous therapy, tuberculous pericarditis | Curative; a six-month regimen of rifampicin, isoniazid, pyrazinamide and ethambutol | yes, all | yes | tens of euro a full course |
| Pericardiocentesis, tamponade | Immediately life-saving; relieves tamponade definitively for that episode | n/a | n/a | hundreds to thousands of euro with ultrasound guidance |
| Pericardial window or pericardiectomy | For recurrent effusion and for constriction; perioperative mortality 6 to 12 per cent for constriction | n/a | n/a | thousands to tens of thousands of euro |

Colchicine is the key fact. A plant-derived alkaloid in use for centuries, off-patent, on the Essential Medicines List, costing tens of euro a course, halves recurrence with a number needed to treat of about 5. The interleukin-1 blockers achieve a larger effect at tens of thousands to hundreds of thousands of euro and above a year, and the effect stops when they stop.

**Simple means.** Sitting forward relieves the pain of pericarditis; it is both a diagnostic feature and free symptom relief. Rest during the acute phase and avoiding strenuous exertion until inflammation settles is consensus. Aspirin or ibuprofen costs a few to tens of euro a course, is on the Essential Medicines List, off-patent, and first-line. Colchicine costs tens of euro a course with a number needed to treat of about 5 for preventing recurrence, and it is a tablet. Withholding corticosteroids in a first episode is a free decision that reduces recurrence.

Pericardiocentesis is one of the few immediately life-saving procedures in this chapter that needs almost no equipment: with a needle, a syringe and ideally ultrasound guidance, tamponade is relieved at the bedside. Historically it was done blind, subxiphoid, with high complication rates; ultrasound guidance reduces complications substantially and is now standard. A handheld ultrasound at thousands to tens of thousands of euro falling, makes it far safer. Auscultation and clinical recognition help: the pericardial friction rub is audible with a stethoscope in roughly a third of cases, and pulsus paradoxus and raised jugular venous pressure identify tamponade clinically with no equipment.

Antituberculous therapy costs tens of euro for a full six-month cure, with all four drugs on the Essential Medicines List and off-patent. In the region where pericarditis is most often fatal, the cure costs tens of euro and the constraint is diagnosis rather than drugs.

The hard limit. Distinguishing viral from tuberculous from malignant pericarditis requires at minimum chest imaging and often pericardial fluid analysis. Constriction requires surgery. An electrocardiogram and a stethoscope identify the syndrome and cannot identify the cause, and the cause determines whether the condition is self-limiting or fatal.

**Gaps.** No GBD global burden figure for pericarditis was retrieved, and this entry is part of the seventeen-condition gap in this chapter's introduction. In 80 to 90 per cent of cases no cause is identified and viral aetiology is presumed rather than demonstrated. Tuberculous pericarditis is 70 to 80 per cent of cases in sub-Saharan Africa and under 5 per cent in high-income countries — the same ICD entity with entirely different natural history and lethality — and most guideline evidence comes from the high-income presentation. IMPI gave a split result for steroids in tuberculous pericarditis: no effect on the primary composite, less constriction, more HIV-associated malignancy, and how to act on it is unresolved. Why recurrent pericarditis recurs is unexplained; the interleukin-1 response suggests autoinflammation and the mechanism is not established. Interleukin-1 blocker effects stop on withdrawal and optimal duration is unknown, and the trials are small at 21 and 61 patients. Incidence figures come essentially from one Italian study extrapolated widely. Progression to constriction cannot be predicted.

## Pulmonary hypertension (ICD-11 BB01)

**What it is.** The pressure in the arteries from the heart to the lungs rises. The right side of the heart has to push against it and eventually fails. Breathlessness on exertion comes first, then swelling and collapse.

**Measured.** No global prevalence, death or DALY figure for pulmonary hypertension was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all. Estimated global prevalence of pulmonary hypertension of all causes is roughly 1 per cent of the world population and up to 10 per cent of people over 65, from a 2016 review in Lancet Respiratory Medicine; that is a modelled estimate.

Pulmonary arterial hypertension, group 1, is rare: prevalence roughly 15 to 60 per million adults with an incidence of 5 to 10 per million a year, from the REVEAL, French and COMPERA registries. Group 2, from left heart disease, and group 3, from lung disease, together account for roughly 80 per cent or more of all pulmonary hypertension, which is the central epidemiological fact: the common forms are consequences of heart failure and chronic lung disease. Schistosomiasis-associated pulmonary arterial hypertension is probably the commonest cause of group 1 disease worldwide. At least 253.7 million people required preventive treatment for schistosomiasis in 2024, and a few per cent of those infected develop pulmonary hypertension. It is almost absent from the registries, which are European and North American. Chronic thromboembolic pulmonary hypertension has an incidence of roughly 3 to 5 per million a year and develops in roughly 3 per cent of pulmonary embolism survivors. Untreated median survival in pulmonary arterial hypertension was 2.8 years in the 1980s registry; with modern therapy, one-year survival is roughly 85 to 90 per cent and five-year roughly 55 to 65 per cent in registries. Idiopathic disease historically presented in young women with a mean age of about 36 in the early registry; contemporary registries show a mean age of 50 to 65 with a much weaker female predominance, a shift that is not fully explained.

**Where it starts.** Left heart disease, group 2 — heart failure with reduced or preserved ejection fraction, valve disease — is the commonest cause overall. Lung disease and hypoxia, group 3 — chronic obstructive pulmonary disease, interstitial lung disease, sleep-disordered breathing, high-altitude residence — is next. Chronic thromboembolic disease, group 4, follows roughly 3 per cent of pulmonary embolisms.

Group 1 causes. Heritable disease: BMPR2 mutations in roughly 70 to 80 per cent of familial cases and 10 to 20 per cent of sporadic idiopathic cases, with penetrance of roughly 20 per cent and lower in men. Connective tissue disease, of which systemic sclerosis is commonest, with pulmonary arterial hypertension in roughly 8 to 12 per cent of scleroderma patients. Congenital heart disease with an uncorrected shunt, giving Eisenmenger syndrome. Schistosomiasis. HIV, with a prevalence of roughly 0.5 per cent, orders of magnitude above background. Portal hypertension. Drugs and toxins: the appetite suppressants aminorex, fenfluramine and dexfenfluramine caused a well-documented epidemic, and dasatinib, interferon, methamphetamine and toxic rapeseed oil have been implicated. Chronic hypoxic pulmonary hypertension occurs in long-term high-altitude residents.

BMPR2 penetrance is roughly 20 per cent, so most carriers never develop disease and the second hit is unknown. Why idiopathic disease overwhelmingly affected young women in the early registries and now presents in older patients of both sexes is unexplained, and it is unclear how much is a change in the disease against a change in who gets investigated. The mechanism linking schistosomiasis to pulmonary vascular remodelling is not established. Whether treating group 2 and group 3 pulmonary hypertension with pulmonary vasodilators helps is not merely unknown but repeatedly shown to be harmful.

**Cure status.** Pulmonary arterial hypertension: RELIEF ONLY. Chronic thromboembolic pulmonary hypertension in operable cases: CURABLE by pulmonary endarterectomy. Group 2 and group 3 disease where the underlying cause is treatable: CONTROLLABLE.

No treatment removes the vascular remodelling in pulmonary arterial hypertension. Modern therapy improves exercise capacity and haemodynamics and, in combination and in meta-analysis, reduces mortality, and the disease progresses and transplantation remains the endpoint for many, with five-year survival of 55 to 65 per cent on treatment.

Pulmonary endarterectomy for chronic thromboembolic disease is genuinely curative in operable cases: pulmonary vascular resistance falls substantially and often normalises, perioperative mortality in expert centres is 2 to 5 per cent, and long-term survival approaches that of the general population in good surgical candidates. That is the one form of pulmonary hypertension with a surgical cure, and it is systematically under-diagnosed, so all pulmonary hypertension patients should be screened for it. Balloon pulmonary angioplasty treats inoperable distal disease with substantial haemodynamic improvement.

In group 2 and group 3, treating the underlying heart or lung disease is the therapy, and pulmonary vasodilators are not indicated and can worsen outcomes. A correctable congenital shunt closed before irreversible remodelling prevents the condition; once Eisenmenger physiology is established, closure is harmful. Lung or heart-lung transplantation for end-stage disease gives five-year survival of roughly 50 to 60 per cent.

**Prevention.**

*Withdrawal of appetite-suppressant drugs — STRONG, historically demonstrated.* The aminorex epidemic in Europe in the 1960s and the fenfluramine epidemic in the 1990s both rose and fell with the drugs' availability. That is a clear, measured prevention by withdrawing a product.

*Early repair of congenital shunts — STRONG* for preventing Eisenmenger syndrome. *Treating left heart disease and chronic obstructive pulmonary disease — STRONG* for preventing groups 2 and 3.

*Schistosomiasis control — MODERATE* in endemic areas: praziquantel mass treatment, snail control, water and sanitation. Praziquantel costs under one euro a treatment, is on the Essential Medicines List in sections 6.1.1, 6.1.3 and 6.1.4†, and is off-patent. Coverage in 2024 was 39.6 per cent globally and 61.7 per cent of school-aged children requiring preventive chemotherapy, with at least 93.9 per cent of those needing treatment living in Africa.

*Anticoagulation after pulmonary embolism and follow-up for persistent breathlessness — MODERATE* for preventing and detecting chronic thromboembolic disease, which develops in about 3 per cent.

*Screening in systemic sclerosis — MODERATE.* Annual echocardiography and the DETECT algorithm identify disease earlier, and earlier treatment is associated with better survival.

*Antiretroviral therapy in HIV — MODERATE*. *Oxygen in chronic hypoxaemia — MODERATE* for limiting hypoxic pulmonary vasoconstriction. *Genetic counselling in BMPR2 families — MODERATE* for information rather than prevention, given penetrance of about 20 per cent.

*Nothing prevents idiopathic pulmonary arterial hypertension.*

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Pulmonary endarterectomy, chronic thromboembolic disease | Curative; perioperative mortality 2 to 5 per cent in expert centres | n/a | n/a | tens of thousands of euro |
| Balloon pulmonary angioplasty, inoperable chronic thromboembolic disease | Substantial haemodynamic improvement | n/a | n/a | tens of thousands of euro across sessions |
| Sildenafil or tadalafil, phosphodiesterase-5 inhibitor | SUPER-1, sildenafil, 278 patients: six-minute walk distance up 45 m at 20 mg three times daily; haemodynamics improved | **Sildenafil is NOT on the 24th Model List in any form** | yes, and this matters | tens to hundreds of euro for generic sildenafil; branded pulmonary formulations far higher |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Bosentan, ambrisentan or macitentan, endothelin receptor antagonists | BREATHE-1, bosentan: six-minute walk distance up 44 m. SERAPHIN, macitentan, 742 patients: morbidity and mortality composite hazard ratio 0.55, one of the few event-driven positive trials | **Bosentan is NOT on the 24th Model List in any form** | Bosentan: generic available | Generic bosentan thousands of euro; macitentan tens of thousands to hundreds of thousands of euro |
| Riociguat, soluble guanylate cyclase stimulator | PATENT-1: six-minute walk distance up 36 m. CHEST-1: the only drug approved for inoperable chronic thromboembolic disease, walk distance up 46 m | no | no | tens of thousands of euro |
| Epoprostenol, intravenous prostacyclin | The only therapy with a demonstrated mortality benefit in a single randomised trial: Barst and colleagues, 1996, 81 patients, 8 deaths in the conventional arm and none in the epoprostenol arm | no | yes, generic epoprostenol exists | €30,000–150,000 including pump and line care |
| Treprostinil, iloprost, selexipag, prostacyclin pathway | GRIPHON, selexipag, 1,156 patients: morbidity and mortality composite hazard ratio 0.60 | no | no | tens of thousands to hundreds of thousands of euro |
| Upfront combination therapy | AMBITION, 500 patients, ambrisentan with tadalafil against monotherapy: clinical failure hazard ratio 0.50 | — | partly | Varies |
| Sotatercept, activin signalling inhibitor | STELLAR, 323 patients: six-minute walk distance up 40.8 m against placebo; the first new mechanism in years | no | no | €240,000 a year, United States list price, year not stated in the source |
| Calcium channel blockers, in the 5 to 10 per cent of patients who are acute vasodilator responders | In true responders, long-term survival is substantially better, and nifedipine, diltiazem and amlodipine are the treatment | yes | yes | a few to tens of euro |
| Diuretics, oxygen, anticoagulation | Supportive; diuretics for right heart failure | yes, furosemide and warfarin | yes | a few to tens of euro |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Pulmonary vasodilators in group 2 or group 3 disease | Harmful or neutral. Sildenafil in heart failure with preserved ejection fraction and in pulmonary fibrosis: no benefit; STEP-IPF null; riociguat in group 3, RISE-IIP, was stopped for increased mortality | — | — | — |
| Lung or heart-lung transplantation | Five-year survival 50 to 60 per cent | n/a | n/a | hundreds of thousands of euro in the first year |

Two cheap, off-patent drugs matter disproportionately. First, calcium channel blockers in the 5 to 10 per cent of patients who are genuine acute vasodilator responders produce substantially better long-term survival at a few to tens of euro a year — and identifying those patients requires right heart catheterisation with acute vasodilator testing. Second, generic sildenafil at tens to hundreds of euro a year delivers the phosphodiesterase-5 inhibitor effect at a fraction of the branded price and is the realistic option in most of the world. Everything else in this entry costs tens of thousands to hundreds of thousands of euro a patient-year.

**Simple means.** Praziquantel for schistosomiasis is the highest-value simple intervention here, given that schistosomiasis-associated disease may be the commonest form of pulmonary arterial hypertension worldwide. It costs under one euro a treatment, is on the Essential Medicines List, off-patent, and is a single oral dose — and it is mass drug administration rather than individual care.

Avoiding pregnancy is the most consequential piece of free advice in the entry: maternal mortality in pulmonary arterial hypertension is roughly 10 to 25 per cent, and contraception counselling is a free intervention with a very large effect.

Exercise training deserves a direct comparison. Supervised rehabilitation improves six-minute walk distance by roughly 50 to 100 m in randomised trials, which is comparable to or larger than the drug effects of plus 36 to plus 46 m, at a tiny fraction of the cost. A training programme matches a tens of thousands of euro drug on the walk-distance endpoint. It does not replace the drugs for survival, which has not been tested.

Supplemental oxygen in chronic hypoxaemia reduces hypoxic vasoconstriction; see the chronic obstructive pulmonary disease entry for the concentrator-against-cylinder comparison. Diuretics for right heart failure: furosemide at a few to tens of euro a year, listed, off-patent and indispensable for congestion. Avoiding high altitude and unpressurised flight in significant disease is behavioural and free. Recognising the condition — breathlessness on exertion with a loud pulmonary second sound, raised jugular venous pressure and peripheral oedema — needs a stethoscope and the eyes; confirmation requires echocardiography and ultimately right heart catheterisation.

The hard limit, stated plainly. Pulmonary arterial hypertension cannot be diagnosed without echocardiography and right heart catheterisation, and it cannot be treated without drugs costing tens of thousands to hundreds of thousands of euro a year, except generic sildenafil and, in the responder minority, calcium channel blockers. Chronic thromboembolic disease, the one curable form, requires a specialist surgical centre of which there are perhaps a few dozen in the world. For most of the world's patients with pulmonary arterial hypertension, no effective treatment is accessible at any price they can pay.

**Gaps.** No GBD global burden figure for pulmonary hypertension was retrieved, and this entry is part of the seventeen-condition gap in this chapter's introduction; the figure of 1 per cent of the world population is a modelled estimate from a single review. The registries are European and North American, and if schistosomiasis-associated disease is the commonest form worldwide then the entire evidence base describes a minority of the disease; that is the largest gap in the entry. The age and sex shift in idiopathic disease, from young women to older patients of both sexes, is unexplained. BMPR2 penetrance is about 20 per cent and the second hit is unknown. Almost all trials use six-minute walk distance, a sur-

rogate; only epoprostenol, in an 81-patient trial from 1996, has a mortality benefit from a single randomised trial, and SERAPHIN and GRIPHON used composite morbidity-mortality endpoints, so a mortality benefit for most of these drugs is not demonstrated. Riociguat in group 3 increased mortality in RISE-IIP and sildenafil in pulmonary fibrosis and in heart failure with preserved ejection fraction was null; vasodilators are harmful outside group 1 and that is widely under-appreciated. Chronic thromboembolic disease is systematically under-diagnosed and it is the only curable form. Prices of tens of thousands to hundreds of thousands of euro a year for drugs with surrogate endpoints make cost-effectiveness a live and unresolved dispute in every health system. Exercise training matches the drug effects on walk distance and has never been compared with drugs on survival. Neither sildenafil nor bosentan is on the 24th Model List in any form, and any claim otherwise is wrong.

## Cardiac arrest (ICD-11 MC82)

**What it is.** The heart stops pumping. The person collapses, stops breathing normally and loses consciousness within seconds. Brain damage begins within minutes and death follows unless the circulation is restarted.

**Measured.** No GBD global cardiac arrest figure exists; it is a mode of death counted under its causes, chiefly ischaemic heart disease. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

In the United States there are more than 350,000 out-of-hospital cardiac arrests a year, and the 2023 American Heart Association statistics report gives over 356,000. Survival to hospital discharge is 9.1 per cent for all emergency-service-treated non-traumatic out-of-hospital arrests in adults, on 2021 United States data. Bystander cardiopulmonary resuscitation is performed in 40.2 per cent of out-of-hospital arrests. Immediate resuscitation can double or triple the chance of survival. One figure needs care: the 436,852 deaths for 2020 on the same page cover any mention of sudden cardiac arrest on a death certificate, not out-of-hospital arrest alone, and the two are frequently conflated.

Global estimates put out-of-hospital incidence at roughly 30 to 97 per 100,000 person-years depending on registry and inclusion criteria, with survival to discharge ranging from under 1 per cent to over 20 per cent between regions and systems — a twentyfold range. In-hospital arrest has an incidence of roughly 1 to 6 per 1,000 hospital admissions, with survival to discharge of roughly 20 to 25 per cent, higher than out-of-hospital because of witnessed onset and immediate response. A shockable initial rhythm — ventricular fibrillation or pulseless ventricular tachycardia — is present in roughly 20 to 25 per cent of out-of-hospital arrests now, down from 60 to 70 per cent in the 1980s. Survival in that group is far higher, roughly 25 to 40 per cent with prompt defibrillation, than in asystole or pulseless electrical activity, at roughly 2 to 5 per cent. Survival falls roughly 7 to 10 per cent for every minute without resuscitation or defibrillation. Neurologically intact survival is roughly 7 to 8 per cent of all emergency-service-treated arrests, slightly below survival to discharge.

**Where it starts.** Coronary artery disease is the underlying cause in roughly 70 to 80 per cent of adult out-of-hospital arrests, with acute infarction or ischaemia the immediate trigger in a large share. Cardiomyopathy — hypertrophic, dilated, arrhythmogenic — is the dominant cause in the young, as are the inherited channelopathies. Congenital coronary anomalies, myocarditis and aortic stenosis contribute. Non-cardiac causes account for roughly 20 to 35 per cent of out-of-hospital arrests: respiratory arrest, drowning, trauma, haemorrhage, overdose and notably opioids, hypoxia, electrolyte disturbance, pulmonary embolism, tension pneumothorax, hypothermia and anaphylaxis. In children the dominant causes are respiratory — hypoxia from airway obstruction, drowning, asthma, bronchiolitis and sepsis — which is why rescue breaths matter more in paediatric arrest than in adult arrest, and the guidelines differ for that reason. The INTERHEART and INTERSTROKE risk factors apply by way of coronary disease. Sudden arrhythmic death syndrome, with a morphologically normal heart at autopsy, is roughly 4 to 10 per cent of sudden cardiac deaths and higher in the young.

The timing of a cardiac arrest is not predictable even with full knowledge of the coronary anatomy and ejection fraction, and that is the central unsolved problem. Most sudden cardiac deaths occur in people who would not have met criteria for a defibrillator: the majority happen in the large population at moderate risk rather than the small population at high

risk, which is why population-level risk stratification has not reduced total sudden death much. Why the proportion of shockable initial rhythms has fallen from 60 to 70 per cent to 20 to 25 per cent over four decades is not fully explained; longer call-to-arrival times, changing substrate, more beta blockade and more reperfusion are all proposed. In sudden arrhythmic death syndrome no cause is found at all.

**Cure status.** All-comers, any rhythm, any setting: RELIEF ONLY. Witnessed arrest with a shockable rhythm, bystander resuscitation and early defibrillation: CURABLE.

RELIEF ONLY describes cardiac arrest as it is encountered: 9.1 per cent survive to discharge and 7 to 8 per cent survive neurologically intact, and nothing removes the predisposition. CURABLE describes the witnessed, shockable, bystander-resuscitated, early-defibrillated stratum, where survival reaches 40 to 60 per cent in the best-performing systems and a survivor with an intact brain and a treated cause is cured of the arrest.

The variation between those two is almost entirely in the system rather than the disease. Survival in the favourable subgroup reaches 40 to 60 per cent in Seattle, North Holland and parts of Scandinavia — the same condition, a five- to sixtyfold difference in outcome depending on the response.

Reversing the cause cures it: primary percutaneous intervention for the infarction that caused the arrest, and an implantable defibrillator for a recurring arrhythmic substrate, where the secondary prevention trials AVID, CIDS and CASH reduced mortality roughly 20 to 30 per cent against antiarrhythmic drugs. On temperature, both results must be printed: HACA and the Bernard trial in 2002 showed benefit at 32 to 34 °C, and TTM2, with 1,900 patients in 2021, found hypothermia at 33 °C gave no mortality benefit against normothermia with fever avoidance, hazard ratio 1.04. Practice has shifted to fever avoidance. No neuroprotective drug has ever been shown to work; every trial has failed.

**Prevention.**

*Treating coronary disease — STRONG*, and quantitatively the largest lever, since 70 to 80 per cent of arrests arise from it. All the measures in the ischaemic heart disease entry apply: statins at a relative risk of 0.78 per mmol/L of LDL reduction, blood pressure lowering at 0.80 per 10 mmHg, smoking cessation at an adjusted hazard ratio of 0.56.

*Bystander resuscitation training at population scale — STRONG.* Denmark and Norway roughly doubled or tripled bystander resuscitation rates and survival over ten to fifteen years through mandatory school and driving-licence training plus dispatcher-assisted resuscitation, and Danish survival rose from roughly 3.5 to 10 to 16 per cent. That is the clearest demonstration that cardiac arrest survival is a function of population training rather than technology.

*Public access defibrillation — STRONG.* The PAD trial, across 993 community units with 19,000 volunteers, found survival doubled with resuscitation plus an automated external defibrillator against resuscitation alone, 30 against 15 survivors. Defibrillation within three to five minutes yields survival of 50 to 70 per cent.

*Dispatcher-assisted telephone resuscitation — STRONG.* It raises bystander resuscitation rates substantially at essentially no cost, and meta-analyses show improved survival.

*Beta blockers after myocardial infarction — STRONG historically*, about a 20 to 25 per cent mortality reduction with much of it sudden death, and *questioned in the reperfusion era with preserved ejection fraction*, since REDUCE-AMI was null.

*Implantable defibrillator for primary prevention — STRONG in ischaemic cardiomyopathy, CONTESTED in non-ischaemic.* SCD-HeFT hazard ratio 0.77, number needed to treat 14 over five years; DANISH null in non-ischaemic cardiomyopathy.

*Drowning prevention, opioid overdose response with naloxone, choking first aid — STRONG* for the non-cardiac causes. Drowning kills about 300,000 people a year worldwide, with 92 per cent of deaths in low- and middle-income countries.

*Family screening after a sudden death in a young person — MODERATE*: a diagnosis is found in 20 to 50 per cent of first-degree relatives. *Athletic pre-participation screening — CONTESTED*.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Bystander resuscitation | Doubles to triples survival; performed in only 40.2 per cent of United States arrests | n/a | n/a | Nothing |
| Early defibrillation | Survival 50 to 70 per cent if within three to five minutes; falls 7 to 10 per cent a minute of delay. PAD trial: survival doubled with a defibrillator added to resuscitation | n/a | n/a | Automated external defibrillator hundreds to thousands of euro |
| Adrenaline 1 mg intravenously | PARAMEDIC2, 8,014 patients: 30-day survival 3.2 against 2.4 per cent, odds ratio 1.39, a real but small benefit; favourable neurological outcome 2.2 against 1.9 per cent, not significantly different; severe neurological impairment more common among survivors, 31 against 18 per cent. Number needed to treat about 112 for 30-day survival | yes | yes | a few euro a dose |
| Amiodarone or lidocaine, shock-refractory fibrillation | ALPS, 3,026 patients: survival to admission improved; no significant difference in survival to discharge or neurological outcome | yes, both | yes | a few to tens of euro a dose |
| Airway management: bag-mask, supraglottic airway, intubation | AIRWAYS-2 and PART: supraglottic airway and tracheal intubation gave broadly similar outcomes, with no clear superiority | n/a | n/a | Bag-mask tens of euro; supraglottic airway a few to tens of euro |
| Targeted temperature management | HACA and Bernard positive at 32 to 34 °C; TTM2, 1,900 patients, found no benefit of 33 °C over normothermia with fever avoidance, hazard ratio 1.04 | n/a | n/a | Cooling device tens of thousands of euro; ice packs and cold saline cost almost nothing |
| Primary percutaneous intervention after arrest with ST elevation | Strongly beneficial; COACT and TOMAHAWK found no benefit of immediate angiography in arrest without ST elevation | n/a | n/a | thousands to tens of thousands of euro |
| Extracorporeal resuscitation | ARREST, 30 patients, and Prague OHCA suggested benefit in highly selected refractory arrest; INCEPTION, 134 patients, found no benefit. Unresolved | n/a | n/a | tens of thousands to hundreds of thousands of euro |
| Secondary prevention defibrillator | AVID, CIDS and CASH: mortality reduced about 20 to 30 per cent against antiarrhythmic drugs | n/a | n/a | tens of thousands of euro |
| Mechanical chest compression devices | LINC and PARAMEDIC: no better than manual compressions | n/a | n/a | tens of thousands of euro |
| Sodium bicarbonate, calcium, high-dose adrenaline, vasopressin, atropine | All removed from routine algorithms for lack of benefit | Varies | yes | — |

The pattern in that table is striking. The two interventions with by far the largest effects — resuscitation and early defibrillation — are the two that cost almost nothing, and every drug and device added on top has a small, absent or unproven effect. Adrenaline's number needed to treat is about 112 for 30-day survival with no clear neurological benefit; mechanical compression devices, extracorporeal resuscitation beyond selected cases, and almost every drug have failed to improve neurologically intact survival.

**Simple means.** This is the entry where simple means dominate completely.

Bystander resuscitation with no equipment at all doubles to triples the chance of survival. It requires two hands and the knowledge to use them, and it is performed in only 40.2 per cent of United States out-of-hospital arrests, so the majority of the available benefit is currently unrealised. Compression-only resuscitation is as good as compression plus rescue breathing for adult out-of-hospital arrest of cardiac cause, from the randomised dispatcher trials SOS-KANTO, Rea and Svensson and from meta-analysis; that removes the mouth-to-mouth barrier that deterred bystanders and is why guidelines now teach hands-only resuscitation to the public. For children, drowning and asphyxial arrest, rescue breaths should be included, because the cause is hypoxic. The technique is the centre of the chest, at least 5 cm deep, 100 to 120 compressions a minute, allowing full recoil and minimising interruptions.

Dispatcher-assisted resuscitation over the telephone, where the call-taker talks the bystander through compressions, raises bystander resuscitation rates substantially and improves survival, and it costs nothing beyond training the dispatchers. Population resuscitation training raised Danish survival from roughly 3.5 to 10 to 16 per cent, chiefly through mandatory school and driving-licence training and dispatcher resuscitation. That is a teaching programme rather than a technology.

Recognising cardiac arrest is unresponsiveness and not breathing normally. Agonal gasping is commonly mistaken for breathing and is the main reason bystanders fail to start resuscitation. Teaching that agonal breathing means start compressions is free and changes outcomes.

An automated external defibrillator costs hundreds to thousands of euro and is usable by an untrained person following voice prompts. Defibrillation within three to five minutes gives survival of 50 to 70 per cent against 9.1 per cent overall. It is the one piece of equipment that genuinely changes the outcome and it requires no medical training.

Fever avoidance after resuscitation can be achieved with ice packs, cold fluids, fans and antipyretics; TTM2 found normothermia with fever avoidance equivalent to cooling at 33 °C, so the tens of thousands of euro cooling device is not required by the current evidence. Naloxone for opioid-overdose arrest costs a few to tens of euro a dose, is listed, off-patent, and can be given intranasally or intramuscularly by a bystander; for that subgroup it is the specific cure. Choking first aid — back blows, abdominal thrusts — and drowning rescue are free techniques for the asphyxial causes.

The honest summary: of everything in this entry, the interventions with the largest measured effects require no industrial supply chain at all — recognising the arrest, compressing the chest, and with a single inexpensive device delivering a shock. The twentyfold variation in survival between regions is explained mainly by how many bystanders act and how fast a defibrillator arrives, not by the drugs or the intensive care that follow.

**Gaps.** No GBD global cardiac arrest figure exists, because the condition is counted under its causes, so global burden is not directly measured; this entry is part of the seventeen-condition gap in this chapter's introduction. Survival ranges from under 1 per cent to over 20 per cent between regions, a twentyfold spread. How much of that is true outcome difference and how much is denominator definition — which arrests are counted, whether unwitnessed and non-attempted resuscitations are included — is unresolved. The Utstein template was created to fix this and compliance remains partial. The 436,852 sudden cardiac arrest deaths for 2020 and the 356,000 out-of-hospital arrests are different quantities and are frequently conflated. Adrenaline improves 30-day survival, 3.2 against 2.4 per cent, without clearly improving neurological outcome, and severe neurological impairment was commoner among survivors, 31 against 18 per cent; whether that is a net benefit is genuinely contested. TTM2 overturned targeted hypothermia; guidelines changed and practice lags, and both are printed. Extracorporeal resuscitation is unresolved: ARREST and Prague positive, INCEPTION null. Immediate angiography in arrest without ST elevation: COACT and TOMAHAWK both null, against prior practice. Why shockable initial rhythms fell from 60 to 70 per cent to 20 to 25 per cent over four decades is unexplained. Most sudden cardiac deaths occur outside any current high-risk criteria, so defibrillator-based prevention cannot address the bulk of the problem, and that structural limit is rarely stated. No neuroprotective drug has ever worked. Registry data from Africa, south Asia and most of Latin America barely exist, and the global incidence range of 30 to 97 per 100,000 rests on high-income registries.

# Chapter 12 — Diseases of the respiratory system

## The obstructed airway

### Chronic obstructive pulmonary disease (ICD-11 CA22)

**What it is.** The airways are permanently narrowed and the air sacs are destroyed, so air cannot be pushed out. Breathlessness builds over years and never fully reverses. Smoke is the main cause — tobacco in rich countries, cooking fires in poor ones.

**Measured.** Deaths in 2023: about 3.4 million, approximately 6 per cent of all global deaths, the third leading cause of death worldwide and the seventh leading cause of poor health measured in DALYs, from the WHO fact sheet of 10 June 2026 carrying 2023 data. WHO's top-ten causes page, dated 2 October 2026, gives 3.6 million for the same year. GBD 2021 gives 3.72 million (3.36–4.09), rank 4, with an age-standardised death rate of 45.2 per 100,000. All three are printed.

DALYs in 2023: 74.9 million (66.2–86.9), rank 7 of all causes; GBD 2021 gave 79.8 million, rank 6. YLDs in 2023: 15.0 million (12.6–17.6), rank 19. Nearly 90 per cent of deaths in people under 70 occur in low- and middle-income countries.

The WHO fact sheet gives no global prevalence figure at all. GBD 2019 estimated roughly 212 million prevalent cases, and the BOLD study found airflow obstruction at GOLD stage II or worse in roughly 10 per cent of adults over 40 across twelve countries. The condition is rare before 40 and prevalence and mortality rise steeply thereafter. Age-standardised mortality is falling while absolute deaths are roughly flat to rising with ageing, and the condition has moved from rank 4 to rank 3 among causes of death. It is substantially under-diagnosed: roughly 60 to 85 per cent of cases in population studies have no prior diagnosis.

**Where it starts.** Tobacco smoking accounts for over 70 per cent of cases in high-income countries and 30 to 40 per cent in low- and middle-income countries. That single sentence is the key epidemiological fact: the majority of the disease in poorer countries is not from tobacco.

Household air pollution is named a major risk factor in low- and middle-income countries on the COPD fact sheet, without a quantified share. The household air pollution fact sheet quantifies it: the condition is 19 per cent of the 2.9 million deaths attributed to household air pollution, and household air pollution causes 23 per cent of adult COPD deaths in low- and middle-income countries, with 2.1 billion people still cooking with solid fuels or kerosene. Ambient air pollution: the condition is 14 per cent of the 4.2 million premature deaths attributed to it.

Occupational exposure to dusts, fumes and chemicals is listed as a cause without a quantified contribution on the WHO page; population-attributable estimates put roughly 14 to 15 per cent of the disease down to occupational exposures. Early-life factors matter more than was long assumed: low birthweight, childhood respiratory infections, childhood asthma and impaired lung growth. A substantial proportion of the disease arises from never reaching normal peak lung function rather than from accelerated decline — roughly half of cases in three cohorts had low baseline FEV1 with normal decline, from a 2015 New England Journal of Medicine analysis. That reframes the condition as partly developmental and is a relatively recent finding. Alpha-1 antitrypsin deficiency accounts for roughly 1 to 2 per

cent of cases, with PiZZ homozygote prevalence of roughly 1 in 2,000 to 5,000 in European-ancestry populations. Post-tuberculous lung damage is a major contributor in high-incidence countries, with odds ratios of roughly 2 to 4 for airflow obstruction. Asthma, HIV, biomass and coal smoke, and chronic bronchitis in non-smokers all contribute.

Only a minority of smokers develop clinically significant disease — roughly 25 to 50 per cent depending on definition and follow-up† — and why those individuals and not others is not explained by any known genetic or environmental factor. The susceptibility question is the central unsolved problem. The relative contributions of impaired lung growth and accelerated decline are still being apportioned. Whether the exacerbation-prone phenotype is a stable trait or a statistical artefact of regression to the mean is debated. The non-smoking disease that dominates in low-income countries is far less studied than tobacco disease, and whether it responds the same way to treatment is largely untested.

**Cure status.** CONTROLLABLE — and more precisely, nothing reverses the airflow obstruction.

By definition the obstruction is not fully reversible, and no drug restores destroyed alveoli or normalises FEV1. Smoking cessation is the only intervention shown to slow the rate of FEV1 decline: the Lung Health Study, with 5,887 participants over eleven years, showed sustained quitters lost FEV1 at roughly half the rate of continuing smokers, about 31 against 62 mL a year in men. It does not recover lost function; it changes the slope.

Long-term oxygen therapy is the only treatment other than smoking cessation shown to prolong survival in hypoxaemic disease. Lung volume reduction surgery in selected upper-lobe-predominant emphysema with low exercise capacity gave a survival benefit in that subgroup in the NETT trial of 1,218 patients, and harm in those with very low FEV1 and homogeneous disease; it removes destroyed tissue to let the remainder work and does not cure. Lung transplantation gives median survival of roughly 6 to 7 years post-transplant and replaces the organ. Alpha-1 antitrypsin augmentation slows emphysema progression on computed tomographic density in the RAPID trial in that 1 to 2 per cent subgroup, and does not reverse disease.

**Prevention.**

*Tobacco control — STRONG, and the dominant measure where tobacco dominates.* Smoking accounts for over 70 per cent of high-income-country disease. Tobacco kills more than 7 million people a year with over 1.6 million second-hand-smoke deaths among non-smokers, and there are 1.2 billion tobacco users, around 80 per cent of them in low- and middle-income countries. Counselling and medication can more than double quit success, and cessation services with full or partial cost coverage exist in 31 countries. A 10 per cent price rise reduces consumption by roughly 4 to 5 per cent, and 41 countries covering 12 per cent of the world's population tax at least 75 per cent of retail price. Smoking cessation halves the rate of FEV1 decline.

*Clean cooking fuel and improved ventilation — STRONG on attributable burden, WEAK on randomised prevention evidence, and both must be printed.* Household air pollution causes 23 per cent of adult COPD deaths in low- and middle-income countries, with 2.1 billion people exposed. Only 78 per cent of the world is projected to have clean cooking access by 2030, leaving about 1.8 billion without, and 923 million people in sub- Saharan Africa lacked access in 2022. Against that: the randomised stove-intervention trials have largely failed to show the expected respiratory benefits. RESPIRE, in Guatemala with chimney stoves, missed its primary pneumonia endpoint; HAPIN, across 3,200 households with liquefied petroleum gas stoves, verified a 66 per cent reduction in fine particulate exposure and missed its primary birth-weight endpoint; CAPS, in Malawi, found no reduction in childhood pneumonia. The most-cited explanation is that the interventions did not reduce exposure far enough to cross the steep part of the exposure-response curve, and that is plausible and unproven. The attributable burden is graded STRONG and the randomised evidence for stove interventions WEAK. This is one of the most important honest disagreements in the chapter.

*Outdoor air quality standards — STRONG on burden, MODERATE on policy effect.* In 2019, 99 per cent of the world's population lived above WHO guideline levels, and the condition is 14 per cent of the 4.2 million ambient air pollution deaths. Natural-experiment studies — the Dublin coal ban, the Utah Valley steel mill closure, the Beijing Olympics — showed

measured falls in respiratory mortality and morbidity; these are quasi-experimental rather than randomised.

*Occupational dust and fume control — STRONG*, with roughly 14 to 15 per cent of the disease attributable to occupational exposure.

*Smoking cessation in established disease — STRONG*, and it is the only disease-modifying intervention.

*Tuberculosis control — MODERATE* in high-incidence settings.

*Influenza and pneumococcal vaccination — MODERATE* for preventing exacerbations and hospitalisation, not for preventing the disease itself; influenza vaccination reduces exacerbations per Cochrane.

*Childhood measures — MODERATE*: avoiding second-hand smoke, treating childhood respiratory infection, breastfeeding, reducing preterm birth, all acting on the lung-growth pathway.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Smoking cessation | Halves the rate of FEV1 decline, Lung Health Study; the only disease-modifying therapy | Nicotine replacement, bupropion and varenicline yes | yes | Nicotine replacement hundreds of euro; generic varenicline tens to hundreds of euro |
| Long-term oxygen therapy, 15 hours a day or more, in chronic hypoxaemia | The MRC trial, 87 hypercapnic patients with arterial oxygen tension 40 to 55 mmHg on more than 15 hours a day: three-year mortality 45.2 against 66.7 per cent without oxygen, **number needed to treat about 5 over three years to prevent one death**. NOTT, 203 patients: continuous oxygen, mean 18 hours a day, against nocturnal-only, 24-month mortality 27 against 41 per cent. This is the largest survival effect of any treatment in this condition. It does not benefit patients with moderate or exertional-only desaturation: the LOTT trial, 738 patients, was null | yes, oxygen | yes | Concentrator hundreds to thousands of euro one-off plus hundreds of euro a year for electricity; cylinders thousands of euro a year |
| Short-acting bronchodilator, salbutamol or ipratropium | Symptom relief and rescue therapy; short-acting bronchodilators last 4 to 6 hours, and salbutamol is generally available in public primary care in less than two-thirds of low and low-middle income countries | yes, both | yes | tens of euro |
| Long-acting muscarinic antagonist, tiotropium | UPLIFT, 5,993 patients over four years: exacerbations reduced, relative risk 0.86, and quality of life improved; it did not slow FEV1 decline, which was its primary endpoint | yes, added 2017 | yes, generics available | €100–600 generic; branded higher |
| Long-acting beta-agonist, formoterol or salmeterol | Exacerbations reduced and symptoms improved | yes, formoterol | yes | tens to hundreds of euro |
| Long-acting beta-agonist with long-acting muscarinic antagonist | Superior to either alone for exacerbations; FLAME found indacaterol with glycopyrronium better than salmeterol with fluticasone, relative risk 0.89 | partly | partly | hundreds of euro |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Inhaled corticosteroid with long-acting beta-agonist | Exacerbations reduced in the frequent-exacerbator and high-eosinophil phenotype; pneumonia risk increased, TORCH 19.6 against 12.3 per cent. TORCH, 6,112 patients: all-cause mortality 12.6 against 15.2 per cent, p=0.052, missing significance | yes, beclometasone | yes | hundreds of euro |
| Triple therapy, inhaled corticosteroid with both long-acting bronchodilators | IMPACT, 10,355 patients: exacerbations reduced against dual therapy, all-cause mortality 1.2 against 1.8 per cent against the two bronchodilators. ETHOS, 8,588 patients: mortality 1.3 against 2.1 per cent. These are the first mortality signals in inhaled therapy for this condition, and both are secondary or post-hoc with incomplete vital-status follow-up, so both are contested | partly | partly | hundreds to thousands of euro |
| Pulmonary rehabilitation after an exacerbation | Hospital readmissions odds ratio 0.44 (95 per cent CI 0.21–0.91), 8 studies and 810 participants, moderate certainty; mortality odds ratio 0.68 (0.28–1.67), not significant, low certainty; St George’s Respiratory Questionnaire quality of life −7.80 points (−12.12 to −3.47), above the 4-point minimal important difference, high certainty; six-minute walk distance plus 62 m (38–86), high certainty. Twenty trials, 1,477 participants, Cochrane 2016. Newer trials showed smaller effects than earlier ones | n/a | n/a | hundreds to thousands of euro a programme |
| Azithromycin prophylaxis | Exacerbations reduced: 1.48 against 1.83 a year, hazard ratio 0.73, Albert and colleagues, 2011; hearing loss and resistance are the concerns | yes, section 6.2.2, Watch group | yes | tens to hundreds of euro |
| Roflumilast | Modest exacerbation reduction in severe disease with chronic bronchitis | no | yes | hundreds of euro |
| Non-invasive ventilation in acute hypercapnic exacerbation | Mortality reduced by roughly 50 per cent and intubation by roughly 60 per cent: Cochrane mortality relative risk 0.54, intubation 0.36, number needed to treat about 10 to prevent one death. One of the largest effects in acute respiratory care | n/a | n/a | Machine thousands of euro reusable for years |
| Systemic corticosteroids in exacerbation | Recovery shortened and treatment failure reduced, Cochrane odds ratio about 0.48; five days is as good as fourteen, per REDUCE | yes, prednisolone | yes | a few euro a course |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Antibiotics in exacerbation | Treatment failure reduced in moderate to severe exacerbations with purulent sputum, per Cochrane | yes, amoxicillin and doxycycline; amoxicillin is listed first-choice for COPD exacerbation | yes | a few to tens of euro a course |
| Lung volume reduction surgery or endobronchial valves | NETT: survival benefit in the upper-lobe, low-exercise-capacity subgroup; harm in low-FEV1 homogeneous disease | n/a | n/a | tens of thousands of euro |
| Alpha-1 antitrypsin augmentation | Slows computed tomographic lung density loss, RAPID, in the 1 to 2 per cent deficient subgroup | no | no | tens of thousands to hundreds of thousands of euro |
| Dupilumab | BOREAS and NOTUS, in type 2 inflammation with eosinophils at 300 or above: exacerbations reduced roughly 30 per cent, rate ratio about 0.70 — the first successful biologic in this condition | no | no | tens of thousands of euro |

The two interventions with a proven survival benefit are smoking cessation and oxygen. The first is free and the second costs hundreds to thousands of euro for a concentrator.

**Simple means.** Pulmonary rehabilitation is the single highest-value non-drug intervention in respiratory medicine, and it requires a trained supervisor and a chair rather than a gymnasium. Quality of life improves 7.8 points against a minimal important difference of 4, six-minute walk distance improves 62 m, both high-certainty, and readmissions fall with an odds ratio of 0.44, moderate certainty. Home-based and community programmes with minimal equipment — walking, sit-to-stand, step-ups, simple weights — achieve comparable results to gym-based programmes in randomised comparisons.

Smoking cessation halves the rate of FEV1 decline, about 31 against 62 mL a year, is the only disease-modifying intervention, and costs nothing in itself. Brief advice from a health worker alone raises quit rates by roughly 2 to 3 percentage points absolute per Cochrane, and combined with pharmacotherapy and support gives sustained quit rates of 10 to 25 per cent.

Breathing retraining is free and teachable in minutes. Pursed-lip breathing reduces dynamic hyperinflation and breathlessness immediately; diaphragmatic and paced breathing are taught in all rehabilitation programmes. Cochrane reviews of breathing exercises find improvements in six-minute walk distance of roughly 35 to 50 m and in dyspnoea scores, with low to moderate certainty. Forward-leaning with arms supported improves diaphragm mechanics and reduces breathlessness measurably.

Oxygen: concentrator against cylinder. A concentrator draws room air and separates nitrogen. It costs hundreds to thousands of euro once, lasts five to ten years, needs mains electricity at roughly 300 to 600 W or hundreds of euro a year, and filter changes; it delivers up to 5 to 10 L a minute continuously and never runs out while the power is on. A cylinder of compressed or liquid oxygen needs no electricity and is portable, and a standard cylinder at 2 L a minute lasts only hours, with the delivery logistics of refilling and transport costing thousands of euro a patient-year and dominating the expense. The MRC trial that proved oxygen prolongs life used a concentrator and provided no portable oxygen, and NOTT’s continuous group averaged eighteen hours a day and did use portable systems. For a static patient with reliable electricity a concentrator is far cheaper over time and is the appropriate choice; for settings without reliable power, cylinders are the only option and the recurring cost is high. Solar-powered and battery-buffered concentrators are being deployed in low-resource settings, and outcome data are not yet available. Fifteen hours a day is the threshold at which a survival benefit was demonstrated; below that no survival benefit has been shown, and LOTT found none for moderate desaturation at all.

Clean cooking measures that cost little or nothing — ventilation, chimneys, moving the fire outdoors, cooking with lids, drying fuel — reduce exposure. The randomised stove trials RESPIRE, HAPIN and CAPS did not show the expected respiratory benefit. The attributable burden and the trial failures are reported together.

Exercise and walking are the active ingredient of pulmonary rehabilitation. Weight management matters at both ends: obesity imposes a mechanical load, and low body mass index is an independent predictor of mortality in this condition. Non-invasive ventilation reduces mortality by roughly 50 per cent in acute hypercapnic exacerbation, Cochrane relative risk 0.54, and the machine costs thousands of euro and is reusable for years; it is the most cost-effective piece of respiratory equipment in acute care. The cheap drugs that matter: prednisolone at a few euro an exacerbation course, with five days as good as fourteen; amoxicillin or doxycycline at a few to tens of euro; salbutamol at tens of euro a year — all listed, all off-patent.

**Gaps.** Two WHO pages give 3.4 and 3.6 million deaths for 2023, and GBD 2021 gives 3.72 million; all three are printed. The WHO fact sheet gives no global prevalence figure. Estimates vary roughly twofold depending on whether spirometric or diagnosed-disease definitions are used, and on whether fixed-ratio or lower-limit-of-normal criteria are applied. The fixed FEV1/FVC below 0.70 criterion over-diagnoses in the elderly and under-diagnoses in the young. That is an unresolved definitional dispute and it changes prevalence substantially. Between 60 and 85 per cent of cases are undiagnosed in population studies, so all prevalence figures are model-dependent. The randomised clean-cooking trials failed while the attributable-burden estimates are large, and that is this chapter's most consequential evidence gap: a measure with a very large estimated burden and no randomised confirmation of benefit. No drug has been shown to slow FEV1 decline, and UPLIFT missed that endpoint. The mortality signals in IMPACT and ETHOS are secondary endpoints with incomplete vital-status ascertainment and are contested. TORCH missed significance for mortality at p=0.052 and is frequently cited as positive. Inhaled corticosteroids reduce exacerbations and increase pneumonia, TORCH 19.6 against 12.3 per cent, and the net effect by phenotype is still being worked out. The developmental and decline pathways are not yet apportioned, and that changes how prevention should be targeted. Why only 25 to 50 per cent of smokers develop the disease is unknown. Non-tobacco disease, which is the majority in low- and middle-income countries, is far less studied, and treatment-response data in that population are thin; almost all trial evidence comes from tobacco-smoking high-income populations. Pulmonary rehabilitation effects were smaller in newer trials than in older ones, and the mortality and readmission effects were heterogeneous, with $I^2$ of 59 and 77 per cent.

## Asthma (ICD-11 CA23)

**What it is.** The airways tighten, swell and fill with mucus in attacks, then open again. Wheezing, coughing and breathlessness come and go. It usually starts in childhood and most of it can be controlled with an inhaled steroid.

**Measured.** An estimated 363 million people had asthma in 2023, from the WHO fact sheet of 28 April 2026 carrying GBD 2023 data. Deaths: an estimated 442,000. YLDs in 2023: 14.1 million (8.80–20.3), rank 20 of all causes, against 10.2 million in GBD 2021. Asthma is the most common chronic disease among children, and the fact sheet gives no numerical figure for children. Most asthma deaths occur in low- and lower-middle-income countries, where the condition is often under-diagnosed and under-treated.

The central fact of global asthma care is an availability figure. In 2023, steroid inhalers were available in public primary health care facilities in fewer than half of low- and low-middle-income countries, and bronchodilators in fewer than two-thirds. The cheap drug that prevents death is absent from most public clinics in poor countries.

Onset is usually in childhood and prevalence is highest in children and adolescents, while deaths are concentrated in older adults. Reported prevalence is highest in high-income English-speaking countries, Latin America and parts of Africa, and mortality is inversely distributed — low prevalence and a high death rate in poor countries. Prevalence rose sharply in high-income countries from the 1960s to the 1990s and has plateaued or fallen since, and mortality has fallen substantially in countries with inhaled corticosteroid access, by roughly 50 to 70 per cent from the 1980s peaks in the UK, New Zealand and Australia.

**Where it starts.** Atopy — sensitisation to inhaled allergens including house dust mite, cat, dog, cockroach, Alternaria, and grass and tree pollen — underlies roughly 70 to 80 per cent of childhood asthma. Twin studies give a heritability of roughly 50 to 60 per cent, with over a hundred genome-wide association loci of which the strongest is at 17q21, around ORMDL3 and GSDMB, and which interacts with early-life rhinovirus infection. Early-life respiratory viral infection with respiratory syncytial virus or rhinovirus bronchiolitis is strongly associated with later asthma; causality is contested, and the MAKI trial of palivizumab prophylaxis in preterm infants reduced later wheeze, which supports a causal role for respiratory syncytial virus. Tobacco smoke exposure including in utero raises childhood asthma risk roughly 1.5- to twofold for maternal smoking in pregnancy. Air pollution: traffic-related pollution and nitrogen dioxide are associated with asthma incidence in children, with roughly 13 per cent of childhood asthma incidence attributed to traffic pollution in one global analysis. Obesity carries an odds ratio of roughly 1.5 to 2, and obese asthma responds less well to inhaled corticosteroids. Occupational asthma is roughly 10 to 15 per cent of adult-onset asthma, from isocyanates, flour, latex, enzymes, wood dust, persulfates and laboratory animals, and that subgroup is curable by removal from exposure if caught early.

One protective finding is unusually reproducible. Growing up on a traditional farm with livestock and unpasteurised milk roughly halves asthma and allergy risk, from PARSIFAL, GABRIELA and the Amish against Hutterite comparisons. Aspirin- and NSAID-exacerbated respiratory disease accounts for roughly 7 per cent of adult asthma. Paracetamol, antibiotics in infancy and caesarean delivery have reported associations that are all CONTESTED and plausibly confounded.

The hygiene and microbial-exposure hypothesis explains the farm effect and the epidemic rise in high-income countries plausibly and has not produced a preventive intervention that works: no primary prevention of asthma has ever been demonstrated in a randomised trial. Why the prevalence rose so steeply and then plateaued is unexplained. Asthma is not one disease: the type-2-high eosinophilic steroid-responsive and type-2-low neutrophilic or paucigranulocytic steroid-resistant phenotypes have different treatment responses, and the type-2-low group has almost no effective therapy. Why some children remit at puberty and others do not is not predictable.

**Cure status.** CONTROLLABLE. Occupational asthma, workers removed from exposure early: CURABLE in roughly a third (complete recovery). Childhood asthma remitting at adolescence: stays CONTROLLABLE, since relapse in adulthood is common.

Inhaled corticosteroids suppress airway inflammation and control symptoms, and airway inflammation and hyperresponsiveness return within weeks of stopping, so the state is held rather than removed. Two trials make the point clearly. START, with 7,241 patients on three years of early budesonide, improved control and reduced severe exacerbations and did not alter the natural history: post-treatment lung function and remission rates converged with placebo. CAMP, with 1,041 children on four to six years of budesonide, found no effect on lung-function growth or on asthma persistence after treatment stopped.

Occupational asthma is CURABLE by removal from exposure if done early: complete recovery occurs in roughly a third of workers removed early, and the probability falls sharply with duration of continued exposure after symptom onset. Early diagnosis and removal is therefore genuinely curative and delay forecloses it.

Natural remission occurs in roughly 30 to 60 per cent of children with asthma, who become symptom-free in adolescence; relapse in adulthood is common and airway hyperresponsiveness often persists subclinically. That is remission.

**Prevention.**

*No primary prevention of asthma has been demonstrated.* Allergen avoidance in infancy, maternal diet modification, probiotics and early allergen introduction — which prevents food allergy, as LEAP showed — have not prevented asthma in randomised trials.

*Inhaled corticosteroids to prevent exacerbations and death — STRONG, and the central fact of asthma care.* A case-control study found each additional canister of inhaled corticosteroid per year was associated with a 21 per cent lower rate of asthma death. Inhaled corticosteroids reduce severe exacerbations by roughly 40 to 55 per cent against placebo across trials.

*Avoiding short-acting beta-agonist monotherapy — STRONG.* Reliever-only treatment is associated with increased mortality; the New Zealand fenoterol epidemic of the 1970s and 1980s and the SMART trial, with 26,355 patients on salmeterol without an inhaled corticosteroid and excess respiratory deaths, established this. GINA no longer recommends reliever-only treatment at any severity.

*Tobacco control, including smoke-free homes and smoke-free pregnancy — STRONG* for reducing incidence and severity.

*Occupational exposure control — STRONG*, and it is the only clearly preventable subtype: eliminating or enclosing isocyanates, flour dust and latex reduces incidence markedly in industry cohorts.

*Air pollution reduction — MODERATE.* Roughly 13 per cent of childhood asthma incidence is attributed to traffic pollution, and natural experiments including the Atlanta Olympics road closures and the Utah Valley mill closure showed measured falls in asthma attacks and admissions.

*Influenza vaccination — MODERATE* for reducing exacerbations. *Weight loss in obese asthma — MODERATE*. *Breastfeeding — WEAK and CONTESTED* for asthma specifically.

*House dust mite avoidance measures — CONTESTED to negative.* Cochrane found no clear benefit of physical or chemical mite-control measures for asthma outcomes. That contradicts very widely given advice and is printed.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Inhaled corticosteroid, beclometasone or budesonide | The foundation. Severe exacerbations reduced roughly 40 to 55 per cent; each extra canister a year associated with 21 per cent lower asthma mortality | yes, both | yes | €10–60 at international generic prices; €100–400 in high-income retail, year not stated in the source for either price |
| Inhaled corticosteroid with formoterol as both maintenance and reliever, or as-needed in mild asthma | SYGMA 1 and 2 and Novel START: as-needed budesonide with formoterol reduced severe exacerbations by roughly 60 per cent against a reliever alone and was comparable to maintenance corticosteroid at a much lower steroid dose. This is now the preferred GINA approach at all severities | Both components yes | yes | tens to hundreds of euro |
| Short-acting beta-agonist, salbutamol | Rescue only; must not be used as monotherapy | yes | yes | a few to tens of euro |
| Long-acting beta-agonist added to an inhaled corticosteroid | Exacerbations reduced and control improved against the corticosteroid alone; never to be used without one | yes, formoterol | yes | tens to hundreds of euro |
| Long-acting muscarinic antagonist, tiotropium, as add-on | Modest FEV1 and exacerbation benefit in uncontrolled asthma | yes | yes | hundreds of euro |
| Leukotriene receptor antagonist, montelukast | Less effective than an inhaled corticosteroid; neuropsychiatric adverse effects led to a United States boxed warning in 2020 | no | yes | €20–150 |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Oral prednisolone for an exacerbation | Shortens the exacerbation and prevents relapse | yes | yes | a few euro a course |
| Intravenous magnesium sulfate in severe acute asthma | Hospital admission reduced in severe exacerbations, per Cochrane | yes, with the Model List restriction to eclampsia and severe pre-eclampsia | yes | a few euro a dose |
| Oxygen with spacer- or nebuliser-delivered salbutamol and ipratropium, acute care | Standard acute care; a spacer is as effective as a nebuliser for acute asthma in children and most adults, per Cochrane | yes | yes | Spacer a few to tens of euro |
| Omalizumab, anti-IgE | Exacerbations reduced roughly 25 to 40 per cent in allergic asthma | **NOT on the 24th Model List in any form** | Biosimilars emerging | tens of thousands of euro |
| Mepolizumab, benralizumab, reslizumab, anti-interleukin-5 | MENSA, mepolizumab: exacerbations reduced 47 to 53 per cent; oral steroid sparing in SIRIUS | no | no | tens of thousands of euro |
| Dupilumab, anti-interleukin-4 receptor alpha | QUEST, 1,902 patients: severe exacerbations reduced about 48 per cent, rate 0.46 against 0.87; FEV1 improved, with a larger effect at high eosinophil counts | no | no | tens of thousands of euro |
| Tezepelumab, anti-thymic stromal lymphopoietin | NAVIGATOR, 1,061 patients: exacerbations reduced 56 per cent, and effective irrespective of eosinophil count — the first biologic with benefit in type-2-low asthma | no | no | tens of thousands of euro |
| Allergen immunotherapy, subcutaneous or sublingual | Symptoms and medication use reduced in allergic asthma; Cochrane supports modest benefit, and a house dust mite sublingual tablet reduced exacerbations | no | partly | hundreds to thousands of euro |
| Bronchial thermoplasty | Modest symptom benefit; declining use | n/a | n/a | tens of thousands of euro |

The price asymmetry is the single most important economic fact in this chapter. An inhaled corticosteroid costing €10 to €60 a patient-year (international generic prices, year not stated in the source) prevents the great majority of asthma deaths and is absent from more than half of public primary care facilities in low- and low-middle-income countries. The biologics cost tens of thousands of euro a patient-year and address the small severe-asthma minority. Essentially all of the 442,000 annual asthma deaths are preventable with the cheap drug rather than the expensive ones.

**Simple means.** A spacer device is the clearest example in the chapter of an effective device that can be made from waste material. A plastic spacer, or a homemade spacer from a 500 mL plastic bottle, makes a metered-dose inhaler far more effective, and WHO's own asthma fact sheet names the homemade 500 mL bottle spacer. Randomised trials in children with acute asthma, by Zar and colleagues in South Africa and by Duarte and colleagues in

Brazil, found a homemade bottle spacer as effective as a conventional commercial spacer for salbutamol delivery. A spacer is as effective as a nebuliser for acute asthma, per Cochrane, and a nebuliser needs electricity while a spacer does not.

An inhaled corticosteroid costs €10 to €60 a patient-year at international generic prices (year not stated in the source), is listed and off-patent, and is associated with 21 per cent lower asthma mortality per extra canister a year. It requires a pharmaceutical chain, a very cheap one, and the barrier is procurement and policy rather than cost.

Written asthma action plans with self-management education are paper and teaching time. Cochrane finds self-management education with a written action plan reduces hospitalisations by roughly 36 to 40 per cent and emergency visits substantially.

Breathing retraining needs printing precisely. Cochrane's review of breathing exercises for asthma finds improved quality of life and reduced symptoms, with effects on quality-of-life scores exceeding the minimal important difference in several trials, and no consistent effect on lung function or exacerbations, at low to moderate certainty. Buteyko and Papworth methods reduce reliever use and improve symptom scores in small trials without changing underlying inflammation. Breathing retraining improves symptoms and reduces reliever use; it does not replace inhaled corticosteroids and does not prevent exacerbations.

Smoking cessation and smoke-free homes reduce severity and improve steroid responsiveness, since smokers respond less well to inhaled corticosteroids. Weight loss in obese asthma improves control and lung function. Removal from occupational exposure is curative in roughly a third if done early; it costs nothing medically, and it costs a job, which is the real barrier. Prednisolone and magnesium in acute attacks cost a few euro a course each, both listed and off-patent. Sitting upright, calm reassurance and pursed-lip exhalation during an attack are free and reduce the work of breathing. Avoiding known triggers — smoke, cold-air exertion without warm-up, NSAIDs in aspirin-exacerbated disease, beta blockers — is free, and the NSAID and beta-blocker avoidance is potentially life-saving in those subgroups.

What does not work: Cochrane found no clear benefit from house dust mite control measures, despite that advice being almost universally given. It is printed.

**Gaps.** The WHO fact sheet gives no figure for children affected despite calling asthma the commonest chronic childhood disease. Prevalence estimates depend heavily on definition — questionnaire-reported wheeze, doctor diagnosis and bronchodilator reversibility give substantially different numbers — and the 363 million figure is model-based. No primary prevention of asthma has ever been demonstrated; the hygiene hypothesis explains the epidemiology and has yielded no working intervention. Why prevalence rose and then plateaued is unexplained. START and CAMP showed early inhaled corticosteroid treatment does not alter natural history, and that is widely misunderstood. House dust mite avoidance: Cochrane null against universal advice. Type-2-low asthma has almost no effective therapy except possibly tezepelumab, and it is a large minority of severe asthma. Mortality data are weakest where mortality is highest: asthma death certification is unreliable, and the 442,000 figure rests on modelling in countries with poor vital registration. Montelukast's neuropsychiatric risk was recognised late and the magnitude remains debated. Biologic trials use exacerbation rates over one year, and long-term disease-modification data do not exist for any biologic. The inverse relation between prevalence and mortality across countries is a treatment-access signal and its magnitude is not precisely quantified. Omalizumab is not on the 24th Model List in any form, and any claim otherwise is wrong.

# Infection and scarring of the lung

## Pneumonia (ICD-11 CA40)

Pneumonia is coded in ICD-11 chapter 12 as CA40, and the organism-specific infections also appear in chapter 01. This entry treats it as a respiratory condition and complements the infectious-disease chapter.

**What it is.** Infection fills the air sacs of the lung with fluid and pus. Fever, cough and fast breathing follow, and the person cannot get enough oxygen. It is the largest infectious killer of children and of older adults.

**Measured.** Deaths from lower respiratory infections in 2023: 2,501,300 (95 per cent uncertainty interval 2,241,000 to 2,812,200), from GBD 2023; 2.7 million, about 4.4 per cent of all deaths and rank 4 of all causes, on WHO's top-ten page. GBD and WHO differ by about 200,000 and both are printed. GBD 2021 gave 2,180,000 (1,980,000–2,360,000), rank 7, with an age-standardised rate of 28.7 per 100,000. DALYs in 2023: 98.7 million (87.7–112), rank 4 of all causes globally. No single global incidence figure was located in the retrieved sources; estimates of roughly 120 to 150 million episodes of childhood pneumonia a year, and roughly 1,500 adult hospitalisations per 100,000 a year over age 65, exist in the literature.

Pneumonia is the single largest infectious cause of death in children under five: roughly 700,000 to 740,000 child deaths a year, about 14 per cent of all under-five deaths, from the WHO and UNICEF estimates. The WHO fact sheet on pneumonia in children, printed in November 2022 and reporting 2019 data, gives 740,180 deaths of children under five, which is 14 per cent of under-five deaths, with 22 per cent of deaths in children aged one to five. It states that only one third of children with pneumonia receive the antibiotics they need. That page is the oldest in the WHO set consulted for this book. For scale, there were 4.9 million under-five deaths in 2024.

Household air pollution causes 44 per cent of child pneumonia deaths and 22 per cent of adult pneumonia deaths, and lower respiratory infection is 21 per cent of the 2.9 million deaths attributed to household air pollution; almost half of under-five lower respiratory infection deaths are caused by particulate matter from household air pollution. A 44 per cent attributable fraction for child pneumonia deaths is the largest single environmental attribution in either chapter. Ambient air pollution: acute lower respiratory infections are 14 per cent of its 4.2 million premature deaths.

The age pattern is U-shaped, with the highest mortality in infants and in those over 70. The great majority of child pneumonia deaths occur in sub-Saharan Africa and south Asia. Child pneumonia deaths have fallen by roughly half since 2000, attributed to vaccination against Haemophilus influenzae type b and pneumococcus, improved case management and reduced undernutrition.

**Where it starts.** The organisms. Streptococcus pneumoniae is the commonest bacterial cause at all ages, followed by Haemophilus influenzae type b, now largely vaccine-preventable, and Staphylococcus aureus. Mycoplasma pneumoniae and Legionella appear in adults. Respiratory syncytial virus is the commonest viral cause in infants, with influenza, SARS-CoV-2, human metapneumovirus and parainfluenza also contributing. Pneumocystis jirovecii occurs in HIV, and Klebsiella and other Gram-negatives in hospital-acquired disease.

Undernutrition is the single largest child risk factor, and stunting and wasting multiply pneumonia mortality several-fold; about 150 million children under five were stunted in 2024, 43 million wasted. Household air pollution carries 44 per cent of child pneumonia deaths. Lack of exclusive breastfeeding in the first six months roughly doubles risk, and exclusive breastfeeding at 0 to 6 months stood at about 47 per cent globally in 2018 to 2025. Low birthweight and prematurity, crowding, second-hand tobacco smoke, incomplete vaccination, vitamin A and zinc deficiency, HIV and measles all contribute. In adults: age, chronic lung disease, heart failure, diabetes, immunosuppression, smoking, alcohol, aspiration risk from stroke, dementia or reduced consciousness, and inhaled corticosteroid use, where TORCH gave pneumonia at 19.6 against 12.3 per cent. Influenza infection predisposes to secondary bacterial pneumonia.

The causative organism is never identified in roughly 40 to 60 per cent of community-acquired pneumonia† even with modern molecular testing, so most treatment is empirical. Whether a given radiographic consolidation is bacterial or viral cannot be reliably determined at the bedside or on the film, which drives large amounts of unnecessary antibiotic use. Why one colonised child develops invasive pneumococcal pneumonia and another does not is not explained. The contribution of viral-bacterial co-infection to mortality is not well quantified.

**Cure status.** Bacterial pneumonia: CURABLE. Viral pneumonia in the immunocompetent: SELF-LIMITING with supportive care. Pneumocystis pneumonia: CURABLE with cotrimoxazole.

This is one of the clearest cures in medicine when the antibiotic reaches the patient in time. Appropriate antibiotics cure bacterial pneumonia in the large majority: untreated lobar pneumococcal pneumonia had a case fatality of roughly 30 per cent in the pre-antibiotic era, falling

to roughly 5 per cent or less with penicillin, in the original comparisons of the 1930s and 1940s. Community case management with oral antibiotics by community health workers reduces child pneumonia mortality by roughly 35 to 42 per cent — a cure delivered by a trained non-clinician with a course of tablets costing cents.

Viral pneumonia is largely SELF-LIMITING in the immunocompetent and becomes lethal through hypoxaemia and secondary bacterial infection, both treatable. Oseltamivir for influenza shortens illness by roughly a day and, in observational data, reduces mortality in hospitalised patients; the trial evidence for mortality is weak and contested. Mortality remains high in the very old and in severe disease: 30-day mortality in hospitalised community-acquired pneumonia is roughly 10 to 15 per cent, and 25 to 50 per cent in those requiring intensive care.

Another chapter of this book declares the same disease CURABLE for bacterial and SELF-LIMITING for viral pneumonia, splitting by cause, which is the same split used here.

**Prevention.**

*Pneumococcal conjugate vaccine — STRONG, with large measured effects.* The vaccine reduces vaccine-type invasive pneumococcal disease by roughly 80 to 90 per cent in vaccinated children and produces substantial herd protection in unvaccinated adults. Radiologically confirmed pneumonia in children was reduced by 37 per cent (95 per cent CI 27–45) per protocol and 36 per cent by intention to treat in the Gambian trial. A figure of 25 per cent as the low end of a range† appears without a traceable source and is not carried here as a measured value. Pneumococcal last-dose coverage was 71 per cent in 2025, and the vaccine is on the Essential Medicines List† and in routine immunisation in most countries.

*Haemophilus influenzae type b vaccine — STRONG.* Near-elimination of invasive disease where coverage is high; coverage was 78 per cent in 2025.

*Measles vaccination — STRONG.* Measles deaths fell from 762,800 in 2000 to 143,600 in 2023, a decline of 81.2 per cent, on GBD 2023; WHO's measles fact sheet gives 95,000 deaths in 2024 against 780,000 in 2000, with nearly 59 million deaths averted by vaccination between 2000 and 2024. Most measles deaths are from pneumonia, so measles vaccination is substantially a pneumonia prevention measure. First-dose coverage was 84 per cent in 2025 and two-dose coverage 77 per cent, with roughly 21 million children missing the routine first dose.

*Exclusive breastfeeding for six months — STRONG.* It roughly halves pneumonia incidence and reduces pneumonia mortality substantially, and it costs nothing. WHO estimates nearly 400,000 under-five deaths a year could be prevented by exclusive breastfeeding for six months and continued breastfeeding to two years or beyond.

*Handwashing with soap — STRONG.* Cluster-randomised trials in Karachi found handwashing promotion reduced pneumonia incidence in children under five by roughly 50 per cent. Soap and water.

*Influenza vaccination — MODERATE* in older adults and chronic disease.

*Respiratory syncytial virus prevention — STRONG and newly available.* Nirsevimab, a long-acting monoclonal antibody, reduced medically attended lower respiratory infection by roughly 75 to 80 per cent in infants, in HARMONIE and MELODY. The maternal RSVpreF vaccine reduced severe infant disease by roughly 70 to 80 per cent in the first 90 days, in MATISSE. Nirsevimab costs hundreds of euro per infant, a price that limits global reach.

*Clean cooking fuel — STRONG on attributable burden, WEAK on randomised evidence, and the single most important unresolved disagreement in this entry.* Household air pollution carries 44 per cent of child pneumonia deaths. RESPIRE, with chimney stoves in Guatemala, missed its primary pneumonia endpoint, though severe pneumonia was reduced in per-protocol analysis. CAPS, with cookstoves across 10,750 children in Malawi, found no reduction in pneumonia. HAPIN, with liquefied petroleum gas stoves, verified a 66 per cent reduction in fine particulate exposure and missed its primary birth-weight endpoint. Both the 44 per cent attribution and the three trial failures are printed, and neither side has conceded; the exposure-response threshold explanation is plausible and unproven.

*Co-trimoxazole prophylaxis in HIV — STRONG*. *Oral care in nursing homes and after stroke — MODERATE* for aspiration pneumonia. *Reducing crowding and second-hand smoke — MODERATE*.

*Zinc supplementation — CONTESTED.* It reduces pneumonia incidence by roughly 15 to 20 per cent in some trials and meta-analyses and not in others, and Cochrane rates it as uncertain for treatment. *Vitamin A supplementation — MODERATE* for child mortality generally, not specifically for pneumonia.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Oral amoxicillin for non-severe childhood pneumonia | Community case management with oral antibiotics reduces child pneumonia mortality roughly 35 to 42 per cent; oral amoxicillin is as effective as injectable penicillin for severe pneumonia, from the APPIS and NO-SHOTS trials | yes, section 6.2.1 Access group, listed first-choice for community-acquired pneumonia | yes | €0.20–1.00 a child course. UNICEF indicative price October 2026: US$0.54 for ten 250 mg dispersible tablets, about US$0.054 a tablet; US$0.41 for a 100 mL bottle of 125 mg/5 mL suspension |
| Amoxicillin or amoxicillin-clavulanate with or without a macrolide, adult community-acquired pneumonia | Standard; mortality reduced against no treatment dramatically | yes | yes | a few to tens of euro a course |
| Benzylpenicillin or ampicillin with gentamicin, severe child pneumonia | The WHO standard for severe disease | yes | yes | a few to tens of euro a course |
| Ceftriaxone, severe disease or resistance | | yes | yes | a few to tens of euro a course |
| Co-trimoxazole, Pneumocystis pneumonia and HIV prophylaxis | Curative for Pneumocystis pneumonia | yes | yes | a few to tens of euro a course |
| Oxygen | The single most important supportive treatment. Hypoxaemia is the main proximate cause of death in child pneumonia, and oxygen systems in Papua New Guinea district hospitals reduced child pneumonia mortality by 35 per cent | yes | yes | Concentrator hundreds to thousands of euro one-off; see the COPD entry for the comparison |
| Pulse oximetry | Identifies hypoxaemia that is invisible clinically; integrating it into case management changes treatment in a substantial minority of children | n/a | n/a | tens to hundreds of euro a device |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Corticosteroids in severe community-acquired pneumonia | CAPE COD, 800 patients with severe pneumonia: 28-day mortality 6.2 against 11.9 per cent, hazard ratio 0.46, absolute risk difference 5.7 percentage points, recomputed number needed to treat 17.5. Earlier trials were mixed and ESCAPe was null. For COVID-19 pneumonia, RECOVERY, 6,425 patients: dexamethasone reduced 28-day mortality 22.9 against 25.7 per cent overall, absolute risk difference 2.8 points, number needed to treat 36, and in ventilated patients 29.3 against 41.4 per cent, absolute risk difference 12.1 points, recomputed number needed to treat 8.3, with a drug costing under €5 | yes, dexamethasone and prednisolone | yes | €1–5 a course. UNICEF indicative price October 2026 for dexamethasone 4 mg: US$24.00 for 100 tablets, about US$0.24 a tablet |
| Oseltamivir, influenza | Symptoms shortened by about a day; the mortality benefit in hospitalised patients is observational and contested | yes | yes | a few to tens of euro a course |
| Non-invasive ventilation or high-flow nasal oxygen | Intubation reduced in hypoxaemic respiratory failure; FLORALI found high-flow oxygen reduced 90-day mortality in non-hypercapnic hypoxaemic failure | n/a | n/a | thousands of euro a machine |
| Mechanical ventilation | Life-saving in respiratory failure | n/a | n/a | tens of thousands of euro a machine plus intensive care |
| Zinc as a treatment adjunct | Cochrane: uncertain benefit for treating child pneumonia | yes | yes | a few to a few euro a course |

Oral amoxicillin at US$0.054 a tablet, the UNICEF indicative price in October 2026, delivered by a community health worker, reduces child pneumonia mortality by roughly 35 to 42 per cent. Against roughly 700,000 annual child pneumonia deaths, that is plausibly the largest measured mortality benefit per euro of any intervention in either chapter. Dexamethasone at a few euro a course with a number needed to treat of about 8 in ventilated COVID-19 pneumonia is the other extreme example.

**Simple means.** Counting respiratory rate is the diagnostic basis of community case management worldwide and needs no equipment. WHO’s integrated management of childhood illness diagnoses pneumonia by counting breaths a minute — fast breathing thresholds of 60 or more under two months, 50 or more at two to eleven months, 40 or more at one to five years — and by looking for chest indrawing. A watch or a simple timer and sixty seconds.

Oral amoxicillin given by a community health worker costs cents a course and reduces child pneumonia mortality by 35 to 42 per cent. Oral is as effective as injectable even for severe pneumonia, per APPIS and NO-SHOTS, which removes the need for syringes, sterile technique and referral in a large share of cases.

Pulse oximetry costs tens to hundreds of euro is battery-powered, needs no consumables, and detects the hypoxaemia that kills. Oxygen is the single highest-yield piece of hospital equipment for pneumonia, and a concentrator with a reliable power supply is the cheap way to provide it: a concentrator costs hundreds to thousands of euro once plus hundreds of euro a year for electricity, while cylinders cost thousands of euro a year in delivery logistics. Oxygen systems in district hospitals reduced child pneumonia mortality by 35 per cent in Papua New Guinea. Solar-powered concentrator installations are in use and outcome data are limited.

Handwashing with soap reduced childhood pneumonia incidence by roughly 50 per cent in the Karachi cluster-randomised trial. Exclusive breastfeeding roughly halves pneumonia incidence, is free, and requires support rather than supply. Dexamethasone costs a few euro a course with a number needed to treat of about 8 for mortality in ventilated COVID-19 pneumonia and about 18 in severe bacterial pneumonia; it is a cheap tablet or ampoule, listed and off-patent. Upright positioning, continued feeding and fluids during illness are nursing care rather than technology. Reducing smoke exposure — moving the cooking fire outside, ventilation, lids on pots, dry fuel — addresses an attributable burden of 44 per cent of child pneumonia deaths, and the randomised stove trials failed to demonstrate benefit; both must be said.

The hard limit. Severe pneumonia with respiratory failure needs oxygen at minimum and sometimes ventilation. Oxygen is the binding constraint in most of the world: the drugs are cheap and available, and the oxygen often is not.

**Gaps.** GBD gives 2,501,300 deaths and WHO gives 2.7 million for 2023, and GBD 2021 gives 2,180,000; all are printed. No single global incidence figure was located. The organism is unidentified in 40 to 60 per cent of cases, so nearly all treatment is empirical and resistance surveillance is weak. The clean-cooking disagreement is the largest in this entry: a 44 per cent attributable fraction for child pneumonia deaths against three failed randomised stove trials. Neither side has conceded and the exposure-response threshold explanation is plausible and unproven. Zinc is contested: Cochrane uncertain, other meta-analyses positive. Corticosteroids in severe community-acquired pneumonia: CAPE COD strongly positive at hazard ratio 0.46, ESCAPe null, earlier trials mixed; the guidelines are changing and the question is not settled. Oseltamivir's mortality benefit rests on observational data, and the randomised evidence is weak and the subject of a long-running public dispute over trial data access. Child pneumonia mortality estimates come from verbal autopsy and modelling in the countries that carry most of the burden, and the roughly 700,000 figure is a model output. Distinguishing bacterial from viral pneumonia is not possible at the bedside, which drives antibiotic overuse of a scale that is not well measured. Oxygen availability in low-income hospitals is poorly documented; surveys suggest a majority of district hospitals in sub-Saharan Africa lack reliable oxygen, and systematic data are thin. One pneumococcal vaccine figure that circulates — a 25 per cent low end for radiologically confirmed pneumonia reduction — appears in no retrievable primary source and is not carried as a measured value. The WHO fact sheet on childhood pneumonia is dated November 2022 and reports 2019 data, the oldest vintage in the WHO set consulted for this book.

## Bronchiectasis (ICD-11 CA24)

**What it is.** The airways are permanently widened and scarred, so mucus pools in them and becomes infected again and again. The person coughs up large amounts of sputum daily and loses lung function in steps. It is usually the end result of earlier severe infection.

**Measured.** No global prevalence, death or DALY figure for bronchiectasis was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all, and for a condition with prevalence over 1 per cent in the elderly it is a substantial hole.

Prevalence in high-income countries runs from roughly 67 to 566 per 100,000 adults depending on country and ascertainment method, from UK, United States, German and Spanish

administrative studies; the eightfold range between studies is itself the finding. UK incidence rose from roughly 21 to 35 per 100,000 a year in women and 18 to 27 in men between 2004 and 2013. Prevalence rises steeply with age, exceeding 1 per cent above 70 in some series. Mortality is roughly 1.5 to 2 times that of the age-matched general population, with median survival after diagnosis of roughly 13 to 17 years in European cohorts. In low- and middle-income countries post-tuberculous bronchiectasis is probably the commonest form and is almost entirely unmeasured; studies in India, China and South Africa report tuberculosis as the cause in 25 to 50 per cent of cases. There is a female predominance in most high-income cohorts, roughly 60 to 65 per cent. Reported prevalence and incidence are rising in high-income countries, attributed largely to increased computed tomographic scanning and recognition rather than to a true increase.

**Where it starts.** Post-infective causes are the largest identified group: childhood pneumonia, pertussis, measles, tuberculosis — dominant in high-burden countries — non-tuberculous mycobacteria and adenovirus. No cause is found in roughly 25 to 45 per cent of cases in high-income cohorts. Bronchiectasis is found on computed tomography in roughly 30 to 50 per cent of moderate to severe chronic obstructive pulmonary disease. Cystic fibrosis is treated as a separate entry below. Primary ciliary dyskinesia affects roughly 1 in 10,000 to 20,000 and accounts for roughly 2 to 3 per cent of bronchiectasis. Immunodeficiency — common variable immunodeficiency, specific antibody deficiency, HIV — accounts for roughly 5 to 10 per cent of cases, and that group matters because immunoglobulin replacement changes the course. Allergic bronchopulmonary aspergillosis accounts for roughly 5 to 10 per cent in some series. Alpha-1 antitrypsin deficiency, rheumatoid arthritis at roughly 3 to 5 per cent of cases, inflammatory bowel disease and Sjögren syndrome all contribute. Aspiration and gastro-oesophageal reflux contribute, and a foreign body or tumour causing localised obstruction gives the one form with a potential surgical cure. Yellow nail syndrome, Mounier-Kuhn syndrome and Williams-Campbell syndrome are rare structural causes.

In 25 to 45 per cent of cases no cause is found at all despite systematic investigation. The vicious vortex model — impaired mucociliary clearance, infection, inflammation and structural damage reinforcing one another — is widely accepted and does not identify which link to break in a given patient. Why some patients are chronically infected with Pseudomonas aeruginosa, a marker of much worse prognosis, and others never are is not predictable. Whether bronchiectasis found incidentally on computed tomography in chronic obstructive pulmonary disease patients is the same disease as primary bronchiectasis is unresolved and has direct treatment consequences.

**Cure status.** Established bronchiectasis: CONTROLLABLE. Localised disease confined to one lobe or segment with an identified local cause: CURABLE by surgical resection.

The airway dilatation is permanent and irreversible, and no treatment reverses it; the structural damage on computed tomography does not resolve. Airway clearance, antibiotics and treatment of the underlying cause slow progression and reduce exacerbations.

Localised bronchiectasis confined to one lobe or segment with an identified local cause — a foreign body, a tumour, prior focal infection — can be cured by surgical resection. Symptom resolution follows in roughly 70 to 90 per cent of selected patients in surgical series, with operative mortality under 2 per cent in modern practice. That is a genuine cure, available only to a small minority with focal disease and good lung function.

Treating the underlying cause changes the trajectory without reversing the damage: immunoglobulin replacement in antibody deficiency sharply reduces infections, steroids and antifungals treat allergic bronchopulmonary aspergillosis, antituberculous therapy treats active tuberculosis, and removal of a foreign body removes the obstruction. Lung transplantation is available for end-stage disease.

**Prevention.**

*Tuberculosis control and complete treatment — STRONG, and quantitatively the most important measure globally*, given that post-tuberculous bronchiectasis dominates in high-burden countries. Tuberculosis caused 1.23 million deaths in 2024 with 10.7 million new cases, and 83 million lives have been saved since 2000.

*Childhood vaccination against measles, pertussis, Haemophilus influenzae type b and pneumococcus — STRONG.* The historical decline of bronchiectasis in high-income countries fol-

lowed vaccination and antibiotic availability; measles deaths fell 81.2 per cent from 2000 to 2023, and measles pneumonia was a major cause of post-infective bronchiectasis.

*Prompt and adequate treatment of childhood pneumonia — STRONG* by the same logic; community case management with oral amoxicillin reduces child pneumonia mortality 35 to 42 per cent.

*Early diagnosis of immunodeficiency — MODERATE*: immunoglobulin replacement prevents the progressive damage, and diagnostic delay in common variable immunodeficiency averages four to nine years, during which bronchiectasis develops.

*Newborn screening for cystic fibrosis — STRONG*; see that entry.

*Removal of inhaled foreign bodies promptly — STRONG* in the specific case. *Early diagnosis and treatment of allergic bronchopulmonary aspergillosis — MODERATE*. *Smoking cessation — MODERATE*. *Influenza and pneumococcal vaccination in established disease — MODERATE* for exacerbations.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Airway clearance physiotherapy | The foundation of treatment. Sputum clearance and quality of life improve; Cochrane finds improved quality of life and reduced symptoms at low to moderate certainty, with no mortality data | n/a | n/a | Training time; devices a few to tens of euro |
| Pulmonary rehabilitation | Exercise capacity and quality of life improve, comparable to the chronic obstructive pulmonary disease effects | n/a | n/a | hundreds to thousands of euro a programme |
| Long-term macrolide, azithromycin or erythromycin | The best-evidenced drug therapy. BAT, azithromycin, 83 patients: exacerbations 0.59 against 1.57 per patient over a year. EMBRACE, 141 patients: exacerbation rate ratio 0.38. BLESS, erythromycin, 117 patients: exacerbations reduced. Roughly a halving of exacerbations across the three trials. Risks: macrolide resistance, hearing loss, QT prolongation, and mycobacterial infection must be excluded first | yes, both | yes | €30–150. UNICEF indicative price October 2026 for azithromycin 250 mg: US$0.56 for six tablets, about US$0.093 a tablet |
| Inhaled antibiotics, colistin, gentamicin, tobramycin, aztreonam | Bacterial load and exacerbations reduced in Pseudomonas-colonised patients; trial results are inconsistent, and the two phase 3 aztreonam trials AIR-BX1 and AIR-BX2 were negative for symptoms | yes, colistin, gentamicin and tobramycin | yes | hundreds to thousands of euro depending on agent |
| Brensocatib, dipeptidyl peptidase-1 inhibitor | ASPEN, 1,721 patients, 2025: exacerbation rate reduced roughly 20 to 21 per cent against placebo — the first drug developed specifically for bronchiectasis to succeed in phase 3 | no | no | Price not established at compilation; expected high |
| Hypertonic saline, nebulised 6 to 7 per cent | Sputum clearance and quality of life improve; the evidence is weaker than in cystic fibrosis and the trials are small | no | yes | tens to hundreds of euro |
| Inhaled mannitol | Failed its primary endpoint of exacerbation rate in a large trial, though quality of life improved | no | no | thousands of euro |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Bronchodilators | Symptomatic, used where airflow obstruction coexists; little bronchiectasis-specific evidence | yes | yes | tens of euro |
| Inhaled corticosteroids | Not recommended unless asthma or chronic obstructive pulmonary disease coexists; they increase pneumonia risk | yes | yes | tens of euro |
| Dornase alfa, recombinant human DNase | **Harmful in non-cystic-fibrosis bronchiectasis** — a randomised trial showed worse FEV1 and more exacerbations. A drug that works in cystic fibrosis is harmful here | no | no | tens of thousands of euro |
| Immunoglobulin replacement, antibody deficiency | Infections sharply reduced and progression slowed in that subgroup | yes, normal immunoglobulin | yes | tens of thousands of euro |
| Surgical resection, focal disease | Symptom resolution in 70 to 90 per cent of selected patients; operative mortality under 2 per cent | n/a | n/a | thousands to tens of thousands of euro |
| Antibiotics for exacerbations, fourteen days, guided by sputum culture | Standard care | yes, amoxicillin, doxycycline, co-amoxiclav, ciprofloxacin | yes | a few to tens of euro a course |
| Lung transplantation | End-stage disease | n/a | n/a | hundreds of thousands of euro in the first year |

**Simple means.** This is a condition where physical technique carries most of the treatment.

Airway clearance by physical technique requires no equipment at all, only instruction. The active cycle of breathing technique, autogenic drainage and postural drainage are the foundation of bronchiectasis care worldwide and improve quality of life and sputum clearance. Twice-daily clearance for 15 to 30 minutes, taught once by a physiotherapist, is the core treatment of a lifelong disease.

Oscillating positive expiratory pressure devices — a flutter valve, an Acapella, an Aerobika — cost tens of euro are reusable for years, and need no power. Bubble positive expiratory pressure can be improvised from a plastic bottle and tubing: blowing through a tube into a bottle of water generates positive expiratory pressure and assists clearance, and it is used in low-resource settings, with small studies supporting an effect comparable to commercial devices.

Azithromycin is the single most cost-effective drug in the entry by a wide margin: tens to hundreds of euro a year, listed, off-patent, oral, and it roughly halves exacerbations across three randomised trials. The precondition is excluding mycobacterial infection, which requires sputum culture.

Exercise and pulmonary rehabilitation improve exercise capacity and quality of life; walking and sit-to-stand, no gymnasium. Hydration and steam or humidification before clearance to loosen secretions is standard practice with low-quality evidence. Hypertonic saline at 6 to 7 per cent can be made from salt and sterile water at trivial cost, though a nebuliser needs power, and the evidence is weaker than in cystic fibrosis. Vaccination against influenza and pneumococcus is listed, cheap and routine. Smoking cessation is free.

The hard limit. Diagnosis requires computed tomography of the chest: bronchiectasis is defined radiologically, no clinical feature or spirometric pattern establishes it, and chest radiography misses most cases. Sputum culture is needed to guide antibiotics and to exclude mycobacteria before macrolides. So the condition cannot be diagnosed or safely treated without computed tomography and a microbiology laboratory, even though its main treatment is a breathing technique and a tens of euro antibiotic.

**Gaps.** No GBD global burden figure for bronchiectasis was retrieved, and this entry is part of the seventeen-condition gap in this chapter's introduction. Reported prevalence varies

eightfold between high-income countries, 67 to 566 per 100,000, on methodology alone. Post-tuberculous bronchiectasis, probably the commonest form globally, is essentially unmeasured and almost absent from a trial evidence base that is European, North American and Australasian. No cause is found in 25 to 45 per cent of cases. The overlap with chronic obstructive pulmonary disease, found in 30 to 50 per cent of moderate to severe cases of that condition, is not resolved as to whether it is the same disease, and the treatment implications differ. Dornase alfa is beneficial in cystic fibrosis and harmful here — a clear demonstration that evidence does not transfer between the two, and a warning against extrapolation. Inhaled antibiotic trials are inconsistent, and AIR-BX1 and AIR-BX2 were negative for symptoms despite a microbiological effect. Airway clearance, the foundation of treatment, has only low to moderate certainty evidence and no mortality data, because trials of physiotherapy are hard to blind and have never been adequately powered for hard endpoints. Brensocatib, from ASPEN in 2025, is the first successful bronchiectasis-specific drug, and its price, durability and place in therapy are not yet established. Mortality and survival figures come from European specialist cohorts with referral bias.

## Pulmonary fibrosis and interstitial lung disease (ICD-11 CB03, CB04)

**What it is.** The tissue between the air sacs thickens and scars, so oxygen cannot cross into the blood. The lungs shrink and stiffen. Breathlessness worsens steadily and in the commonest form, idiopathic pulmonary fibrosis, it is relentless.

**Measured.** No global prevalence, death or DALY figure for interstitial lung disease was retrieved from the GBD 2023 tables. GBD carries interstitial lung disease and pulmonary sarcoidosis as a cause and no figure was retrieved. GBD 2019 estimates gave roughly 4.7 million prevalent cases and roughly 180,000 deaths a year globally, from an earlier round.

Idiopathic pulmonary fibrosis incidence, from a systematic review in the European Respiratory Journal in 2015, read in a repository copy. In Europe and North America from 2000 onward under narrow criteria it runs at roughly 3 to 9 per 100,000 a year, with a results-section range of 2.8 to 9.3. The UK figures are 4.6 for 1991 to 2003, 7.44 for 2000 to 2008 and 8.65 for 2000 to 2012. Denmark gives 7.27 for 1995 to 2000 and 5.28 for 2001 to 2005, with a later local-records study giving 1.3 for 2003 to 2009. The United States gives 16.3 broad and 6.8 narrow in a 2006 claims analysis; Medicare over 65 for 2001 to 2011 gives 31.1 to 43.0 broad and 15.9 to 31.1 narrow, with an overall rate of 93.7; Minnesota over 50 gives 17.4 broad and 8.8 narrow. Italy, in Lazio, gives 7.5 by coding and 9.3 after case review. East Asia gives 1.2 to 4.16 across Taiwan, South Korea and Japan. South America gives 0.26 in Brazil in 1996 rising to 0.48 in 2010, with the discussion giving 0.4 to 1.2. Questionnaire-survey European estimates are Turkey 4.69, Spain 1.4 to 2.9, Greece 0.93 and Flanders 0.22.

Mortality per 100,000 a year, same review: a ten-country age-standardised comparison runs from 4.68 in Sweden to 13.36 in Northern Ireland on broad codes, and from 4.64 in Spain to 8.28 in England and Wales on specific codes. Multiple-cause mortality gives 12.98 for England and Wales in 2010 and 9.37 for the United States. The UK gives 2.54 overall for 1968 to 2008, rising from 0.92 in 1968 to 1972 to 5.10 in 2005 to 2008, roughly 5 per cent a year. The United States gives 3.65 in 1991, 5.08 for 1992 to 2003 and 7.57 for 1999 to 2003 on multiple-cause coding. Brazil rises from 0.65 in 1996 to 1.21 in 2010, and Japan gives 10.26 on broad coding.

The review excluded prevalence studies, so it reports no prevalence figures, and it does not report survival figures, noting only that a Taiwanese cohort had more severe disease and lower survival. Elsewhere, median survival in untreated idiopathic pulmonary fibrosis is roughly three to five years from diagnosis, which is worse than many cancers. The trend direction disagrees between datasets. Most studies show rising incidence, especially in UK datasets. Denmark fell from 2001 to 2005, with possible diagnostic transfer, and United States Minnesota fell in later years with low case numbers. A 2014 analysis found stable Medicare incidence from 2001 to 2011, and United States multiple-cause mortality plateaued from 2003. Mortality rose in most countries, with no change in Germany or New Zealand in one comparison. All of them are printed. Idiopathic pulmonary fibrosis is rare below 50 and rises steeply, with a median age at diagnosis of roughly 65 to 70 and a male predominance of roughly 1.5 to 2 to 1.

**Where it starts.** Idiopathic pulmonary fibrosis has no known cause by definition. Established associations follow.

Cigarette smoking: odds ratio roughly 1.6 to 2.9. Age is the strongest determinant.

Genetics. The MUC5B promoter variant rs35705950 is the strongest known risk factor. It is present in roughly 35 per cent of patients against 11 per cent of controls, with an odds ratio of roughly 4.5 heterozygous and 20 homozygous, and it is paradoxically associated with better survival. Telomerase mutations in TERT, TERC, RTEL1 and PARN appear in roughly 10 to 25 per cent of familial cases, and short telomeres predict worse outcome and worse response to immunosuppression.

Occupational and environmental dusts, including metal dust, wood dust, stone and silica, farming, livestock and birds: odds ratios of roughly 1.5 to 2.5 across case-control studies.

Gastro-oesophageal reflux and microaspiration are strongly associated and causality is contested. Viral infection with Epstein-Barr virus and other herpesviruses is associated without established causality.

Other interstitial lung diseases have known causes. Hypersensitivity pneumonitis from birds, mould, hot tubs or metalworking fluid, where antigen avoidance can halt or reverse it, making this the identifiable and partly curable group. Connective tissue disease interstitial lung disease: systemic sclerosis with lung involvement in roughly 50 to 80 per cent on computed tomography, rheumatoid arthritis, myositis with anti-MDA5 or anti-synthetase antibodies, Sjögren syndrome, lupus. Drug-induced disease from amiodarone, methotrexate, nitrofurantoin, bleomycin, immune checkpoint inhibitors and radiation. The pneumoconioses, treated in the occupational entry below. Sarcoidosis, cause unknown, with roughly 10 to 30 per cent developing fibrosis. Smoking-related forms — respiratory bronchiolitis-associated interstitial lung disease, desquamative interstitial pneumonia, Langerhans cell histiocytosis — which improve or resolve with smoking cessation.

The cause of idiopathic pulmonary fibrosis is unknown. The MUC5B variant is common in the general population and most carriers never develop fibrosis, so it is a susceptibility marker rather than a cause. Why the fibrosis is progressive and self-sustaining once started is not explained. Whether reflux and microaspiration cause the disease or result from it has not been resolved, and the one randomised trial of anti-reflux surgery was inconclusive. Why antifibrotics slow decline by roughly half and never stop or reverse it is unexplained. The very wide between-country ranges in both incidence, 0.22 to 93.7 per 100,000 depending on criteria and population, and mortality, 4.64 to 13.36, reflect coding and case-definition differences more than true variation, and the true global burden is therefore not known.

**Cure status.** Idiopathic pulmonary fibrosis: RELIEF ONLY. Hypersensitivity pneumonitis in the acute and subacute stages: CURABLE by antigen avoidance. Smoking-related interstitial disease: CURABLE by cessation. Drug-induced disease: CURABLE by stopping the drug. Sarcoidosis: SELF-LIMITING in roughly 60 to 70 per cent. Connective tissue disease interstitial lung disease: CONTROLLABLE.

No treatment reverses established pulmonary fibrosis. Antifibrotics slow the rate of forced vital capacity decline by roughly 50 per cent and do not restore lost function.

Immunosuppression is actively harmful in idiopathic pulmonary fibrosis. The PANTHER-IPF trial, of prednisone with azathioprine and N-acetylcysteine, was stopped early for increased death and hospitalisation, with mortality of 8 against 1 per cent. That is one of the most important negative results in respiratory medicine: the standard treatment for decades made the disease worse.

Hypersensitivity pneumonitis is reversible or curable by antigen avoidance in the acute and subacute stages, and once fibrotic it behaves like idiopathic pulmonary fibrosis. Smoking-related interstitial disease improves or resolves with cessation. Drug-induced disease is often reversible on stopping the drug. Sarcoidosis remits spontaneously in roughly 60 to 70 per cent within two to three years, and corticosteroids control symptoms and have not been shown to alter long-term outcome. Connective tissue disease interstitial lung disease is CONTROLLABLE: immunosuppression with mycophenolate, cyclophosphamide, rituximab or tocilizumab in scleroderma stabilises or improves lung function in a substantial proportion, unlike in idiopathic disease. Lung transplantation is the only intervention that removes

the disease, with median survival after transplantation for idiopathic pulmonary fibrosis of roughly five to six years against three to five years untreated.

**Prevention.**

*Antigen avoidance in hypersensitivity pneumonitis — STRONG, and genuinely curative if early.* Removing birds, remediating mould, changing metalworking fluid practice.

*Avoiding and monitoring fibrogenic drugs — STRONG*: amiodarone, methotrexate, nitrofurantoin, bleomycin, checkpoint inhibitors.

*Smoking cessation — MODERATE* for idiopathic pulmonary fibrosis, odds ratio 1.6 to 2.9, and *STRONG* for smoking-related interstitial disease, which improves or resolves on quitting.

*Occupational dust control — MODERATE.* Metal, wood, stone and silica dust carry odds ratios of roughly 1.5 to 2.5; see the pneumoconiosis entry for the control measures.

*Screening in systemic sclerosis — MODERATE*, since early treatment of scleroderma lung disease is more effective than late.

*Family screening and genetic counselling in familial pulmonary fibrosis — WEAK*: informative, with no preventive intervention available.

*Nothing prevents idiopathic pulmonary fibrosis.*

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Pirfenidone | ASCEND, 555 patients: the proportion with a 10 per cent or greater decline in forced vital capacity or death reduced 47.9 per cent. CAPACITY pooled: decline slowed roughly 50 per cent. Pooled analyses show reduced mortality, hazard ratio about 0.52 at one year | no | **yes — generics available** | Branded tens of thousands of euro; generic thousands of euro in some markets |
| Nintedanib | INPULSIS 1 and 2, 1,066 patients: annual forced vital capacity decline −114.7 against −239.9 mL and −113.6 against −207.3 mL, roughly a 50 per cent reduction in decline; also effective in progressive fibrosing interstitial lung disease in INBUILD and in scleroderma lung disease in SENSCIS | no | no | tens of thousands of euro |
| Lung transplantation | Median survival five to six years post-transplant | n/a | n/a | hundreds of thousands of euro in the first year |
| Long-term oxygen therapy | Relieves exertional hypoxaemia and improves exercise capacity; a survival benefit has never been demonstrated in fibrosis, unlike in chronic obstructive pulmonary disease | yes, oxygen | yes | Concentrator hundreds to thousands of euro; see the COPD entry |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Pulmonary rehabilitation | Six-minute walk distance improves by roughly 35 to 50 m and quality of life improves; the benefit wanes within six months without maintenance | n/a | n/a | hundreds to thousands of euro a programme |
| Mycophenolate, cyclophosphamide, rituximab or tocilizumab, connective tissue disease interstitial lung disease | Scleroderma Lung Study II: mycophenolate equivalent to cyclophosphamide with less toxicity; tocilizumab in focuSSced preserved forced vital capacity | Mycophenolate no; cyclophosphamide yes; rituximab is a listed medicine in sections 5.1.2 and 8.2.2 | yes, both | Mycophenolate hundreds to thousands of euro; cyclophosphamide hundreds of euro |
| Corticosteroids, in sarcoidosis, hypersensitivity pneumonitis, acute exacerbations and drug-induced disease | Symptoms controlled; in sarcoidosis no effect on long-term outcome has been demonstrated | yes | yes | a few to tens of euro |
| Corticosteroids or immunosuppression in idiopathic pulmonary fibrosis | **HARMFUL.** PANTHER-IPF stopped early: mortality 8 against 1 per cent | — | — | — |
| N-acetylcysteine | No benefit in idiopathic pulmonary fibrosis overall; possible benefit in TOLLIP genotype subgroups, unconfirmed | yes | yes | tens to hundreds of euro |
| Sildenafil, for associated pulmonary hypertension | STEP-IPF null on its primary endpoint; INSTAGE null | **NOT on the 24th Model List in any form** | yes | tens to hundreds of euro |
| Anti-reflux therapy or surgery | Observational associations with slower decline; the WRAP-IPF randomised trial was inconclusive | Proton pump inhibitor yes | yes | tens to hundreds of euro |
| Opioids for refractory breathlessness, palliative | Low-dose morphine reduces breathlessness and is the best-evidenced symptom treatment in advanced fibrosis | yes, oral morphine, section 2.2 | yes | tens to hundreds of euro |

Generic pirfenidone is the key economic point. It is now off-patent with generics available at thousands of euro a patient-year against tens of thousands of euro for the brand, and it slows forced vital capacity decline by roughly 50 per cent with a pooled one-year mortality signal, hazard ratio about 0.52. Nintedanib remains on patent at tens of thousands of euro.

**Simple means.** Antigen avoidance is the only cure in this entry and costs nothing medically: removing the birds, remediating the damp, changing the job. In acute and subacute hypersensitivity pneumonitis it is curative. Stopping the offending drug in drug-induced disease is free and often reversible. Smoking cessation resolves or improves smoking-related interstitial disease and reduces idiopathic pulmonary fibrosis risk, and it is free.

Avoiding immunosuppression in idiopathic pulmonary fibrosis is a free decision that avoids the harm demonstrated in PANTHER-IPF, mortality 8 against 1 per cent. Not doing something is the intervention.

Pulmonary rehabilitation and walking give plus 35 to 50 m on the six-minute walk and improved quality of life; home-based programmes with a chair and a measured corridor achieve

much of the benefit. The benefit wanes within six months without maintenance, so it must be continued.

Breathing retraining and pacing — pursed-lip breathing, paced activity, forward-lean positioning — and a hand-held fan to the face are free or nearly so. A fan directed at the face measurably reduces the sensation of breathlessness in randomised crossover trials, and it is one of the cheapest symptom interventions in medicine. Low-dose oral morphine for refractory breathlessness costs €10 to €100 a year, is listed and off-patent, and is the best-evidenced treatment for the symptom that dominates the illness; the UNICEF indicative price in October 2026 for morphine sulfate injection 10 mg/mL was US$5.71 for a box of ten ampoules, about US$0.57 an ampoule.

Oxygen relieves exertional hypoxaemia and improves exercise capacity, and no survival benefit has been shown in fibrosis. Concentrator against cylinder as in the chronic obstructive pulmonary disease entry: hundreds to thousands of euro once plus hundreds of euro a year for power, against thousands of euro a year for cylinders. Ambulatory oxygen matters more here than in chronic obstructive pulmonary disease because the desaturation is exertional. Vaccination against influenza, pneumococcus and COVID-19 is cheap, and acute infection precipitates fatal exacerbations.

The hard limit, stated plainly, and this is the clearest case in either chapter where diagnosis rather than treatment is the binding constraint. Interstitial lung disease cannot be diagnosed without high-resolution computed tomography, and distinguishing idiopathic pulmonary fibrosis from hypersensitivity pneumonitis and from connective tissue disease interstitial lung disease determines whether immunosuppression will help or kill: the same drug is beneficial in one and lethal in the other. That distinction requires high-resolution computed tomography, autoantibody testing and often multidisciplinary review or biopsy. Without it, treatment is a coin toss with a demonstrated mortality cost. There is no simple-means substitute.

**Gaps.** No GBD 2023 figure for interstitial lung disease was retrieved, and the roughly 180,000 deaths and 4.7 million prevalent cases come from an earlier round; this entry is part of the seventeen-condition gap in this chapter's introduction. The incidence range in the primary systematic review spans 0.22 to 93.7 per 100,000 depending on country, criteria and population — a 400-fold range that is mostly methodological — and no reliable global incidence figure exists. The review excluded prevalence studies entirely and reports no prevalence and no survival figures. Mortality coding is the central problem: broad against specific ICD codes give rates differing roughly twofold within the same country, and the ten-country comparison ranges from 4.64 to 13.36. The trend direction disagrees between datasets — rising in the UK, falling in Denmark and Minnesota, stable in United States Medicare from 2001 to 2011, plateauing in United States multiple-cause mortality from 2003, no change in Germany and New Zealand — and all of them are printed. The cause of idiopathic pulmonary fibrosis is unknown. Antifibrotics slow decline by about 50 per cent and do not stop it, and whether they extend survival rests on pooled and post-hoc analyses rather than a mortality-powered trial. Reflux is an observational association with an inconclusive trial. Sarcoidosis: corticosteroids control symptoms with no demonstrated effect on long-term outcome, and are widely used long-term. Oxygen has no demonstrated survival benefit in fibrosis, unlike in chronic obstructive pulmonary disease, and this is often assumed rather than known. Almost all evidence comes from Europe, North America and east Asia; incidence in Africa, south Asia and Latin America is essentially unmeasured, and the Brazilian figures of 0.26 to 0.48 are implausibly low and almost certainly ascertainment. Sildenafil is not on the 24th Model List in any form.

## Occupational lung diseases: silicosis, asbestosis and coal workers' pneumoconiosis (ICD-11 CA60–CA6Z)

**What it is.** Dust breathed in at work lodges permanently in the lungs and scars them. Stone and sand dust cause silicosis, asbestos fibres cause asbestosis, coal dust causes black lung. All three are entirely caused by the work and all three are irreversible.

**Measured.** All the pneumoconiosis figures below are aggregate across types, because the primary GBD 2021 analysis does not report silicosis, asbestosis and coal workers' pneumoconiosis separately. Everything in this table was read off its source.

| Measure | 1990 | 2021 | Trend |
|---|---|---|---|
| Incident cases | 42,188 (35,786–48,913) | 62,866 (54,617–71,103) | Counts rose; age-standardised incidence roughly flat, estimated annual percentage change −0.02 (95 per cent CI −0.09 to 0.06) |
| Deaths | 17,471 (15,589–19,436) | 18,323 (16,041–20,916) | Counts rose slightly; age-standardised death rate fell from 0.46 to 0.22 per 100,000, estimated annual percentage change −1.21 |
| DALYs | — | 507,425, a 2017 figure cited from the paper's introduction | Only age-standardised DALY rates by region are reported for 2021 |
| Prevalence | Not reported as a global total | About 527,500 for 2021, cited in the introduction from a separate source rather than from GBD 2021 | Regional rates only; East Asia has the highest male rate at 19.00 per 100,000 |

Projections: roughly 62,061 incident cases in 2030 and 62,434 in 2035; roughly 15,246 deaths in 2030 and 13,863 in 2035.

Type-specific fragments exist, and none of them are GBD 2021 figures. For silicosis, China's National Occupational Disease Monitoring System reported an annual decline in incidence since 2010, average annual percentage change −4.7, and a separate 1990 to 2019 study reported a global decline in silica-attributed mortality, with an age-standardised mortality rate estimated annual percentage change of −1.22. For coal workers' pneumoconiosis, a GBD 2017 study reported declines in middle and low sociodemographic index regions without numbers, and incidence remains disproportionately high in low- and middle-income countries, again without figures. Asbestosis is reported as rising in high-sociodemographic-index countries, without figures.

Asbestos-related disease beyond asbestosis is roughly an order of magnitude larger. WHO estimates roughly 200,000 or more deaths a year from all occupational asbestos exposure, including mesothelioma at roughly 30,000 to 38,000 deaths a year and asbestos-attributed lung cancer. The asbestosis figure alone therefore understates asbestos mortality by roughly a factor of ten.

Silicosis is re-emerging in high-income countries through engineered stone benchtop fabrication. Australian and United States case series report rapid, severe, progressive silicosis in young workers, with roughly 20 to 40 per cent of screened engineered-stone workers affected in some Australian cohorts. Australia banned engineered stone from July 2024, the first national ban.

Disease appears after ten to thirty years of exposure, so incidence peaks in middle and older age, and accelerated and acute silicosis can appear within months to five years at very high exposures. East Asia has the highest male rate at 19.00 per 100,000, and the burden is concentrated in mining, construction, stone-working and shipbreaking economies.

**Where it starts.** The cause is known completely and precisely in all three, and that is the distinguishing feature of this entry: there is no uncertainty about aetiology at all.

Silicosis comes from inhaled respirable crystalline silica, in mining, quarrying, tunnelling, sandblasting, foundry work, ceramics, glass, stone cutting, engineered stone fabrication and gemstone polishing, with an established dose-response where risk rises with cumulative exposure and with concentration. Asbestosis comes from inhaled asbestos fibres, with the amphiboles crocidolite and amosite more potent than chrysotile for mesothelioma and both fibrogenic, in mining, insulation, shipbuilding, construction, brake linings and shipbreaking, and in secondary household exposure from workers' clothing. Coal workers' pneumoconiosis comes from inhaled coal mine dust, and the respirable silica content of the dust is a major determinant of severity, which is why modern United States cases in thin-seam Appalachian mining have been unusually severe and rapidly progressive.

Co-factors multiply risk. Smoking multiplies asbestos-related lung cancer risk roughly fifty-fold over non-smoking non-exposed people and roughly fivefold over non-smoking asbestos-exposed people — a multiplicative interaction, and one of the best-documented in occupational medicine. Silica exposure roughly triples tuberculosis risk and silicosis raises it further,

and silicotuberculosis is a major problem in southern African mining. Silica is an IARC Group 1 lung carcinogen, and asbestos is Group 1 for lung cancer, mesothelioma, laryngeal and ovarian cancer. Silica exposure is associated with rheumatoid arthritis, systemic sclerosis, lupus, ANCA-associated vasculitis and chronic kidney disease.

Why, at the same cumulative exposure, some workers develop progressive massive fibrosis and others only simple pneumoconiosis is not explained; host factors are suspected and not identified. There is no established safe exposure threshold for asbestos, and whether one exists for silica is disputed — the United States permissible limit of 50 µg/m³ is associated with measurable residual risk in modelling. The determinants of latency variation, from months to decades, are not understood. The reason modern Appalachian coal workers' pneumoconiosis is more severe than historical disease is attributed to silica content and not definitively established. Most importantly: in low- and middle-income countries, where most exposure occurs, there is essentially no surveillance, so the true incidence is unknown and the GBD figures almost certainly understate it substantially.

**Cure status.** RELIEF ONLY. This is the clearest RELIEF ONLY classification in either chapter.

No treatment removes or reverses pneumoconiosis. The dust is permanently retained, the fibrosis is established, and the disease progresses even after exposure ends; progression after cessation of exposure is documented in all three diseases. No drug has been shown to alter the course of any of them: corticosteroids, tetrandrine, whole-lung lavage and antifibrotics have been tried and none has established disease-modifying benefit in adequate trials. Whole-lung lavage removes some dust burden and is used in acute silicoproteinosis without altering long-term outcome. Lung transplantation is the only intervention that removes the diseased organ, and outcomes in silicosis are comparable to other fibrotic indications. Antifibrotics, nintedanib in particular, are indicated for progressive fibrosing interstitial lung disease, which can include pneumoconiosis, on the basis of INBUILD, and pneumoconiosis-specific trial evidence is thin.

Treating the complications is effective, and that matters: tuberculosis is curable, which is important in silicotuberculosis, and pneumothorax, cor pulmonale, infections and hypoxaemia are all treatable.

So the disease cannot be cured, cannot be stopped, and is entirely preventable. That combination is the whole point of this entry.

**Prevention.** Prevention is complete and the evidence is unambiguous: eliminating exposure eliminates the disease. Every grade here is STRONG.

*Banning asbestos — STRONG, and demonstrated at national scale.* Roughly 70 countries have banned all forms of asbestos. In the countries that banned it early — Scandinavia, the Netherlands, the UK in 1999, Australia in 2003 — mesothelioma incidence has peaked and begun to fall in the cohorts born after the ban, with a thirty- to forty-year lag. Chrysotile asbestos is still mined and used in Russia, Kazakhstan, China, India and elsewhere, and WHO, the International Labour Organization and every major scientific body call for a global ban. This is the single clearest preventable occupational disease burden in the world, and the obstacle is commercial rather than scientific.

*Substitution and process change — STRONG.* Replacing silica sand in abrasive blasting, replacing engineered stone, wet cutting instead of dry. Australia's engineered stone ban of July 2024 is the first national prohibition of a silica product.

*Engineering controls — STRONG*: wet methods, local exhaust ventilation, enclosure, on-tool dust extraction. Wet cutting reduces respirable silica generation by roughly 80 to 95 per cent in workplace measurements.

*Exposure limits and enforcement — STRONG where enforced.* The United States respirable crystalline silica standard of 50 µg/m³ from 2016 and comparable European limits reduce measured exposures; the evidence that enforcement reduces disease is historical and ecological, and residual risk remains at the current limits.

*Tuberculosis screening and preventive therapy in silica-exposed workers — STRONG*: silica exposure roughly triples tuberculosis risk, and isoniazid preventive therapy reduced tuberculosis incidence in South African gold miners.

*Smoking cessation — STRONG*, because of the multiplicative interaction with asbestos for lung cancer, roughly fiftyfold combined.

*Medical surveillance by chest radiography or computed tomography and spirometry — MODERATE* for detection and for removing workers from further exposure, which slows but does not stop progression.

*Respiratory protection — MODERATE.* Effective when correctly fitted and worn, and it is the last line of the hierarchy of controls rather than the first; real-world protection factors fall well below laboratory ratings.

*Compensation and surveillance systems — MODERATE*, indirectly: recognised compensable disease creates economic pressure for control.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Removal from further exposure | Slows but does not stop progression; it is the first action in every case | n/a | n/a | Nothing medically; the cost is the job |
| Tuberculosis treatment and preventive therapy | Curative for tuberculosis; isoniazid preventive therapy reduced tuberculosis incidence in silica-exposed miners | yes, all first-line agents | yes | tens of euro a full curative course; isoniazid prophylaxis a few to tens of euro |
| Pulmonary rehabilitation | Exercise capacity and quality of life improve, as in other fibrotic disease, plus 35 to 50 m on the six-minute walk | n/a | n/a | hundreds to thousands of euro |
| Long-term oxygen therapy | For chronic hypoxaemia; the chronic obstructive pulmonary disease survival evidence, three-year mortality 45.2 against 66.7 per cent, has not been replicated in pneumoconiosis | yes | yes | Concentrator hundreds to thousands of euro |
| Bronchodilators | Symptomatic where airflow obstruction coexists, which is common in coal workers | yes | yes | tens of euro a year |
| Influenza and pneumococcal vaccination | Infective exacerbations reduced | yes | yes | a few to tens of euro |
| Whole-lung lavage | Removes dust burden in acute silicoproteinosis; no effect on long-term outcome demonstrated | n/a | n/a | thousands to tens of thousands of euro |
| Corticosteroids | No established disease-modifying benefit | yes | yes | a few to tens of euro |
| Nintedanib, progressive fibrosing phenotype | INBUILD supports use in progressive fibrosing interstitial lung disease generally; pneumoconiosis-specific evidence is thin | no | no | tens of thousands of euro |
| Tetrandrine, used in China for silicosis | A claimed antifibrotic effect; the evidence is low quality and not accepted internationally | no | yes | hundreds of euro |
| Lung transplantation | The only intervention that removes the diseased organ | n/a | n/a | hundreds of thousands of euro in the first year |
| Compensation and income support | Not a medical treatment, and it is the principal intervention available to an affected worker | n/a | n/a | Varies by jurisdiction |

**Simple means.** Wet cutting is the single highest-impact simple means in either chapter, because it prevents an incurable disease with water. Water applied at the cutting point reduces respirable silica generation by roughly 80 to 95 per cent. A hose, a water-bottle attachment or a water-fed tool.

Working outdoors or in ventilated space, positioning upwind, enclosing the dusty process, wetting down before sweeping, and never dry-sweeping settled dust are all free or nearly free and all reduce exposure substantially. Not using the material at all — substituting non-silica abrasives, not using asbestos, not using engineered stone — is achievable at national scale, as Australia's engineered stone ban shows.

Changing and washing work clothes before going home prevents a disease in someone who never entered the workplace: household asbestosis and mesothelioma in workers' spouses and children from contaminated clothing is documented, and washing clothes at work is free.

Respirators cost a few to tens of euro for disposable FFP2 or FFP3 masks and tens of euro for reusable half-masks with P3 filters. They are effective when fitted and worn, and they are the last line of defence; fit-testing matters, and beard growth, poor fit and discomfort reduce real-world protection substantially.

Smoking cessation is the largest single mortality intervention available to an asbestos-exposed worker: the multiplicative interaction means cessation removes most of the lung-cancer excess, from roughly fiftyfold combined down toward the fivefold exposure-only level. It is free.

Tuberculosis treatment and isoniazid preventive therapy cost tens of euro for a full curative course, with all drugs listed and off-patent. In silica-exposed populations that is the treatable, curable part of the disease burden, and it is cheap. Pulmonary rehabilitation and walking give plus 35 to 50 m on the six-minute walk. Breathing retraining, pacing, forward-lean positioning and a fan to the face relieve breathlessness as in the fibrosis entry. Low-dose morphine for refractory breathlessness costs tens to hundreds of euro a year, listed and off-patent.

The honest summary, stated plainly. There is no treatment for these diseases and there never has been. Everything in the treatment table above is supportive or treats a complication. The entire effective intervention is prevention, and the core of prevention — water on the blade, not using asbestos, washing the clothes, not smoking — requires no industrial supply chain at all. The chain that is required is regulatory and organisational: exposure limits, inspection, enforcement and compensation. The binding constraint is not technology or money; it is whether the controls are applied.

**Gaps.** GBD 2021 does not report silicosis, asbestosis and coal workers' pneumoconiosis separately. For three diseases with entirely different causes, prevention and politics, only the aggregate exists in the primary global dataset, and that is a serious structural gap. No global prevalence total is reported in GBD 2021; the figure of about 527,500 comes from a separate source cited in the paper's introduction rather than from GBD 2021. No 2021 global DALY total is given, only the 2017 figure of 507,425, and the source round for that DALY figure is not clearly named in the paper. Surveillance is weakest where exposure is heaviest: mining, stone-working and shipbreaking in low- and middle-income countries have little or no occupational disease registration, so the 62,866 incident cases and 18,323 deaths are near-certainly substantial underestimates. Age-standardised rates are flat or falling while absolute counts rise — the disease is being described as improving while more people get it. The asbestosis figure captures only a small part of asbestos mortality; mesothelioma and asbestos-attributed lung cancer are counted elsewhere, and WHO's roughly 200,000 or more annual asbestos deaths is about an order of magnitude above the pneumoconiosis total. Engineered-stone silicosis is a new epidemic with no global figures at all, only national case series. Whether a safe exposure threshold exists for silica is disputed, and for asbestos none is established. No safe or effective treatment exists, and tetrandrine is used in China on evidence not accepted elsewhere — a genuine international disagreement about a drug given to patients. Asbestos is still mined and traded while every scientific body calls for a ban; that is a gap between evidence and policy rather than a gap in evidence.

# The upper airway, the sleeping airway, and the pleural space

## Sleep-disordered breathing — obstructive sleep apnoea (ICD-11 7A41, chapter 07)

A note on placement. In ICD-11 the sleep-related breathing disorders were moved into a new standalone chapter 07, sleep-wake disorders, having been dispersed across the nervous system, mental and behavioural, and respiratory chapters in ICD-10. Obstructive sleep apnoea is therefore coded in chapter 07 rather than chapter 12. It is placed here because it is managed as a respiratory condition and because the respiratory chapter is where a reference

work's reader will look for it. No condition in ICD-11 chapter 07 is a GBD level-3 cause, so no GBD burden figures exist for it, and its burden is distributed in GBD across cardiovascular, mental and respiratory causes.

**What it is.** The throat collapses repeatedly during sleep, so breathing stops for seconds at a time, dozens or hundreds of times a night. The person snores, wakes unrefreshed and is sleepy all day. It is very common and mostly undiagnosed.

**Measured.** Global prevalence among **adults aged 30 to 69**, using the 2012 American Academy of Sleep Medicine criteria. Mild to severe obstructive sleep apnoea, apnoea-hypopnoea index 5 events an hour or above: 936 million (95 per cent CI 903 to 970 million). Moderate to severe disease, index 15 or above: 425 million (399 to 450 million). The age band is part of the figure and must travel with it: both numbers are for adults aged 30 to 69 only, not all adults, and a book that prints 936 million people worldwide without the age band overstates the claim's scope. **The study's funding statement is the single word ResMed**, which manufactures continuous positive airway pressure devices, and that is printed wherever either figure is used.

No GBD death or DALY figure exists, for the reason given in the placement note. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Prevalence estimates are highly sensitive to the diagnostic threshold and the scoring rules: the 2012 criteria give roughly double the prevalence of the older 1999 criteria, because hypopnoeas with 3 rather than 4 per cent desaturation are counted. Population studies find moderate to severe disease in roughly 10 to 17 per cent of men and 3 to 9 per cent of women in middle age, in the Wisconsin Sleep Cohort and HypnoLaus. Roughly 80 to 90 per cent of those affected are undiagnosed. Prevalence rises with age to a plateau around 60 to 70, with a male predominance of roughly 2 or 3 to 1 narrowing after menopause. Central sleep apnoea and obesity hypoventilation syndrome are separate entities; obesity hypoventilation affects roughly 0.15 to 0.3 per cent of adults and 8 to 20 per cent of patients referred for sleep apnoea with a body mass index above 30.

**Where it starts.** Obesity is the dominant modifiable factor: a 10 per cent weight gain predicts roughly a 32 per cent increase in the apnoea-hypopnoea index and a sixfold increase in the odds of developing moderate to severe disease, from the Wisconsin Sleep Cohort. For scale, 940 million adults, about 16 per cent, were living with obesity in 2024, and adult obesity has more than doubled since 1990. Craniofacial anatomy matters: retrognathia, maxillary narrowing, a long soft palate, a large tongue. East Asian populations have comparable prevalence to western populations at substantially lower body mass index because of craniofacial structure, which is an important and well-documented finding. Male sex, age and menopause contribute. Tonsillar and adenoidal hypertrophy is the dominant cause in children, and the reason adenotonsillectomy is curative in childhood disease. Alcohol and sedatives before sleep reduce upper airway tone. Smoking, nasal obstruction and supine sleep position contribute, as do hypothyroidism, acromegaly, Down syndrome and neuromuscular disease. Rostral fluid redistribution overnight contributes in heart failure and kidney failure.

The apnoea-hypopnoea index correlates poorly with symptoms and with outcomes: many people with a high index are not sleepy, and sleepiness does not track the index closely. That is the central problem of the field — the defining measurement may not be the clinically relevant one — and alternative metrics such as hypoxic burden and arousal intensity are proposed and not standardised. Which patients will derive cardiovascular benefit from treatment is not known, and the randomised trials have been null. Whether treating asymptomatic disease found on screening helps at all is unknown, and no trial supports it.

**Cure status.** Adults: CONTROLLABLE. Children with tonsillar and adenoidal hypertrophy: CURABLE by adenotonsillectomy. Selected adults with skeletal retrusion: CURABLE in roughly 40 to 45 per cent by maxillomandibular advancement, an index below 5, in meta-analysis. Disease caused by hypothyroidism or acromegaly: CURABLE by correcting the cause.

Continuous positive airway pressure abolishes the obstruction while it is worn and the apnoea returns the night it is stopped. That is the clearest "holds the state" treatment in either chapter.

Weight loss is genuinely disease-modifying. Bariatric surgery and large dietary weight loss produce remission in roughly 40 to 60 per cent of patients, and the Sleep AHEAD trial showed the index fell 5.2 events an hour more with intensive lifestyle intervention than control, with remission in roughly three times as many participants.

Adenotonsillectomy in children is curative in roughly 70 to 80 per cent of otherwise healthy children with the condition. The CHAT trial, with 464 children, showed improved behaviour, quality of life and polysomnographic normalisation against watchful waiting, 79 against 46 per cent. That is a genuine cure of a common childhood condition by one operation. Maxillomandibular advancement surgery in selected adults with skeletal retrusion gives surgical success in roughly 85 to 90 per cent and cure, an index below 5, in roughly 40 to 45 per cent in meta-analysis — the most effective surgical option in adults. Correcting hypothyroidism or acromegaly resolves the apnoea they caused. Hypoglossal nerve stimulation reduced the index by 68 per cent at twelve months in the STAR trial in selected patients and is not a cure.

**Prevention.**

*Weight management — STRONG, and the only intervention with a demonstrated effect on incidence.* A 10 per cent weight gain predicts roughly a 32 per cent increase in the index and sixfold higher odds of developing moderate to severe disease.

*Avoiding alcohol and sedatives before sleep — MODERATE*. *Smoking cessation — WEAK*. *Treating nasal obstruction and allergic rhinitis — WEAK* for severity.

*Early treatment of childhood tonsillar hypertrophy — MODERATE*, and it may prevent persistence into adulthood, though that is not established by trial. *Orthodontic maxillary expansion in children — MODERATE* in selected cases.

*Screening asymptomatic adults — NOT RECOMMENDED, and CONTESTED.* The United States Preventive Services Task Force concluded in 2017 and again in 2022 that the evidence is insufficient to assess the balance of benefits and harms of screening asymptomatic adults. Given the null cardiovascular trials, population screening has no demonstrated benefit.

*Nothing prevents the craniofacial contribution*, which is the dominant factor in much of Asia.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Continuous positive airway pressure | Sleepiness, quality of life and blood pressure improve; cardiovascular events do not. The SAVE trial, 2,717 randomised, 1,346 to treatment and 1,341 to usual care, mean 3.7 years follow-up: primary composite of serious cardiovascular events 17 against 15.4 per cent, hazard ratio 1.1 (95 per cent CI 0.91–1.32, p=0.34) — **no benefit**. Mean use 3.3 hours a night, with only about 42 per cent using it four hours or more. It did improve daytime sleepiness, health-related quality of life, mood and work attendance. RICCADSA and ISAACC were also null for cardiovascular events. Blood pressure falls by roughly 2 to 3 mmHg systolic on meta-analysis, more in resistant hypertension | no | n/a, a device | Machine hundreds to thousands of euro lasting five to ten years; masks and filters hundreds of euro a year. Another chapter of this book gives the device as hundreds of US dollars one-off and consumables as hundreds of US dollars a year, with no service life stated; both stand |
| Mandibular advancement, an oral appliance | The index reduced by roughly 50 per cent, less than continuous positive airway pressure, with better adherence, so health outcomes are often equivalent in randomised comparisons | no | n/a | hundreds to thousands of euro custom; tens to hundreds of euro thermoplastic |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Weight loss by lifestyle intervention | Sleep AHEAD: the index 5.2 events an hour lower than control, with roughly threefold higher remission | n/a | n/a | Nothing |
| Bariatric surgery | Remission in roughly 40 to 60 per cent | n/a | n/a | thousands to tens of thousands of euro |
| Tirzepatide | SURMOUNT-OSA, 469 patients, 2024: the index reduced by 25 to 29 events an hour against 5 to 6 with placebo — the first drug with a large effect on severity | no | no | tens of thousands of euro a year |
| Adenotonsillectomy in children | CHAT: polysomnographic normalisation 79 against 46 per cent with watchful waiting; behaviour and quality of life improved | n/a | n/a | thousands of euro |
| Maxillomandibular advancement in adults | Surgical success 85 to 90 per cent; cure, index below 5, in 40 to 45 per cent | n/a | n/a | tens of thousands of euro |
| Positional therapy | Effective in the roughly 25 to 30 per cent with supine-predominant disease | n/a | n/a | tens to hundreds of euro or free with improvised methods |
| Hypoglossal nerve stimulation | STAR: the index reduced 68 per cent at twelve months in selected patients | no | no | tens of thousands of euro |
| Non-invasive ventilation in obesity hypoventilation | **Reduces mortality** in obesity hypoventilation syndrome, unlike continuous positive airway pressure in sleep apnoea; the Pickwick trial | n/a | n/a | thousands of euro |
| Modafinil or solriamfetol, residual sleepiness on treatment | Wakefulness improved; symptomatic | no | Modafinil yes | Modafinil hundreds of euro; solriamfetol thousands to tens of thousands of euro |
| Supplemental oxygen alone | Oxygenation improves; sleepiness and the index do not, and it may prolong apnoeas. **Not a treatment for this condition** | yes, oxygen | yes | — |

**Simple means.** Weight loss is the only intervention that modifies the disease itself: the index 5.2 events an hour lower than control in Sleep AHEAD with roughly threefold higher remission, and a 10 per cent weight gain raises the index roughly 32 per cent. It costs nothing and is hard.

Positional therapy can be improvised at no cost. In the 25 to 30 per cent with supine-predominant disease, keeping off the back abolishes much of the problem. A tennis ball sewn into the back of a shirt, a backpack or a pillow wedge — tested against commercial devices with comparable short-term effect, and adherence to improvised methods is poor over months.

Avoiding alcohol and sedatives in the evening is free and the effect on upper airway tone is immediate. Raising the head of the bed by 30 to 45 degrees reduces the index measurably in small studies: bricks under the bed legs. Nasal saline and treating nasal obstruction is cheap and improves treatment tolerance and reduces mouth breathing.

Myofunctional therapy — tongue and soft-palate exercises, and didgeridoo or wind-instrument playing — reduces the index by roughly 50 per cent and reduces snoring in small randomised trials. No equipment, ten to twenty minutes daily. The evidence is from small trials and effect sizes vary widely.

Thermoplastic boil-and-bite mandibular advancement devices cost tens to hundreds of euro against hundreds to thousands of euro for custom ones; they are less effective and less well tolerated and are far cheaper.

The honest comparison between a thermoplastic device or a tennis ball and a hundreds to thousands of euro machine: continuous positive airway pressure controls the apnoea best

and is used only 3.3 hours a night on average, while the cheap measures have smaller effects and comparable real-world adherence problems. Because the randomised cardiovascular trials were null, the realistic goal of all of them is symptom relief, and for symptom relief the cheap options are a reasonable first step where the machine is unavailable.

Recognising the condition takes eight questions on paper and no equipment. Witnessed apnoeas, loud snoring, daytime sleepiness and the STOP-BANG questionnaire identify high-risk individuals with a sensitivity of around 84 to 93 per cent for moderate to severe disease, with low specificity. Confirmation needs at minimum overnight oximetry, a tens to hundreds of euro device, and preferably polysomnography or home sleep testing.

The hard limit. Diagnosis requires overnight measurement — oximetry at minimum, ideally a home sleep apnoea test. Continuous positive airway pressure requires a machine and mains power. Where neither exists, weight loss, position, alcohol avoidance and oropharyngeal exercises are the whole of what can be offered, and they address symptoms rather than any demonstrated cardiovascular risk.

**Gaps.** ICD-11 places sleep-disordered breathing in chapter 07, and no condition in chapter 07 is a GBD level-3 cause, so no GBD burden figures exist. A reference work must treat that chapter as a structural addition with no corresponding burden series. For a condition affecting 936 million people aged 30 to 69 there is no global mortality or DALY figure at all, and this entry is part of the seventeen-condition gap in this chapter's introduction. The 936 million and 425 million figures are from a single literature-based analysis funded by ResMed rather than from a population measurement programme, and both are for adults aged 30 to 69 only. Prevalence doubles or halves with the scoring criteria used, 2012 against 1999, so the headline figure is definition-dependent to an unusual degree.

Continuous positive airway pressure does not reduce cardiovascular events: SAVE gave a hazard ratio of 1.1 at p=0.34, and RICCADSA and ISAACC were also null. That contradicts a very large observational literature and a great deal of clinical and commercial messaging. The standard defence is that adherence was too low, at 3.3 hours with 42 per cent using four hours or more, and that sleepy patients were excluded — both are true and neither has been tested in a trial that resolves the question. The null results and the adherence figures are printed together.

The apnoea-hypopnoea index correlates poorly with symptoms and outcomes, and no replacement metric is standardised: the disease is defined by a number that may not be the right number. Screening asymptomatic adults has no demonstrated benefit, and screening is widely promoted. Between 80 and 90 per cent is undiagnosed, so all clinical-cohort data are heavily selected. Oral appliances are less effective than the machine on the index and often equivalent on outcomes because of adherence, and the field has no agreed way to handle that trade-off. Tirzepatide's large effect on the index has no outcome data and costs tens of thousands of euro a year. The craniofacial contribution means body-mass-index-based risk models developed in western populations underestimate risk in east Asian populations. Device and consumable prices differ between chapters of this book, in currency and in range, and both stand.

## Chronic rhinosinusitis (ICD-11 CA0A)

**What it is.** The lining of the nose and the sinuses stays inflamed for months. The nose is blocked, discharge runs, the face feels full and smell fades. Some people grow polyps in the sinuses.

**Measured.** No global prevalence, death or DALY figure for chronic rhinosinusitis was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all, and for a condition affecting roughly 10 per cent of adults with quality-of-life impairment comparable to angina and chronic obstructive pulmonary disease, it is one of the largest unmeasured burdens in either chapter.

Prevalence by symptom-based criteria is roughly 10.9 per cent of adults in Europe, from the GA²LEN multicentre survey across twelve countries, 11.9 per cent in the United States, and roughly 8 per cent in China. Prevalence falls to roughly 3 to 6 per cent when endoscopic or computed tomographic confirmation is required rather than symptoms alone — a two- to threefold difference driven entirely by the definition. Chronic rhinosinusitis with nasal polyps affects roughly 2 to 4 per cent of adults, and the form without polyps is the larger group.

Mortality is essentially zero and the burden is entirely morbidity. Quality-of-life impairment is comparable to angina, chronic obstructive pulmonary disease and chronic back pain on generic instruments in several studies, which is one of the better-documented findings in the field. Direct and indirect costs are high: roughly US$10 to 13 billion a year in the United States, much of it productivity loss, and roughly €1,500 to €2,000 a patient-year in European estimates. Prevalence peaks in middle age, roughly 40 to 60. Reported prevalence is broadly similar across high-income countries, and data from low-income countries are very thin.

**Where it starts.** Allergic rhinitis coexists in roughly 40 to 80 per cent of cases, though causality is contested. Asthma coexists in roughly 20 to 60 per cent, and the association is strongest with polyps and with eosinophilic disease — the united airway pattern. Aspirin-exacerbated respiratory disease, combining asthma, polyps and NSAID sensitivity, affects roughly 9 to 16 per cent of patients with polyps, and that subgroup has the most severe and recurrent disease. Smoking and second-hand smoke carry an odds ratio of roughly 1.5 to 2. Anatomical factors — septal deviation, concha bullosa — carry a weaker association than is widely assumed, and surgical correction of anatomy alone often does not resolve the disease. Impaired mucociliary clearance from primary ciliary dyskinesia or cystic fibrosis, where chronic rhinosinusitis affects the great majority, contributes. Immunodeficiency — common variable immunodeficiency, specific antibody deficiency — accounts for roughly 10 to 20 per cent of refractory cases in referral series. Biofilm formation and Staphylococcus aureus superantigen are proposed mechanisms in polyposis and neither is established as causal. Allergic fungal rhinosinusitis occurs in a minority, and invasive fungal sinusitis in immunocompromised patients is a separate, rapidly fatal disease. Occupational irritant exposure, air pollution and gastro-oesophageal reflux contribute, the last contested. Granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis present with destructive sinus disease — rare, and the one group where missing the diagnosis is dangerous.

The cause is not established. The condition is defined by symptoms and duration rather than by a mechanism, and it is almost certainly several diseases. The division into type-2 eosinophilic, polyp-associated, biologic-responsive inflammation and non-type-2 inflammation is the most useful current framework and is not a complete account. Whether bacteria cause the chronic phase or colonise an already inflamed mucosa is unresolved, which is why the antibiotic evidence is so weak. Why polyps recur after apparently complete surgery in roughly 40 per cent of cases is not explained.

**Cure status.** Most cases: CONTROLLABLE. Odontogenic sinusitis, roughly 10 to 30 per cent of unilateral maxillary sinusitis: CURABLE by treating the dental source. A fungal ball, an obstructing tumour or a foreign body: CURABLE by removal. Acute rhinosinusitis: SELF-LIMITING.

Neither medical nor surgical treatment removes the disease in the common forms. Intranasal corticosteroids control symptoms while used, and symptoms return on stopping. Endoscopic sinus surgery improves symptoms substantially and is not curative: polyps recur in roughly 40 per cent within five years, and revision surgery rates are roughly 15 to 20 per cent. Biologics shrink polyps and improve symptoms dramatically and the effect reverses on withdrawal, which is the clearest demonstration that this is control rather than cure. Immunoglobulin replacement in antibody deficiency changes the course.

Acute rhinosinusitis is SELF-LIMITING, and that matters because acute sinusitis is one of the largest single reasons for inappropriate antibiotic prescribing worldwide. Roughly 70 to 80 per cent resolve within two weeks without antibiotics. Cochrane finds antibiotics give a small benefit, with a number needed to treat of roughly 11 to 15 for cure at seven to fourteen days, against substantial adverse-effect rates.

**Prevention.**

*Avoiding unnecessary antibiotics in acute rhinosinusitis — STRONG* as a stewardship measure, since 70 to 80 per cent resolve spontaneously and the number needed to treat is 11 to 15.

*Avoiding NSAIDs in aspirin-exacerbated respiratory disease — STRONG* for preventing acute deterioration in that subgroup. *Treating dental disease — STRONG* for odontogenic sinusitis specifically.

*Smoking cessation and avoiding second-hand smoke — MODERATE*, odds ratio 1.5 to 2. *Occupational irritant control — MODERATE*.

*Aspirin desensitisation in aspirin-exacerbated respiratory disease — MODERATE*: polyp recurrence and revision surgery are reduced in that subgroup.

*Early diagnosis of immunodeficiency and vasculitis — MODERATE* in the refractory minority.

*Treating allergic rhinitis — WEAK*: the association is strong and the preventive effect of treating it is not established. *Nasal saline irrigation — WEAK* for preventing recurrence.

*Nothing prevents the common forms.*

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Intranasal corticosteroid, beclometasone, budesonide, fluticasone, mometasone | First-line. Cochrane: symptoms improved and polyp size reduced against placebo, at moderate to high certainty | yes, beclometasone | yes | tens of euro |
| Nasal saline irrigation, high volume | Cochrane: symptoms improved as an adjunct, at low to moderate certainty; large-volume low-pressure irrigation is better than a spray | n/a | n/a | a few to tens of euro or near zero home-made |
| Short course of oral corticosteroid | Substantial short-term polyp and symptom reduction; the effect wanes within three to six months and repeated courses carry cumulative harm | yes | yes | a few euro a course |
| Long-term macrolide, azithromycin or clarithromycin | Benefit in non-type-2 disease with normal IgE; the trials are inconsistent and the evidence is weak | yes | yes | tens to hundreds of euro |
| Antibiotics for acute exacerbations | Modest; acute rhinosinusitis number needed to treat 11 to 15, with 70 to 80 per cent resolving spontaneously | yes, amoxicillin, co-amoxiclav, doxycycline; amoxicillin is listed first-choice for sinusitis | yes | a few to tens of euro a course |
| Endoscopic sinus surgery | Substantial symptom improvement; polyp recurrence about 40 per cent at five years, revision 15 to 20 per cent | n/a | n/a | thousands of euro |
| Dupilumab, anti-interleukin-4 receptor alpha | SINUS-24 and SINUS-52, 724 patients: nasal polyp score −1.80 against +0.17, nasal congestion −1.25 against −0.38, smell markedly improved, and the need for surgery reduced by roughly 75 per cent | no | no | tens of thousands of euro |
| Omalizumab, anti-IgE | POLYP 1 and 2: polyp score and symptoms improved | **NOT on the 24th Model List in any form** | Biosimilars emerging | tens of thousands of euro |
| Mepolizumab, anti-interleukin-5 | SYNAPSE: polyp score and need for surgery reduced | no | no | tens of thousands of euro |
| Aspirin desensitisation, aspirin-exacerbated respiratory disease | Polyp recurrence and revision surgery reduced in that subgroup | yes, aspirin | yes | a few to tens of euro |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Antifungals, topical or systemic | **No benefit** in chronic rhinosinusitis, per Cochrane — a negative result against a once-popular hypothesis | Varies | Varies | — |
| Antihistamines, decongestants, montelukast | Little evidence in chronic rhinosinusitis itself | partly | yes | tens to hundreds of euro |

The price asymmetry is extreme here too. An intranasal corticosteroid at tens of euro a patient-year is first-line and effective for most; the biologics cost tens of thousands of euro a patient-year for the severe polyp minority, in a condition with essentially zero mortality.

**Simple means.** Nasal saline irrigation costs essentially nothing beyond the vessel. Home-made isotonic or hypertonic saline from table or non-iodised salt, baking soda and boiled or distilled water, delivered by a neti pot, a squeeze bottle or a syringe. Cochrane supports symptom improvement as an adjunct, and large-volume low-pressure irrigation is better than a spray. One safety requirement must accompany the advice: the water must be boiled, distilled or appropriately filtered, because fatal Naegleria fowleri and Acanthamoeba infections have followed irrigation with untreated tap water.

Steam inhalation does not work, and that is worth printing because it is the commoner home remedy. Cochrane and the large UK primary-care trial found steam inhalation gave no benefit for chronic or recurrent sinus symptoms, while nasal irrigation did help.

An intranasal corticosteroid at tens of euro a patient-year is the single most effective medical treatment, with beclometasone on the Essential Medicines List and off-patent. It needs a pharmaceutical chain, a cheap one. Smoking cessation and smoke-free homes are free. Avoiding NSAIDs in aspirin-exacerbated disease is free and prevents severe reactions. Dental care cures odontogenic sinusitis, which is 10 to 30 per cent of unilateral maxillary disease. Not taking antibiotics for acute sinusitis is a free decision that avoids harm and resistance: 70 to 80 per cent resolve spontaneously and the number needed to treat is 11 to 15. Sleeping with the head elevated, humidifying dry indoor air and avoiding known irritants are low-cost symptomatic measures with little trial evidence.

The hard limit. Distinguishing chronic rhinosinusitis from a tumour, from invasive fungal disease in the immunocompromised and from vasculitis requires endoscopy and computed tomography. Those three are rare and dangerous, and missing them is the main risk of managing the condition on symptoms alone. The common disease itself can be treated substantially with saline and a cheap corticosteroid spray.

**Gaps.** No GBD global burden figure for chronic rhinosinusitis was retrieved for a condition affecting roughly 10 per cent of adults with quality-of-life impairment comparable to angina and chronic obstructive pulmonary disease, and this entry is part of the seventeen-condition gap in this chapter's introduction. Prevalence varies two- to threefold with the definition — symptoms alone at 10.9 to 11.9 per cent against endoscopic or computed tomographic confirmation at 3 to 6 per cent — and there is no agreed diagnostic standard for epidemiology. The cause is unknown and the condition is almost certainly several diseases pooled by symptom definition. Why polyps recur in about 40 per cent after complete surgery is unexplained. Antifungals: Cochrane null, against a once-dominant hypothesis. Steam inhalation: null, against near-universal popular use. Long-term macrolides: inconsistent trials, and the phenotype that benefits is not reliably identifiable in practice. Biologic against surgery has barely been compared head-to-head, and the cost difference is roughly five- to fifteenfold. Almost all epidemiology and all trial evidence comes from high-income countries, and data from low-income settings are very thin. Repeated oral corticosteroid courses are widely used with cumulative harm that is acknowledged and not well quantified in this population. Omalizumab is not on the 24th Model List in any form.

## Allergic rhinitis (ICD-11 CA08)

**What it is.** Pollen, dust mite or animal protein triggers an allergic reaction in the lining of the nose. It runs, blocks, itches and sets off sneezing, often with itchy eyes. It is not dangerous and it is very common, and it wrecks sleep and concentration. Mould is also a trigger. Symptoms come seasonally or year-round.

**Measured.** No global prevalence, death or DALY figure for allergic rhinitis was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Prevalence is roughly 10 to 30 per cent of adults and up to 40 per cent of children in high-income countries. The ISAAC and Global Asthma Network studies found rhinoconjunctivitis symptoms in roughly 8.5 per cent of six- and seven-year-olds and 14.6 per cent of thirteen- and fourteen-year-olds across 98 countries, with a twentyfold range between centres. The estimated global total is roughly 400 million people, and that is a modelled figure rather than a measurement. Mortality is essentially zero. The condition coexists with asthma in roughly 15 to 38 per cent of patients, and roughly 80 per cent of asthmatics have rhinitis — the one airway relation.

A second source line gives a global range of 10 to 40 per cent, depending on definition and region, and says about 20 per cent is commonly quoted for high-income countries†. The International Study of Asthma and Allergies in Childhood covered about 1.2 million children in 98 countries in its third phase†. It found current rhinoconjunctivitis symptoms in roughly 8 to 9 per cent of children aged 6 to 7 and roughly 14 to 15 per cent of adolescents aged 13 to 14†. Between-centre variation was more than ten-fold, from under 1 per cent to over 45 per cent†. The two source lines disagree on that range: more than ten-fold here, twentyfold in the paragraph above. Both are printed. The ten-fold figure carries a dagger; the twentyfold figure names its source, which was not opened again.

There is one well-measured functional effect. A UK study found students with symptoms on the day of an examination were roughly 40 per cent more likely to drop a grade than predicted, and sedating antihistamine use increased that further. Onset is usually in childhood or adolescence, prevalence peaks in the twenties and thirties, and it declines in later life. Prevalence rose substantially in high-income countries through the late twentieth century and has plateaued in many, and it is still rising in many low- and middle-income countries as they urbanise.

One source line gives onset in childhood or early adult life. The paragraph above gives childhood or adolescence. The two lines agree on the peak and on the decline in later life.

One source line states that GBD counts allergic rhinitis among conditions with high prevalence and low disability weight, so that its years lived with disability are substantial while its mortality is zero. The paragraph above records that no GBD 2023 figure for allergic rhinitis was retrieved. The two source lines disagree. One asserts a substantial GBD total without a figure. The other found no figure to read.

The third phase of the childhood survey, set against the first, showed increases in most low- and middle-income centres and a plateau or decline in several high-prevalence high-income centres. The trend above names its source, which was not opened again; here it carries a dagger.

One source line reports the same examination finding without a figure: United Kingdom adolescents with symptomatic seasonal rhinitis sitting summer examinations did measurably worse. It carries a dagger, where the finding above names its source, which was not opened again.

**Where it starts.** IgE sensitisation to inhaled allergens: house dust mite, grass, tree and weed pollens, cat, dog, horse, cockroach, Alternaria and other moulds. Atopic predisposition, with a heritability of roughly 33 to 91 per cent across twin studies, strong familial clustering and shared genome-wide loci with asthma and eczema. The atopic march — eczema and food allergy in infancy, then asthma and allergic rhinitis — is a consistent temporal sequence whose mechanism is incompletely understood. Urban living and the loss of early microbial exposure: growing up on a traditional farm roughly halves allergic rhinitis and sensitisation risk, from PARSIFAL, GABRIELA and the Amish against Hutterite comparison, which is the most reproducible protective finding in the field. Air pollution, particularly traffic-related

and diesel exhaust, is associated with sensitisation and symptom severity, and diesel particles act as an adjuvant to pollen allergen in experimental studies. Climate change has changed the exposure itself: pollen seasons in the northern hemisphere have lengthened by roughly 20 days and pollen concentrations have risen by roughly 20 per cent since 1990 in North American monitoring data. Second-hand tobacco smoke in childhood contributes, and caesarean delivery and early antibiotic use are both CONTESTED and confounded. Occupational rhinitis from flour, latex, laboratory animals, enzymes and wood dust usually precedes occupational asthma and is a warning sign.

On re-exposure, mast cells degranulate and release histamine, leukotrienes and prostaglandins, and a late-phase infiltrate of eosinophils follows. This sequence is established.

A second source line puts twin-study heritability at roughly 0.33 to 0.75, commonly around 0.6†. The paragraph above gives roughly 33 to 91 per cent. The two source lines disagree on the upper bound. The first figure carries a dagger; the second names its source, which was not opened again. Genome-wide association studies have identified over 40 loci, each with a small effect. Parental atopy roughly doubles to triples a child's risk, and two atopic parents raise it more.

The same line states the farm effect as roughly 50 per cent lower risk of allergic rhinitis and atopic sensitisation in children who grow up on a traditional farm with livestock and drink unprocessed farm milk, in PARSIFAL, GABRIELA and related European studies. The association is strong, dose-related with the diversity of microbial exposure, replicated and observational. The paragraph above gives the same finding with a named source that was not opened again; here it carries a dagger.

The same line lists as established risk factors higher socioeconomic status in low- and middle-income settings, small family size, and indoor dampness and mould. It also lists caesarean delivery (modest) and early-life antibiotic exposure (modest and confounded) as established, and traffic-related air pollution as modest and consistent. The paragraph above calls caesarean delivery and early antibiotic use CONTESTED and confounded. The two source lines disagree on whether these two are established.

The pollen figures come from Anderegg and colleagues, *PNAS*, 2021, for North America between 1990 and 2018. Season length and pollen intensity are increasing with rising temperatures and carbon dioxide.

Pet ownership in infancy, long assumed to raise risk, shows neutral-to-protective associations in cohort studies.

Why sensitisation produces symptoms in some people and silent sensitisation in others is not explained — roughly a third of sensitised individuals have no symptoms. The hygiene and microbial-diversity hypothesis explains the epidemiology well and has produced no preventive intervention that works. Why prevalence rose and then plateaued is unexplained. The mechanism of the atopic march is not established, and whether treating one stage prevents the next is the central unresolved question.

Attempts to reduce the farm effect to a single organism or endotoxin dose have not succeeded. A large share of people with specific IgE to an allergen have no symptoms on exposure. That makes allergy testing a poor population-screening tool.

**Cure status.** CONTROLLABLE, by both routes. Drugs and allergen immunotherapy control the disease. Avoidance where a single removable allergen is responsible also controls it.

Pharmacotherapy controls symptoms while taken and they return on stopping. Allergen immunotherapy is the only treatment in either chapter with demonstrated persistence of benefit after withdrawal. The Preventive Allergy Treatment study, with 205 children on three years of grass or birch subcutaneous immunotherapy, found asthma developed in significantly fewer treated children and the effect persisted seven and ten years after treatment ended, with an odds ratio of roughly 2.5 for asthma in the control group. The GAP trial, with 812 children on a three-year grass sublingual tablet and two years of follow-up, reduced asthma symptoms and medication use at two years post-treatment, and its primary endpoint of asthma onset was not met. GT-08, with a grass sublingual tablet, showed symptom benefit sustained for two years after three years of treatment. Whether to call it cure is contested;

it is at minimum genuine disease modification and in many patients effectively a lasting remission.

A second source line gives the improvement in symptom and medication scores against placebo on meta-analysis as roughly 20 to 40 per cent†, a modest average that conceals large responders and non-responders. The treatment table below gives roughly 30 to 40 per cent. The two source lines disagree on the lower bound. The first figure carries a dagger; the second names its source, which was not opened again. The same line reports persistent benefit and reduced asthma development at 10 years in the Preventive Allergy Treatment study. It reports a sustained effect in the two years after a three-year course of a five-grass sublingual tablet in the GAP trial. It gives the asthma result as roughly 2.5-fold lower odds in treated children at long-term follow-up†, and calls this the strongest claim for disease modification in allergy. The paragraph above gives the same odds ratio, roughly 2.5, and names a source that was not opened again; here it carries a dagger. Treatment takes three to five years, and the subcutaneous route carries a small risk of a systemic reaction.

Avoidance where a single removable allergen is responsible — rehoming a cat, changing an occupation — is CONTROLLABLE and not a cure. The sensitisation persists and the symptoms return on re-exposure, so staying away is a continuing measure. This book draws the same line elsewhere: coeliac disease on a strict lifelong gluten-free diet is CONTROLLABLE, because reintroducing gluten reinstates the disease. Natural remission occurs in a minority with age.

The two source lines weigh avoidance differently, and the weaker reading is the better supported. One holds it curative with a single removable allergen. The other finds the evidence for allergen avoidance individually weak, and grades pet removal once sensitised WEAK, saying the evidence does not support routine pet removal. There is no avoidance row in the treatment table and no outcome figure behind the curative claim.

**Prevention.**

*No primary prevention of allergic rhinitis has been demonstrated.* Allergen-avoidance regimens in infancy, maternal diet modification, hydrolysed formula and probiotics have not prevented it in randomised trials.

One distinction is routinely blurred and must be printed: early allergen introduction prevents food allergy, with LEAP giving an 81 per cent relative reduction in peanut allergy, and has not been shown to prevent allergic rhinitis.

*Allergen immunotherapy to prevent asthma in children with allergic rhinitis — MODERATE.* The Preventive Allergy Treatment study showed persisting asthma reduction at seven and ten years; GAP missed its primary endpoint and showed reduced asthma symptoms and medication. This is secondary prevention of the next stage of the atopic march, and it is the best evidence that the march can be interrupted.

*Occupational allergen control — STRONG* for occupational rhinitis. *Avoiding second-hand tobacco smoke — MODERATE*. *Air pollution reduction — MODERATE*.

*House dust mite avoidance — CONTESTED to negative.* Cochrane found no clear benefit of mite-avoidance measures for allergic rhinitis outcomes, as for asthma. The advice is near-universal and the evidence does not support it, and that is printed.

*The farm effect is reproducible and has not been translatable* into an intervention; trials of farm-dust-derived products are early.

A second source line adds the following items.

*Allergen immunotherapy to prevent new sensitisations and asthma onset in children with established rhinitis — MODERATE*, from the Preventive Allergy Treatment study and GAP. Open-label elements and heterogeneity are the weakness. This line reads GAP as supporting the prevention of asthma onset. The paragraph above records that GAP missed its primary endpoint of asthma onset. The two source lines disagree on what GAP shows, and both are printed. The prevention of new sensitisations appears in this line only.

*Breastfeeding — CONTESTED* for allergic rhinitis specifically. Meta-analyses find a small protective association for asthma and eczema in early childhood and little consistent effect on rhinitis.

*Avoiding tobacco smoke in pregnancy and infancy — MODERATE.*

*House dust mite avoidance.* This line finds the evidence weak and the sources in disagreement. Cochrane reviews of mite-impermeable bedding for rhinitis and asthma have generally found no clinically important benefit as single measures, while multi-component environmental interventions show some effect. The grade above is CONTESTED to negative. The two lines differ on the grade and agree on the Cochrane finding.

*Early-life exposure to farm environments and unprocessed milk — MODERATE* as an association, and not actionable as an intervention. Raw milk carries infection risk, and no trial has tested it.

*Pet removal once sensitised — WEAK*. The evidence does not support routine pet removal. This sits against the avoidance stratum in the cure status above.

There is no established primary prevention of atopy itself. The rise in allergic disease over the twentieth century has no demonstrated preventive counter-measure at population level.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Intranasal corticosteroid, beclometasone, budesonide, fluticasone, mometasone | The most effective single drug class. Superior to oral antihistamines for nasal congestion and overall symptoms in head-to-head trials and meta-analysis | yes, beclometasone | yes | tens of euro |
| Second-generation oral antihistamine, cetirizine, loratadine, fexofenadine | Effective for sneezing, itch and rhinorrhoea; less effective than an intranasal steroid for congestion; non-sedating | yes, loratadine and cetirizine | yes | a few to tens of euro |
| First-generation antihistamine, chlorphenamine, diphenhydramine | Effective and sedating, and associated with impaired examination performance and driving; should not be first-line | yes, chlorphenamine | yes | a few to tens of euro |
| Intranasal antihistamine, azelastine | Faster onset than oral; useful as add-on | no | yes | tens to hundreds of euro |
| Intranasal corticosteroid with azelastine | Superior to either alone | no | partly | hundreds of euro |
| Nasal saline irrigation | Symptoms improved as an adjunct, at low to moderate certainty | n/a | n/a | a few to tens of euro or near zero home-made |
| Leukotriene receptor antagonist, montelukast | Comparable to antihistamines and less effective than an intranasal steroid; neuropsychiatric boxed warning in the United States from 2020 | no | yes | €20–150 |
| Subcutaneous allergen immunotherapy | Symptom and medication scores reduced roughly 30 to 40 per cent on meta-analysis; benefit persists years after stopping, per the Preventive Allergy Treatment study and GT-08; small risk of a systemic reaction | no | partly | hundreds to thousands of euro across three to five years of treatment |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Sublingual immunotherapy, tablets or drops | Comparable efficacy to subcutaneous for grass and mite, and much safer, with no anaphylaxis deaths reported with tablets; GAP and GT-08 show persisting benefit | no | partly | hundreds to thousands of euro |
| Intranasal ipratropium | For rhinorrhoea specifically | yes | yes | tens to hundreds of euro |
| Oral or intranasal decongestant | Short-term only; rhinitis medicamentosa with use beyond five to seven days | partly | yes | a few to tens of euro |
| Oral corticosteroid | A short rescue course only; depot injectable corticosteroid is not recommended | yes | yes | a few euro a course |
| Omalizumab | Effective, and not licensed or cost-justified for allergic rhinitis alone | **NOT on the 24th Model List in any form** | Biosimilars emerging | tens of thousands of euro |

A second source line gives drug prices in US dollars, on the basis of generic or lowest available acquisition cost, 2024. The table above gives prices in euro, with market and year not stated. Both are printed. The two source lines do not reconcile them, and they disagree on listing status where noted below.

Intranasal corticosteroids work on all nasal symptoms including blockage. They take several days to work and must be used continuously. Off-patent, at US$5 to US$40 a patient-year at generic or lowest available acquisition cost, 2024†. The table gives tens of euro. The table lists beclometasone as on the Model List. This line says the nasal-formulation listing of beclometasone and budesonide needs checking against the 24th List†.

Second-generation oral antihistamines include desloratadine and bilastine as well as loratadine, cetirizine and fexofenadine. Off-patent, at US$2 to US$20 a patient-year at generic or lowest available acquisition cost, 2024†. The table gives a few to tens of euro. This line says listing status needs checking against the 24th List†. The table lists loratadine and cetirizine as on it.

Intranasal azelastine has onset within about 15 minutes, which oral agents do not match. Off-patent, at US$30 to US$100 a patient-year at generic or lowest available acquisition cost, 2024†. The table gives tens to hundreds of euro. This line says EML status needs checking against the 24th List†. The table says no.

Allergen immunotherapy is given subcutaneously, with the largest evidence base, or as sublingual tablets for grass, ragweed, house dust mite and tree, over three to five years. It costs US$500 to US$3,000 a patient-year at lowest available acquisition cost, 2024†. The table gives hundreds to thousands of euro across the whole three to five years. One figure is a year and the other a course. These are biological extracts, and standardised tablets are patented. This line says EML status needs checking against the 24th List†. The table says no.

Montelukast, off-patent, costs US$10 to US$50 a patient-year at generic or lowest available acquisition cost, 2024†. The table gives €20–150. This line says EML status needs checking against the 24th List†. The table says no.

First-generation antihistamines are off-patent and cost cents a day. The table gives a few to tens of euro. This line says chlorphenamine's listing status needs checking against the 24th List†. The table lists chlorphenamine as on it.

Generic loratadine and generic nasal beclometasone both cost under US$40 a year at generic or lowest available acquisition cost†.

**Simple means.** This is a condition affecting roughly 400 million people that can be controlled for tens of euro a year per person with Essential Medicines List drugs. Loratadine

and cetirizine cost a few to tens of euro a year, are listed and off-patent, and beclometasone nasal spray costs tens of euro a year, listed and off-patent.

Nasal saline irrigation is essentially free: home-made saline from salt, baking soda and boiled or distilled water, in a neti pot or squeeze bottle, improves symptoms and reduces medication need as an adjunct. The same safety warning applies as in chronic rhinosinusitis — the water must be boiled, distilled or filtered, because fatal amoebic infections have followed irrigation with untreated tap water.

One source line finds from Cochrane and later reviews that saline irrigation gives modest but consistent symptom improvement, reduced medication use and no meaningful harm, with an effect smaller than that of intranasal steroids. That line does not mention the water warning above.

Allergen avoidance works where the allergen is single and removable: rehoming a cat, removing a bird, changing bedding, keeping windows shut during peak pollen, showering and changing clothes after outdoor exposure, drying washing indoors in pollen season. House dust mite measures specifically are the exception: Cochrane found no clear benefit, despite being the most commonly advised.

The same line adds staying indoors during peak pollen hours, washing hair after outdoor exposure, a pet-free bedroom, lower indoor humidity and less visible mould, and removing carpets in mite-sensitised households. It calls the evidence for these individually weak, at zero cost. The paragraph above says avoidance works where the allergen is single and removable. The two source lines disagree on how strong the evidence for avoidance is.

Pollen timing costs nothing: counts peak in early morning and evening for grasses, and planning outdoor activity accordingly is free. Wrap-around sunglasses and a mask during high pollen exposure reduce conjunctival and nasal deposition, with small studies supporting benefit. Petroleum jelly or a nasal barrier balm around the nostrils traps pollen, cheaply and with limited evidence. Smoke-free homes are free.

Cold compresses ease eye symptoms. Starting an intranasal steroid before the pollen season, and not after symptoms begin, improves control measurably and costs nothing extra.

Avoiding sedating first-generation antihistamines is a free choice with a measured benefit, since sedating antihistamine use was associated with further impairment of examination performance in the UK study. Chlorphenamine is the cheapest and most widely available antihistamine in low-income settings, which makes this a real trade-off rather than a simple recommendation.

The hard limit. Identifying which allergen is responsible requires skin prick testing or specific IgE measurement, and allergen immunotherapy — the only disease-modifying treatment — requires a standardised allergen extract, a supply chain and supervised administration. Symptom control, however, needs only saline and two cheap generic drugs.

One source line finds that the main access problem is not price but the absence of basic diagnosis, and of over-the-counter availability in some health systems.

**Gaps.** No GBD global burden figure for allergic rhinitis was retrieved, for a condition affecting roughly 400 million people with measured effects on sleep, school performance and productivity, and this entry is part of the seventeen-condition gap in this chapter's introduction; the 400 million figure is a modelled estimate. ISAAC found a twentyfold prevalence range between centres, and how much is genuine and how much is questionnaire interpretation across languages and cultures is unresolved. No primary prevention has been demonstrated, and the farm effect is robust and has produced no usable intervention. Early allergen introduction prevents food allergy and not allergic rhinitis, and the two are routinely conflated. House dust mite avoidance: Cochrane null against near-universal advice. Whether immunotherapy prevents asthma is not settled: the Preventive Allergy Treatment study was positive and persisting at ten years, and GAP missed its primary endpoint; both are printed. Immunotherapy's optimal duration, and how long the benefit lasts, are not established — three to five years is convention rather than trial-derived. Montelukast's neuropsychiatric risk magnitude remains debated. Pollen seasons have lengthened by about 20 days and concentrations risen by about 20 per cent since 1990 in North American data; the clinical consequence has not been quantified prospectively, and comparable monitoring does not exist for most of the world. Almost all trial evidence is from high-income countries with

temperate pollen seasons, and tropical allergen profiles — mite, cockroach, fungal — are under-represented. Omalizumab is not on the 24th Model List in any form.

Prevalence figures span 10 to 40 per cent because definitions vary. Self-reported symptoms, physician diagnosis, and symptoms with confirmed sensitisation give very different numbers, and they are not interchangeable. Breastfeeding's effect on allergic rhinitis specifically is contested. House dust mite avoidance: Cochrane reviews find no benefit for single measures, while allergy guidelines continue to recommend multi-component avoidance, and sources disagree openly. Immunotherapy's average effect is modest, heterogeneity between trials is high, no biomarker predicts who will respond, and most trials are manufacturer-sponsored. The cause of the twentieth-century rise is unknown, so no evidence-based population prevention strategy exists. The two source lines for this condition also differ on the between-centre range of the childhood survey, twin heritability, the evidence for allergen avoidance, what GAP shows for asthma prevention, whether caesarean delivery and early antibiotics are established risk factors, and the drug prices and listing statuses. Each is printed where it arises.

## Pleural effusion (ICD-11 CB27)

**What it is.** Fluid collects between the lung and the chest wall and presses the lung inward. Breathlessness builds and the chest feels heavy. It is always a consequence of something else, never a disease in itself.

**Measured.** No global prevalence, death or DALY figure for pleural effusion was retrieved from the GBD 2023 tables, and the structural reason is that it is a sign rather than a GBD cause. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Incidence in high-income countries is roughly 300 to 400 per 100,000 population a year, which is roughly 1.5 million cases a year in the United States, from long-standing United States estimates. The commonest causes in high-income series are heart failure, roughly 500,000 a year in United States estimates, pneumonia at about 300,000, malignancy at about 200,000, pulmonary embolism at about 150,000, and then cirrhosis, post-cardiac surgery and renal failure.

In high-tuberculosis-burden countries, tuberculous pleural effusion is the commonest cause of an exudative effusion in young adults, accounting for roughly 25 to 50 per cent of effusions in series from sub-Saharan Africa, India and China, against under 5 per cent in western Europe. That is as sharp a geographic divergence as in the pericarditis entry.

Malignant pleural effusion develops in roughly 15 per cent of all cancer patients, with median survival after diagnosis of roughly four to nine months, varying by tumour type — shorter for lung and ovarian, longer for breast and mesothelioma — from the LENT and PROMISE prognostic scores. Pleural infection, empyema and complicated parapneumonic effusion, is rising in incidence in both children and adults, with mortality of roughly 10 to 20 per cent in adults and higher in the elderly and in those with comorbidity. Heart failure and malignant effusions rise with age, and tuberculous effusion is a disease of young adults.

**Where it starts.** Mechanistically, either raised hydrostatic pressure or reduced oncotic pressure, which gives a transudate, or increased pleural permeability or impaired lymphatic drainage, which gives an exudate. Light's criteria separate the two with roughly 98 per cent sensitivity for exudates, at the cost of misclassifying roughly 25 per cent of transudates in diuretic-treated heart failure as exudates.

Transudates: heart failure, the commonest single cause overall; cirrhosis with ascites; nephrotic syndrome; peritoneal dialysis; hypoalbuminaemia; constrictive pericarditis. Exudates: parapneumonic effusion and empyema; malignancy of lung, breast, lymphoma, ovary or mesothelium; tuberculosis; pulmonary embolism; rheumatoid arthritis; lupus; pancreatitis; oesophageal rupture; post-cardiac-surgery states; drug-induced disease; asbestos-related benign effusion; chylothorax. The risk factors are those of the underlying diseases; there is no independent risk factor for pleural effusion as such.

Roughly 15 to 20 per cent of effusions remain undiagnosed after full investigation including pleural fluid analysis and often biopsy, and a substantial share of those turn out to be malignant or tuberculous on follow-up. Light's criteria misclassify a quarter of diuretic-treated

heart failure effusions, and the proposed corrections — the serum-to-pleural albumin gradient, N-terminal pro-B-type natriuretic peptide — are not universally applied. Why some parapneumonic effusions loculate and become empyema while others resolve with antibiotics alone is not predictable at presentation. Whether drainage of a malignant effusion improves survival as well as symptoms is unknown, because no trial has been designed to answer it.

**Cure status.** Where the underlying cause is curable — parapneumonic effusion, empyema, tuberculous effusion, heart failure effusion: CURABLE. Malignant effusion: RELIEF ONLY.

Drainage relieves breathlessness immediately and definitively for that episode, and thoracocentesis is one of the most immediately effective procedures in medicine.

Parapneumonic effusion and empyema are CURABLE with antibiotics plus drainage. MIST2, with 210 patients, showed intrapleural tissue plasminogen activator plus DNase reduced pleural opacity and surgical referral, from 16 to 4 per cent, against placebo, and either agent alone was ineffective. Tuberculous pleural effusion is CURABLE with standard antituberculous therapy; most resolve without drainage, and corticosteroids do not improve outcome and are not recommended. Heart failure effusion resolves with treatment of the heart failure — diuretics rather than drainage.

Malignant pleural effusion is RELIEF ONLY and recurs unless the pleural space is obliterated. Talc pleurodesis gives success in roughly 70 to 80 per cent at one month, and the TAPPS trial, with 330 patients, found talc poudrage at thoracoscopy no better than talc slurry via a chest tube, with pleurodesis failure of 22 against 24 per cent — so the cheaper bedside method is equivalent. An indwelling pleural catheter: TIME2, with 106 patients, gave equivalent breathlessness relief to talc pleurodesis with fewer hospital days, 1 against 4.5, and more adverse events, and AMPLE confirmed the reduction in hospital days. Neither cures; both manage the fluid. Chylothorax, oesophageal rupture and trapped lung need specific surgical management.

**Prevention.** Nothing prevents pleural effusion as such; prevention is entirely prevention of the underlying diseases.

*Treating heart failure to target — STRONG*, since heart failure is the commonest cause: per 10 mmHg systolic reduction, heart failure relative risk 0.72, and the four pillars reduce hospitalisation substantially.

*Prompt and adequate antibiotic treatment of pneumonia — STRONG* for preventing empyema. *Pneumococcal and influenza vaccination — MODERATE* for preventing the parapneumonic effusions and empyemas that follow pneumonia; the pneumococcal vaccine reduces invasive pneumococcal disease by 80 to 90 per cent in vaccinated children with herd protection.

*Tuberculosis control and complete treatment — STRONG* where tuberculous effusion dominates.

*Asbestos elimination — STRONG* for mesothelioma and benign asbestos effusion. *Thromboprophylaxis — STRONG* for the embolism-related effusions. *Smoking cessation — STRONG* for lung cancer and therefore for malignant effusion.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Diagnostic and therapeutic thoracocentesis | Immediate relief of breathlessness; the diagnostic yield of fluid analysis is roughly 75 per cent for the cause | n/a | n/a | A needle, a syringe, a three-way tap and a drainage bag: a few to tens of euro |
| Ultrasound guidance | Reduces pneumothorax risk from roughly 10 to 18 per cent down to 1 to 3 per cent and reduces iatrogenic complications substantially; it is now standard of care for all pleural procedures | n/a | n/a | Handheld thousands to tens of thousands of euro and falling |
| Treating the cause: diuretics, antibiotics, antituberculous therapy, anticoagulation | Curative where the cause is curable; a full tuberculosis cure costs tens of euro | yes, all | yes | a few to tens of euro |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Chest tube drainage, empyema or a large effusion | Small-bore tubes of 10 to 14 French are as effective as large-bore and much less painful | n/a | n/a | tens to hundreds of euro |
| Intrapleural tissue plasminogen activator with DNase, empyema | MIST2: surgical referral reduced from 16 to 4 per cent; either agent alone ineffective | no | partly | thousands of euro a course |
| Talc pleurodesis, by slurry through a tube or by poudrage | Success 70 to 80 per cent at one month; TAPPS found slurry equivalent to poudrage, failure 24 against 22 per cent | no | yes, talc is cheap | Talc tens to hundreds of euro; the procedure thousands of euro |
| Indwelling pleural catheter | TIME2: equivalent breathlessness relief to pleurodesis, hospital days 1 against 4.5, more adverse events | no | n/a | hundreds to thousands of euro plus drainage supplies |
| Surgical decortication or video-assisted thoracoscopic surgery | For failed drainage in empyema and for trapped lung | n/a | n/a | thousands to tens of thousands of euro |
| Corticosteroids in tuberculous effusion | **No outcome benefit; not recommended** | yes | yes | — |
| Systemic anticancer therapy | Effective in chemosensitive tumours — lymphoma, small cell carcinoma, breast cancer — which can resolve the effusion | Varies | Varies | Varies widely |

**Simple means.** This entry has an unusually favourable ratio of effect to equipment.

Thoracocentesis with a needle and a syringe is one of the highest immediate-benefit-per-euro interventions in all of medicine. A needle, a syringe, a three-way tap and a drainage bag — a few to tens of euro of consumables — relieve breathlessness within minutes, at the bedside. The one essential safety addition is ultrasound guidance, which reduces pneumothorax risk from roughly 10 to 18 per cent down to 1 to 3 per cent; handheld ultrasound now costs thousands to tens of thousands of euro and is falling. Without ultrasound the procedure is still done and still works, at higher complication risk, and clinical site selection by percussion and auscultation is the fallback.

Clinical examination detects a moderate or large effusion reliably with no equipment at all: stony dull percussion, absent breath sounds and reduced vocal resonance. Percussion and a stethoscope. Sensitivity for effusions over roughly 500 mL is good, and small effusions are missed. Positioning — sitting upright and leaning toward the affected side — improves ventilation of the unaffected lung, and is free.

Treating the cause with cheap drugs: furosemide for heart failure effusion at a few to tens of euro a year, amoxicillin for parapneumonic effusion at a few to tens of euro a course, and antituberculous therapy for tuberculous effusion at tens of euro for a full curative course — all listed and off-patent. In the setting where pleural effusion is most often tuberculous, the cure costs tens of euro and needs no drainage.

Talc costs tens to hundreds of euro and sterile graded talc is the pleurodesis agent of choice; talc slurry through a small chest tube is equivalent to thoracoscopic poudrage per TAPPS, so the cheap bedside route is not inferior. Small-bore chest tubes cost tens to hundreds of euro and are as effective as large-bore and much less painful. Low-dose morphine and a fan to the face relieve refractory breathlessness in malignant effusion where drainage is not appropriate: tens to hundreds of euro a year for morphine, listed and off-patent.

The hard limit. Determining the cause requires pleural fluid analysis — protein, lactate dehydrogenase, glucose, pH, cytology, culture, and adenosine deaminase or a nucleic acid test for tuberculosis. Light's criteria need a laboratory that can measure protein and lactate dehydrogenase in both serum and pleural fluid. Without that, management is empirical, and imaging, a chest radiograph at minimum, is needed to confirm. So the relief is nearly free and immediate, and the diagnosis requires a laboratory.

**Gaps.** Pleural effusion is not a GBD cause, so no global burden figure exists at all, and this entry is part of the seventeen-condition gap in this chapter's introduction; the figure of roughly 1.5 million United States cases a year is an old estimate repeated widely. Be-

tween 15 and 20 per cent remain undiagnosed after full investigation†, and a substantial share prove malignant or tuberculous later. Light's criteria misclassify roughly a quarter of diuretic-treated heart failure effusions as exudates, and the corrections are not consistently applied. Tuberculous effusion is the commonest exudative cause in young adults in high-burden countries and under 5 per cent of cases in western Europe, and the guidelines and the trial evidence are largely from low-burden settings. Whether drainage of a malignant effusion affects survival is unknown; no trial has been designed to test it. TAPPS showed the expensive thoracoscopic route is not better than bedside slurry, and practice has not fully followed. Which parapneumonic effusions will loculate is not predictable, so the timing of intrapleural fibrinolytics and of surgery rests on judgement. Empyema incidence is rising in both children and adults and the reason is not established. Malignant effusion survival estimates of four to nine months come from specialist referral cohorts.

## Pneumothorax (ICD-11 CB21)

**What it is.** Air leaks into the space between the lung and the chest wall, and the lung collapses away from the wall. There is sudden one-sided chest pain and breathlessness. If the pressure builds, it pushes the heart aside and kills within minutes.

**Measured.** No global prevalence, death or DALY figure for pneumothorax was retrieved from the GBD 2023 tables. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Primary spontaneous pneumothorax has an incidence of roughly 7.4 to 18 per 100,000 a year in men and 1.2 to 6 per 100,000 a year in women, from UK, United States and Scandinavian population studies. Secondary spontaneous pneumothorax runs at roughly 6.3 per 100,000 a year in men and 2.0 in women. Primary spontaneous pneumothorax is rarely fatal; secondary spontaneous pneumothorax carries mortality of roughly 10 per cent, because the underlying lung disease, usually chronic obstructive pulmonary disease, leaves little reserve. Recurrence after a first primary spontaneous pneumothorax is roughly 30 per cent within one to five years, rising to roughly 60 per cent after a second. Tension pneumothorax is the immediately lethal form; its incidence is not separately measured anywhere, and it is commonest in trauma and in ventilated patients. Primary spontaneous pneumothorax is a disease of tall thin young men, typically aged 15 to 34, with a sex ratio of roughly 3 to 6 to 1 male; secondary spontaneous pneumothorax peaks over 55 with chronic obstructive pulmonary disease.

**Where it starts.** Smoking is the dominant modifiable risk factor for primary spontaneous pneumothorax, and the relative risk is among the largest for any disease: the lifetime risk is roughly 12 per cent in male smokers against 0.1 per cent in male non-smokers, an approximately hundredfold relative risk, and the risk is dose-dependent.

A tall, thin body habitus contributes, because the apical pleural pressure gradient is more negative in a tall chest. Subpleural blebs and emphysema-like changes are found at surgery or on computed tomography in roughly 80 to 90 per cent of patients, including in the contralateral lung. Male sex and family history, with roughly 10 per cent having an affected relative, contribute. Genetic causes: Birt-Hogg-Dubé syndrome from FLCN mutations, with pneumothorax in roughly 75 to 80 per cent of affected individuals alongside renal tumours and skin fibrofolliculomas; Marfan syndrome; Ehlers-Danlos syndrome; alpha-1 antitrypsin deficiency.

Secondary causes. Chronic obstructive pulmonary disease is the commonest. Tuberculosis and post-tuberculous cavitation dominate in high-burden countries. Cystic fibrosis carries a lifetime risk of roughly 3 to 4 per cent. Pneumocystis pneumonia in HIV, lung cancer and lymphangioleiomyomatosis — the last with pneumothorax in roughly 65 to 80 per cent, often as the presenting event in young women — all contribute, as do necrotising pneumonia, interstitial lung disease, and catamenial or thoracic endometriosis. Iatrogenic causes: central line insertion, pleural procedures — reduced from 10 to 18 per cent down to 1 to 3 per cent with ultrasound guidance — transbronchial and transthoracic biopsy, and mechanical ventilation with high pressures. Trauma, penetrating and blunt chest injury. Diving and altitude change, and cannabis and crack cocaine smoking.

Why the bleb ruptures at a given moment is not predictable, and most episodes occur at rest rather than during exertion. Whether the subpleural blebs seen in 80 to 90 per cent of

patients are the actual site of air leak is disputed — leaks are often found elsewhere at surgery, and the term “emphysema-like changes” was introduced partly to reflect that uncertainty. Why recurrence is roughly 30 per cent and who will recur cannot be predicted from imaging. Whether conservative management is safe in a wider group than currently treated is only now being tested.

**Cure status.** The episode: CURABLE — it resolves completely and lung function returns to normal. The recurrence risk: CURABLE in 95 to 99 per cent by video-assisted thoracoscopic pleurectomy or mechanical pleurodesis, recurrence 1 to 5 per cent. Tension pneumothorax: CURABLE instantly by decompression. Secondary spontaneous pneumothorax: the episode is CURABLE; the underlying lung disease remains and carries its own label.

A pneumothorax resolves completely. Air is reabsorbed at roughly 1.25 to 2.2 per cent of the hemithorax a day spontaneously and faster with supplemental oxygen; the lung re-expands and function normalises.

Conservative management is effective and often sufficient, and that is a major and recent reversal. The PSP trial, published in the New England Journal of Medicine in 2020, randomised 316 patients with moderate to large primary spontaneous pneumothorax to conservative or interventional management. Lung re-expansion at eight weeks was 94.4 per cent conservative against 98.5 per cent interventional, a risk difference of −4.1 percentage points, which met non-inferiority in the complete-case analysis. Serious adverse events and recurrences were fewer in the conservative arm. Watching is as good as draining for a substantial proportion.

Surgical pleurodesis or pleurectomy reduces recurrence from roughly 30 per cent to 1 to 5 per cent after video-assisted thoracoscopic surgery with pleurectomy or mechanical pleurodesis. That is a genuine and durable cure of the recurrence risk. Chemical pleurodesis with talc through a chest tube gives recurrence of roughly 8 to 15 per cent, less effective than surgery and far less invasive. Tension pneumothorax is cured instantly by decompression: a needle through the chest wall converts an immediately lethal condition into a survivable one in seconds.

**Prevention.**

*Smoking cessation — STRONG, and quantitatively the most important.* Lifetime risk roughly 12 per cent in male smokers against 0.1 per cent in non-smokers, and cessation reduces recurrence risk substantially. This is among the largest relative risk reductions available from quitting for any single disease.

*Surgical pleurodesis or pleurectomy after recurrence — STRONG.* Recurrence from 30 per cent down to 1 to 5 per cent.

*Ultrasound guidance for all pleural procedures — STRONG* for iatrogenic pneumothorax: 10 to 18 per cent down to 1 to 3 per cent.

*Lung-protective, low tidal volume ventilation — STRONG* for ventilator-associated pneumothorax.

*Tuberculosis control and treatment — STRONG* where post-tuberculous cavitation is a leading cause.

*Avoiding diving after a pneumothorax — STRONG by consensus*; diving is contraindicated permanently unless definitive surgical pleurodesis has been performed.

*Cannabis and crack cessation — MODERATE*. *Screening relatives in Birt-Hogg-Dubé syndrome — MODERATE*, chiefly for the renal tumour risk.

*Avoiding air travel for a defined interval* after resolution, commonly one to two weeks after radiographic resolution, is consensus with WEAK evidence.

*Avoiding strenuous exertion — WEAK and CONTESTED*: most episodes occur at rest, and routine activity restriction is not evidence-based.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Needle decompression for tension pneumothorax | **Immediately life-saving, in seconds.** A large-bore cannula in the second intercostal space or in the fourth or fifth space in the mid-axillary line | n/a | n/a | A cannula: a few to a few euro |
| Conservative observation, primary spontaneous pneumothorax | PSP trial: re-expansion 94.4 against 98.5 per cent interventional, with fewer serious adverse events and fewer recurrences | n/a | n/a | Nothing but observation |
| Supplemental high-concentration oxygen | Increases the rate of air reabsorption roughly three- to fourfold by nitrogen washout | yes | yes | Concentrator or cylinder; see the COPD entry |
| Needle aspiration, 14 to 16 gauge | Success roughly 60 to 70 per cent, and as effective as chest tube drainage for primary spontaneous pneumothorax with fewer hospital admissions, per Cochrane and British Thoracic Society guidance | n/a | n/a | A cannula and a syringe: a few to tens of euro |
| Small-bore chest drain, 8 to 14 French, with or without a one-way valve | Effective; ambulatory devices allow outpatient management, and the RAMPP trial showed a shorter hospital stay | n/a | n/a | Tube tens to hundreds of euro; Heimlich valve tens of euro |
| Large-bore chest drain | No more effective than small-bore and more painful | n/a | n/a | tens to hundreds of euro |
| Talc or doxycycline chemical pleurodesis | Recurrence roughly 8 to 15 per cent | yes, doxycycline | yes | Talc tens to hundreds of euro; doxycycline a few to tens of euro |
| Thoracoscopic pleurectomy or mechanical pleurodesis | Recurrence from 30 per cent down to 1 to 5 per cent | n/a | n/a | thousands to tens of thousands of euro |
| Open thoracotomy pleurectomy | The lowest recurrence, about 1 per cent, and the most invasive | n/a | n/a | thousands to tens of thousands of euro |
| Autologous blood patch pleurodesis | For a persistent air leak; the patient's own blood instilled through the drain, with success of roughly 70 to 90 per cent in small series | n/a | n/a | Essentially free |
| Endobronchial valves | For a persistent air leak in patients not fit for surgery | no | no | thousands to tens of thousands of euro |

**Simple means.** This entry contains the single most dramatic example of a no-equipment life-saving intervention in either chapter.

Needle decompression of a tension pneumothorax: a large-bore cannula costing well under five euro, pushed through the chest wall, converts an immediately fatal condition into a survivable one within seconds. The diagnosis is clinical — breathlessness, hypotension, distended neck veins, tracheal deviation away from the affected side, absent breath sounds and hyper-resonance on that side — and a chest radiograph should not be waited for. That is the clearest case in either chapter where a trained person with almost nothing saves a life.

Conservative observation costs nothing and is the treatment for a substantial share of primary spontaneous pneumothorax: the PSP trial gave 94.4 per cent re-expansion with conservative management against 98.5 per cent with intervention, with fewer serious adverse events and fewer recurrences.

Needle aspiration with a cannula and a syringe costs a few to tens of euro has a success rate of 60 to 70 per cent, and is as effective as a chest tube for primary spontaneous pneumothorax with fewer admissions. A Heimlich one-way valve costs tens of euro and allows ambulatory management, and an underwater seal can be improvised from a bottle of water and tubing — the classic low-resource chest drainage system, requiring no suction and no power. High-concentration oxygen increases the reabsorption rate roughly three- to fourfold.

Autologous blood patch pleurodesis is effectively free and uses nothing the patient did not already have: the patient's own blood, drawn from a vein and instilled down the existing drain, achieves pleurodesis in roughly 70 to 90 per cent of persistent air leaks in small series.

Smoking cessation is the single largest preventive effect in the entry and it is free: lifetime risk 12 per cent in male smokers against 0.1 per cent in non-smokers. Clinical examination — hyper-resonant percussion, absent breath sounds and reduced chest expansion on one side — diagnoses a large pneumothorax with percussion and a stethoscope; ultrasound, showing absent lung sliding, is more sensitive, and a radiograph is confirmatory. Sitting upright reduces the work of breathing.

The hard limit, with one critical caveat. A small pneumothorax cannot be reliably distinguished from other causes of chest pain without imaging, a chest radiograph at minimum, and ultrasound is more sensitive than supine radiography. Recurrence prevention requires surgery. And the caveat: the clinical signs that justify blind needle decompression are those of tension pneumothorax, and decompressing a chest that has no pneumothorax causes one. The judgement, not the equipment, is the constraint.

**Gaps.** No GBD global burden figure for pneumothorax was retrieved, and this entry is part of the seventeen-condition gap in this chapter's introduction. Incidence estimates vary roughly 2.5-fold between countries, 7.4 to 18 per 100,000 in men, on ascertainment differences. Tension pneumothorax incidence is not separately measured anywhere, despite being the immediately lethal form. The PSP trial reversed standard practice, and its non-inferiority margin and handling of missing data have been debated; guidelines are changing unevenly and practice varies widely, so both the trial result and the fact that practice has not uniformly followed are printed. Whether subpleural blebs are the actual site of air leak is disputed, so the basic pathological account is uncertain. Who will recur cannot be predicted, so the indication for surgery after a first episode is a judgement rather than a measurement. Air travel and diving restrictions after a pneumothorax are consensus-based with essentially no trial evidence, and the recommended intervals differ between guidelines. Activity restriction is widely advised and not evidence-based, since most episodes occur at rest. Post-tuberculous and HIV-related pneumothorax dominate in high-burden settings and are almost absent from a guideline evidence base that is European, North American and Australasian. Secondary spontaneous pneumothorax mortality of about 10 per cent comes from small series.

# The failing lung and the inherited lung

## Acute respiratory distress syndrome (ICD-11 CB00)

**What it is.** A severe insult — infection, injury, inhalation — makes the lungs leak fluid into the air sacs everywhere at once. Oxygen cannot cross and the person needs a ventilator within hours. Many die, and those who live often take a year to recover.

**Measured.** No global prevalence, death or DALY figure for acute respiratory distress syndrome was retrieved from the GBD 2023 tables, and the structural reason is that it is a syndrome rather than a GBD cause. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Incidence is roughly 10.1 to 86.2 per 100,000 person-years depending on the country and the definition used — a nearly ninefold range across United States, Scandinavian, Australian and European estimates. The highest figures come from United States cohorts and the lowest from Europe, and the difference is widely attributed to ascertainment and intensive care bed availability rather than to true variation.

The LUNG SAFE study covered 459 intensive care units in 50 countries in 2016. It found the syndrome present in 10.4 per cent of intensive care admissions and 23.4 per cent of mechanically ventilated patients. Hospital mortality was 34.9 per cent for mild, 40.3 per

cent for moderate and 46.1 per cent for severe disease. The single most reproducible finding about practice is under-recognition: clinicians recognised the syndrome in only 60.2 per cent of cases and in only 51.3 per cent of mild cases.

COVID-19 produced the largest cohort in history. GBD 2023 records 797,600 COVID-19 deaths (722,900 to 857,000) in 2023 alone, ranked twentieth, down from 7.89 million in 2021 when it ranked second; a large share of those deaths were acute respiratory distress syndrome. Survivors have persistent exercise limitation, muscle wasting, cognitive impairment and psychiatric morbidity; the Toronto cohort found persistent functional limitation at five years, with median six-minute walk distance of roughly 76 per cent of predicted. Incidence rises with age and mortality rises steeply with age. Mortality has fallen modestly over three decades, attributed mainly to lung-protective ventilation and to general improvements in critical care rather than to any specific drug.

**Where it starts.** The syndrome is always secondary to a precipitant. Pneumonia is the commonest cause at roughly 35 to 60 per cent, and non-pulmonary sepsis follows at roughly 30 per cent. Aspiration of gastric contents, major trauma especially with pulmonary contusion, long-bone fracture or massive transfusion, and transfusion-related acute lung injury — reduced substantially by excluding multiparous female plasma donors — all contribute. So do pancreatitis, burns and smoke inhalation, drowning, drug overdose with opioids or salicylates, inhaled toxins including chlorine, phosgene and paraquat, fat embolism, and high altitude as a related but distinct syndrome.

Risk-modifying factors: chronic alcohol use roughly doubles risk after a given insult; obesity, hypoalbuminaemia, cigarette smoking and air pollution exposure raise risk; and diabetes appears protective, a reproducible and unexplained finding. Mechanical ventilation itself causes lung injury and can initiate or worsen the syndrome, which is why the single most effective treatment is ventilating less aggressively.

The syndrome is defined by a consensus definition rather than by a mechanism, and the definition has changed four times: the 1967 description, the 1994 American-European Consensus Conference, the 2012 Berlin definition and the 2023 global definition. Each change alters measured incidence and mortality, which is why the incidence range is ninefold. The hyperinflammatory and hypoinflammatory subphenotypes identified by latent class analysis have different mortality and opposite responses to positive-end-expiratory-pressure strategy and to fluid management in retrospective reanalyses, which is the leading explanation for why dozens of drug trials were null in unselected populations, and it has not yet been tested prospectively. Why some patients fibrose and others resolve completely is unexplained. Why diabetes is protective is unknown.

**Cure status.** The lung injury itself: RELIEF ONLY. The episode, in survivors: SELF-LIMITING — it resolves under supportive care.

No treatment reverses the lung injury, and every disease-modifying drug trial has been null: surfactant, inhaled nitric oxide, prostacyclin, ketoconazole, lisofylline, N-acetylcysteine, statins in unselected patients in SAILS and HARP-2, beta-agonists in BALTI-2 and ALTA, neutrophil elastase inhibitors and granulocyte-macrophage colony-stimulating factor.

The episode is SELF-LIMITING in those who survive it. The injury resolves on its own, and the interventions that work — low tidal volume ventilation, prone positioning, conservative fluid management, extracorporeal support in refractory cases — support the lung and avoid adding harm rather than treating the syndrome. Hospital mortality is 34.9 to 46.1 per cent by severity, so the self-limiting course is not a benign one.

Lung function in survivors largely recovers, with most having near-normal spirometry by six to twelve months, and functional limitation, muscle weakness, cognitive impairment and psychiatric morbidity persist for years, with six-minute walk distance at roughly 76 per cent of predicted at five years. Corticosteroids are the one drug exception and they are mixed: positive in COVID-19 disease in RECOVERY, positive in DEXA-ARDS, and negative or harmful in earlier and in late-phase non-COVID trials.

**Prevention.**

*Lung-protective ventilation in patients at risk and during surgery — STRONG.* Low tidal volume ventilation reduces the incidence of the syndrome in at-risk ventilated patients, and

intraoperative lung-protective ventilation, in the IMPROVE trial, reduced post-operative pulmonary complications.

*Treating pneumonia and sepsis promptly — STRONG*, since those are 65 to 90 per cent of precipitants. Early appropriate antibiotics in sepsis.

*Conservative transfusion thresholds and male-donor or screened plasma — STRONG* for transfusion-related acute lung injury, which fell substantially after donor screening was introduced.

*Vaccination against influenza, pneumococcus and COVID-19 — STRONG* for preventing the commonest precipitants.

*Conservative fluid management in at-risk patients — MODERATE*. *Aspiration precautions — head elevation, swallow assessment after stroke, avoiding over-sedation — MODERATE*. *Alcohol reduction — MODERATE*: chronic alcohol use roughly doubles risk after a given insult. *Smoking cessation — MODERATE*.

*Aspirin and statins for prevention — CONTESTED to negative.* LIPS-A, with aspirin, was null for preventing the syndrome in at-risk patients.

*No drug prevents acute respiratory distress syndrome.*

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Low tidal volume ventilation, 6 mL/kg predicted body weight, plateau pressure 30 cm$H_2O$ or below | ARMA, the ARDSNet trial, 861 patients: **mortality 31.0 against 39.8 per cent, number needed to treat 11 to prevent one death.** This is the single most important treatment and it consists of setting the ventilator differently | n/a | n/a | **Nothing — it is a setting** |
| Prone positioning, 16 hours a day or more in severe disease | PROSEVA, 466 patients with an arterial oxygen tension to inspired oxygen fraction ratio below 150: **28-day mortality 16.0 against 32.8 per cent, hazard ratio 0.39; 90-day mortality 23.6 against 41.0 per cent — number needed to treat 6 to prevent one death.** One of the lowest numbers needed to treat in all of critical care | n/a | n/a | **Nothing but staff time — it requires four or five people and no equipment** |
| Conservative fluid management | FACTT, 1,000 patients: more ventilator-free days, 14.6 against 12.1, and more intensive-care-free days; no mortality difference | n/a | n/a | **Nothing — it is a strategy** |
| Neuromuscular blockade with cisatracurium in severe disease | ACURASYS, 340 patients: adjusted 90-day mortality hazard ratio 0.68 favouring blockade; ROSE, 1,006 patients, was null with a lighter-sedation control arm. Unresolved, and both are printed | yes, atracurium | yes | tens to hundreds of euro a course |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Corticosteroids | DEXA-ARDS, 277 patients on dexamethasone: ventilator-free days 12.3 against 7.5, 60-day mortality 21 against 36 per cent. RECOVERY, in COVID-19, 6,425 patients: 28-day mortality 22.9 against 25.7 per cent overall, and 29.3 against 41.4 per cent in ventilated patients — number needed to treat about 8 in that group, with a drug costing a few euro. Earlier and late-phase non-COVID steroid trials were negative or harmful | yes, dexamethasone | yes | a few euro a course |
| Higher positive-end-expiratory-pressure strategy | Meta-analysis: benefit confined to moderate to severe disease, with ALVEOLI, LOVS and EXPRESS individually null. ART, 1,010 patients, with recruitment manoeuvres plus pressure titration, found **increased mortality**, hazard ratio 1.20 | n/a | n/a | **Nothing — a setting** |
| Venovenous extracorporeal membrane oxygenation | EOLIA, 249 patients: 60-day mortality 35 against 46 per cent, p=0.09 — did not reach significance, with 28 per cent crossover from control to treatment; post-hoc Bayesian and meta-analytic reanalyses favour it | n/a | n/a | tens of thousands to hundreds of thousands of euro |
| Inhaled nitric oxide | Oxygenation improves transiently; no mortality benefit, and increased renal dysfunction on meta-analysis | no | no | thousands to tens of thousands of euro a course |
| Surfactant, beta-agonists, statins, N-acetylcysteine, colony-stimulating factor, elastase inhibitors | All null for mortality in unselected disease | Varies | Varies | — |
| Early antibiotics and source control for the precipitant | The mortality benefit in sepsis is well established, and each hour of delay in septic shock is associated with increased mortality | yes | yes | a few to tens of euro a course |
| Nutritional support, thromboprophylaxis, head-of-bed elevation, sedation minimisation, early mobilisation | Bundled supportive care; each component has modest independent evidence | yes, enoxaparin | yes | tens to hundreds of euro |

The defining economic fact. The three interventions with the largest measured mortality benefits — low tidal volume ventilation at a number needed to treat of 11, prone positioning at 6, and dexamethasone in COVID-19 disease at about 8 in ventilated patients for a few euro a course — cost almost nothing. Every expensive drug has failed, and extracorporeal support at tens of thousands to hundreds of thousands of euro missed significance in its only randomised trial. A ventilator is required and costs tens of thousands of euro; how it is set is free and matters more than anything else.

**Simple means.** Setting the ventilator correctly is the most important treatment and it is free. Low tidal volume ventilation at 6 mL/kg of predicted body weight reduces mortality

from 39.8 to 31.0 per cent, number needed to treat 11. It is a number entered on a machine already in use. Predicted body weight must be calculated from height rather than from actual weight, which is a calculation done with a tape measure.

Prone positioning requires four or five people, pillows and a protocol, and no equipment whatsoever. It gives 28-day mortality of 16.0 against 32.8 per cent and 90-day mortality of 23.6 against 41.0 per cent in severe disease, number needed to treat 6. It is among the most effective interventions in critical care and its only cost is staff time and training. Awake proning was used widely in COVID-19 and reduced intubation in a meta-analysis of randomised trials, though a mortality benefit was not established.

Dexamethasone costs a few euro a course, is listed and off-patent, and has a number needed to treat of about 8 for mortality in ventilated COVID-19 disease. A cheap old steroid is the only drug that has clearly reduced mortality in this syndrome in a large trial.

Conservative fluid management is a strategy rather than a product and gives more ventilator-free days, 14.6 against 12.1, free. Head-of-bed elevation to 30 to 45 degrees, oral care, sedation minimisation and early mobilisation are nursing practice, free, and reduce ventilator-associated complications. Early antibiotics for the precipitating infection cost a few to tens of euro a course, listed and off-patent. Pulse oximetry costs tens to hundreds of euro and identifies the hypoxaemia that defines the syndrome. Vaccination against the precipitants is cheap, listed and routine.

The hard limit, stated as plainly as possible. This syndrome cannot be survived without mechanical ventilation in the great majority of cases. The minimum chain is a ventilator at tens of thousands of euro reliable oxygen, continuous nursing at roughly one nurse per one or two patients, sedation, suction, and blood gas or at minimum pulse oximetry monitoring. No positioning, drug or technique substitutes for that. What the simple means achieve is that once a ventilator exists, nearly all of the additional mortality benefit available comes free — from how it is set, from turning the patient over, and from a a few euro steroid. The inequity in outcomes worldwide is almost entirely about whether a ventilator and a nurse exist, not about whether the effective treatments are affordable.

**Gaps.** No GBD burden figure for acute respiratory distress syndrome exists, because it is a syndrome rather than a GBD cause, and this entry is part of the seventeen-condition gap in this chapter’s introduction. Incidence estimates range nearly ninefold, 10.1 to 86.2 per 100,000, driven by definition and intensive care availability rather than by disease frequency. The definition has changed four times — 1967, 1994, 2012 and 2023 — and each change alters measured incidence and mortality, so figures from different eras are not comparable. The syndrome is recognised by clinicians in only 60.2 per cent of cases and 51.3 per cent of mild cases, so the epidemiology is built on a syndrome that is half-missed in practice. Dozens of drug trials have been null, and the subphenotype hypothesis — hyperinflammatory against hypoinflammatory, with opposite responses to pressure and fluid strategy in retrospective reanalysis — is the leading explanation and has never been tested prospectively. Neuromuscular blockade is unresolved: ACURASYS positive, ROSE null. Corticosteroids are unresolved: RECOVERY and DEXA-ARDS positive, earlier and late-phase trials negative or harmful, and the patient group and timing that benefit are not settled. Higher positive end-expiratory pressure is unresolved and clinically consequential: meta-analysis suggests benefit in moderate to severe disease while ART found increased mortality with recruitment manoeuvres. EOLIA missed significance for extracorporeal support at p=0.09 with 28 per cent crossover, reanalyses favour it, and practice has expanded on contested evidence at tens of thousands to hundreds of thousands of euro a patient. Why diabetes is protective is unknown. Long-term outcome data come from a small number of high-income cohorts, and survivorship in low-resource settings is essentially unmeasured. Most of the world has no epidemiology for this syndrome at all, because it has no intensive care registries.

## Cystic fibrosis lung disease (ICD-11 CA25, respiratory manifestation of 5C57.0)

A note on placement. Cystic fibrosis is classified in ICD-11 under chapter 05, endocrine, nutritional and metabolic diseases, as 5C57.0, with the bronchiectasis of cystic fibrosis coded in chapter 12. It is included here for its respiratory manifestation, which is what kills.

**What it is.** A single inherited faulty protein makes mucus thick and sticky throughout the body. In the lungs the mucus cannot be cleared, so infection and scarring build from infancy. Until recently it killed in childhood or early adulthood.

**Measured.** No global figure for cystic fibrosis was retrieved from the GBD 2023 tables or the chapter map. This is one of the seventeen conditions in this chapter for which the global data carry nothing at all.

Birth incidence is roughly 1 in 2,500 to 3,500 live births in European-ancestry populations, far rarer in east Asian populations at roughly 1 in 30,000 to 100,000, and intermediate in Latin American, Middle Eastern and African-ancestry populations. Carrier frequency is roughly 1 in 25 to 30 in European-ancestry populations. Roughly 105,000 people are diagnosed across 94 countries, from 2022 modelling, and modelling suggests the true number may be substantially higher, with large under-diagnosis in Asia, Africa and Latin America.

Median predicted survival has transformed: from under five years in the 1950s to the mid-thirties and now over fifty years in high-income countries with registry data, with the UK and United States registries reporting median predicted survival in the fifties for children born recently. Respiratory failure causes roughly 60 to 80 per cent of deaths. In low- and middle-income countries median survival remains far lower and many patients are never diagnosed; the registry data describing the transformation come almost entirely from North America, Europe and Australasia. The adult population now exceeds the paediatric population in high-income countries — a complete inversion within one generation.

**Where it starts.** Autosomal recessive mutations in CFTR, the cystic fibrosis transmembrane conductance regulator, a chloride and bicarbonate channel. Over 2,000 variants have been described and roughly 400 to 700 are established as disease-causing. F508del is the commonest variant, present on roughly 70 per cent of alleles in European-ancestry populations and in roughly 85 to 90 per cent of patients on at least one allele.

The genotype-phenotype correlation is strong for pancreatic status and weak for lung disease: lung disease severity varies widely between siblings with identical CFTR genotypes, which is the central unexplained observation. Modifier genes — TGFB1, SLC26A9, EHF, the HLA region — explain part of the variance and much remains unassigned. Environmental modifiers with measured effects: second-hand tobacco smoke, which worsens lung function; air pollution; socioeconomic status, with a large and reproducible effect on survival independent of healthcare system; nutritional status, where body mass index strongly predicts lung function and survival; and early acquisition of Pseudomonas aeruginosa, a major adverse prognostic event.

Why siblings with identical genotypes have very different lung disease is unexplained, and modifier genes account for only part of it. The mechanism connecting channel dysfunction to the specific pattern of airway infection is incompletely understood: whether the primary defect is airway surface dehydration, bicarbonate-dependent mucus abnormality or impaired innate immunity is still argued. Whether modulators started in infancy will prevent lung disease entirely is not yet known — the first cohorts treated from infancy are only now growing up, and that is the most important open question in the field. The long-term durability and off-target effects of modulators over decades are unknown.

**Cure status.** CONTROLLABLE. That distinction must be stated precisely because it is widely blurred.

CFTR modulators restore partial channel function and dramatically improve disease, and they do not remove the genetic defect; treatment is lifelong and the benefit is lost on stopping. The landmark is elexacaftor with tezacaftor and ivacaftor. In patients with at least one F508del allele, roughly 85 to 90 per cent of all patients, the phase 3 trials of 2019 gave FEV1 improvement of roughly 14 percentage points, a 63 per cent reduction in pulmonary exacerbations, large sweat chloride falls and weight gain. Registry data since show falling transplant rates and falling mortality.

Roughly 10 per cent of patients have genotypes not responsive to any current modulator — nonsense, frameshift and splice variants with no channel protein to modulate — and they have had no share in the transformation. That is the central equity problem within the disease.

Lung transplantation replaces the organ, with median survival after transplant of roughly eight to ten years in cystic fibrosis, better than for most other indications. Gene therapy

and gene editing are in trials; no genetic cure exists, and the repeated failure of inhaled gene therapy over thirty years should temper claims. Newborn screening does not cure and changes the trajectory: screened children have better nutritional status and lung function than those diagnosed clinically.

**Prevention.**

*Newborn screening, immunoreactive trypsinogen plus DNA analysis — STRONG.* Randomised and cohort comparisons show better nutritional status, growth and lung function in screened children, and screening is now routine in most high-income countries. It costs a few to tens of euro per infant screened within an existing dried-blood-spot programme.

*Infection prevention and segregation — STRONG.* Cohort segregation and strict infection control reduced epidemic Pseudomonas and Burkholderia cepacia complex transmission substantially after the outbreaks of the 1990s, and patients are no longer allowed to meet each other in person at clinics — a measure with a measured effect and a real human cost.

*Early eradication of a first Pseudomonas aeruginosa isolation — STRONG.* The EPIC and ELITE trials: inhaled tobramycin eradicates early Pseudomonas in roughly 65 to 90 per cent of cases and delays chronic infection.

*Nutritional optimisation — STRONG.* Body mass index predicts lung function and survival; the measures are a high-calorie diet, pancreatic enzyme replacement and fat-soluble vitamins.

*Avoiding second-hand tobacco smoke — STRONG* for lung function in diagnosed patients.

*Carrier screening and genetic counselling — MODERATE* for reducing incidence where offered; Ashkenazi Jewish community screening programmes and population carrier screening have measurably reduced birth incidence. This is prevention of births, and a reference work should state it as such rather than as a purely technical measure.

*Vaccination against influenza, pneumococcus and COVID-19 — MODERATE*. *Air pollution reduction — MODERATE*.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Airway clearance physiotherapy | The historical foundation and still daily practice. Sputum clearance improves; Cochrane finds short-term benefit with no evidence that any one technique is superior | n/a | n/a | Training; devices a few to tens of euro |
| Dornase alfa, recombinant human DNase | FEV1 improved by roughly 5 to 6 per cent and exacerbations reduced by roughly 30 per cent, from the 1994 New England Journal of Medicine trial — **effective in cystic fibrosis and harmful in non-cystic-fibrosis bronchiectasis** | no | no | tens of thousands of euro |
| Hypertonic saline, nebulised 7 per cent | FEV1 improved modestly, roughly 3 per cent, and exacerbations reduced, from the 2006 New England Journal of Medicine trial | no | yes | hundreds of euro |
| Inhaled tobramycin or colistin for chronic Pseudomonas | FEV1 improved and exacerbations and hospitalisation reduced, from the 1999 New England Journal of Medicine trial | yes, both | yes | €2,000–25,000 depending on formulation and market |
| Azithromycin, chronic, three times weekly | FEV1 improved and exacerbations reduced in Pseudomonas-infected patients | yes | yes | €30–150. UNICEF indicative price October 2026: US$0.56 for six 250 mg tablets, about US$0.093 a tablet |

| Intervention | Effect size | EML | Off-patent | Cost per patient-year |
|---|---|---|---|---|
| Pancreatic enzyme replacement | Essential for nutrition in the roughly 85 per cent who are pancreatic insufficient, and nutritional status drives lung outcome | yes, listed as a medicine for cystic fibrosis, section 7, complementary | yes | hundreds to thousands of euro |
| Elexacaftor with tezacaftor and ivacaftor | FEV1 up about 14 percentage points; pulmonary exacerbations down 63 per cent; weight gain and sweat chloride fall; registry data show falling transplant rates and mortality | no | no | €250,000–300,000; United States list price above US$300,000, year not stated in the source; negotiated European prices lower and confidential |
| Ivacaftor, gating mutations, about 4 to 5 per cent of patients | FEV1 up 10.6 percentage points, from the 2011 New England Journal of Medicine trial | no | no | €250,000–300,000, United States list price, year not stated in the source |
| Lumacaftor with ivacaftor, tezacaftor with ivacaftor | Smaller effects, FEV1 up 3 to 4 points, largely superseded | no | no | Hundreds of thousands of euro |
| Antibiotics for exacerbations, intravenous and oral | Standard care; exacerbations shortened and lung function preserved | yes, most agents | yes | tens to thousands of euro a course |
| Inhaled bronchodilator | Symptomatic; given before clearance and nebulised therapies | yes | yes | tens of euro |
| Fat-soluble vitamins A, D, E and K | Prevent deficiency | yes | yes | tens to hundreds of euro |
| Lung transplantation | Median survival eight to ten years post-transplant | n/a | n/a | hundreds of thousands of euro in the first year |
| High-dose ibuprofen, anti-inflammatory | Slowed FEV1 decline in a single-centre randomised trial; rarely used, very cheap, and never replicated at scale | yes | yes | tens to hundreds of euro |

The price structure here is the starkest in either chapter. The drug that transformed the disease costs €250,000 to €300,000 a patient-year (United States list price, year not stated in the source) and is on patent. Against that, the entire traditional regimen — airway clearance technique, hypertonic saline, azithromycin, pancreatic enzymes, vitamins and antibiotics for exacerbations — costs on the order of hundreds to thousands of euro a patient-year at generic prices. That regimen is what delivered the rise in median survival from under five years to the mid-thirties, before any modulator existed. Modulators are accessible to a small fraction of the world’s patients, and most of the historical gain was made with cheap means and organised care.

**Simple means.** Airway clearance by physical technique needs no equipment at all: the active cycle of breathing technique, autogenic drainage, postural drainage and percussion. Cochrane finds short-term benefit with no one technique superior. Twice or three times daily, 20 to 30 minutes, for life. This plus nutrition is what raised survival from under five years to the mid-thirties before any modulator existed, and it remains daily practice.

Oscillating positive expiratory pressure devices — a flutter valve, an Acapella — cost tens of euro are reusable and need no power. Bubble positive expiratory pressure from a bottle and tubing is improvised and used where devices are unavailable. Exercise improves exercise capacity and is associated with slower lung function decline in cohort data; it is both therapy and clearance, and it is free.

Hypertonic saline at 7 per cent can be prepared from salt and sterile water at trivial cost, and it improves FEV1 and reduces exacerbations; a nebuliser needs power. Nutrition is food plus enzyme replacement: nutritional status is one of the strongest predictors of lung function and survival, and pancreatic enzymes are on the Essential Medicines List, off-patent, at hundreds to thousands of euro a year, and they are the one indispensable non-respiratory drug.

Azithromycin is the best effect-per-euro drug in the entry: tens to hundreds of euro a year, listed, off-patent, and it improves FEV1 and reduces exacerbations in Pseudomonas-infected

patients. Salt supplementation in hot climates prevents hyponatraemic dehydration and is table salt. Avoiding second-hand smoke is free, with a measured effect on lung function.

Infection control is soap, water and segregation policy: handwashing, not sharing nebulisers, cleaning and drying equipment, avoiding contact with other patients. The Burkholderia cepacia epidemics of the 1990s showed the measured cost of getting this wrong. Newborn screening costs a few to tens of euro per infant within an existing dried-blood-spot programme and improves nutrition and lung function through earlier diagnosis.

The hard limit, stated plainly. Diagnosis requires sweat chloride testing — a cheap, low-technology test at tens to hundreds of euro needing pilocarpine iontophoresis apparatus — or genetic testing. Chronic Pseudomonas management needs inhaled antibiotics and a nebuliser with power. The modulators, the drugs that changed the disease, cost €250,000 to €300,000 a year (United States list price, year not stated in the source) and are out of reach for the great majority of patients worldwide. For them the regimen is the pre-modulator one: clearance technique, nutrition, azithromycin, hypertonic saline and antibiotics for exacerbations. That regimen is cheap, it works, and it delivered most of the historical survival gain — and it leaves survival far below what modulators now achieve, and the gap is a matter of price.

**Gaps.** No global burden figure for cystic fibrosis exists in the retrieved GBD tables, and this entry is part of the seventeen-condition gap in this chapter's introduction; the roughly 105,000 diagnosed across 94 countries is a modelled figure, and under-diagnosis in Asia, Africa and Latin America is believed large and is unquantified. Why siblings with identical genotypes differ so much in lung disease is unexplained. Whether modulators started in infancy will prevent lung disease entirely is unknown, and it is the most important open question, answerable only by waiting. Roughly 10 per cent of patients have no modulator-responsive genotype and have gained nothing from the transformation. Long-term modulator durability, off-target effects over decades and effects on the many non-pulmonary manifestations are unknown. All registry data describing the survival transformation come from high-income countries, and outcomes elsewhere are largely unmeasured. Dornase alfa helps in cystic fibrosis and harms in non-cystic-fibrosis bronchiectasis — a standing warning against extrapolation between the two. High-dose ibuprofen slowed FEV1 decline in a single trial, costs tens to hundreds of euro a year, and was never replicated at scale; a cheap intervention left untested is itself a gap. Airway clearance, the foundation of care, has only short-term evidence and no technique shown superior, because physiotherapy trials cannot be blinded and have never been powered for hard endpoints. Modulator pricing of €250,000 to €300,000 a year (United States list price, year not stated in the source) against a cheap regimen that delivered most of the historical gain is the central unresolved equity question in the disease, and negotiated European prices are confidential, so even the real prices are not public.

## Upper respiratory tract infections — the common cold, acute pharyngitis, acute sinusitis, laryngitis (ICD-11 CA00–CA0F)

**What it is.** Viruses infect the nose, throat and sinuses. The nose runs and blocks, the throat is sore, there is a cough and sometimes a fever for a few days. It gets better by itself.

**Measured.** Deaths in 2023: 27,100 (95 per cent uncertainty interval 6,100 to 77,300), down from 38,300 in 2000, a change of −29.4 per cent, from GBD 2023. That uncertainty interval spans more than a twelvefold range, the widest of any figure in either chapter, so the death count is effectively unknown.

No global incidence figure was retrieved. Commonly cited estimates are two to four colds per adult a year and six to ten per child a year in high-income countries, which makes upper respiratory infection the commonest acute illness of human beings and the leading cause of absence from work and school. GBD 2019 estimated roughly 17 billion incident episodes a year globally, more episodes than any other condition, and that is a model output. Otitis media deaths in 2023: 700 (300 to 1,700), down from 1,000 in 2000, a change of −35.3 per cent. Incidence is highest in young children, particularly those in day care, and declines through adulthood. Mortality is concentrated in infants, the very old and the immunocompromised.

Upper respiratory infection is the single largest driver of inappropriate antibiotic prescribing worldwide. Roughly 40 to 70 per cent of consultations in high-income primary care result in an antibiotic prescription, for a condition that is overwhelmingly viral, and the figure exceeds

80 per cent in several low- and middle-income settings. For scale, about one in six laboratory-confirmed bacterial infections worldwide was resistant in 2023, resistance rose for over 40 per cent of monitored pathogen-antibiotic combinations between 2018 and 2023 at 5 to 15 per cent a year, and more than 4.7 million deaths were linked to bacterial antimicrobial resistance in 2021. Group A streptococcal pharyngitis accounts for roughly 5 to 15 per cent of sore throat in adults and 20 to 30 per cent in children — the minority in which antibiotics have a real indication.

**Where it starts.** Rhinoviruses cause roughly 30 to 50 per cent of colds, with over 160 serotypes, which is why immunity does not accumulate usefully. Coronaviruses including the four endemic seasonal ones and SARS-CoV-2, influenza A and B, respiratory syncytial virus, parainfluenza, human metapneumovirus, adenovirus, enteroviruses and bocavirus all contribute.

Group A Streptococcus is the important bacterial cause of pharyngitis and the one that causes rheumatic fever if untreated: roughly 0.3 to 3 per cent of untreated streptococcal sore throats lead to acute rheumatic fever in susceptible populations. Other bacterial causes: Fusobacterium necrophorum giving Lemierre syndrome, group C and G streptococci, Mycoplasma, and diphtheria, now rare at 4,000 deaths in 2023, down 82.8 per cent from 2000.

Transmission is by respiratory droplets, aerosols, and contaminated hands and surfaces. Rhinovirus survives on surfaces for hours and self-inoculation via the hands to the nose and eyes is a major route, which is why handwashing works. Risk factors: young age, day care and school attendance, household crowding, winter season, psychological stress — a reproducible finding in experimental inoculation studies — sleep deprivation, smoking and secondhand smoke, and vitamin D deficiency, contested. Cold exposure itself has partial experimental support: nasal cooling impairs mucociliary clearance and innate immune responses, and rhinovirus replicates better at 33 °C than at 37 °C. It does not cause the infection; there must be a virus.

Why some people infected with the same inoculum develop symptoms and others do not is not fully explained — in experimental rhinovirus inoculation roughly 25 to 30 per cent of infected volunteers remain asymptomatic†. Why psychological stress reproducibly increases susceptibility in controlled inoculation studies is not mechanistically settled. There is still no effective antiviral for rhinovirus after seventy years of effort, and no prospect of a vaccine given the number of serotypes. Why some people develop a post-viral cough lasting weeks is not explained.

**Cure status.** SELF-LIMITING. This is the clearest SELF-LIMITING classification in either chapter, and the classification itself is the clinically important fact. Group A streptococcal pharyngitis, diphtheria, epiglottitis, quinsy, Lemierre syndrome and retropharyngeal abscess: CURABLE with antibiotics and, where needed, drainage and airway protection.

The common cold resolves in seven to ten days without any treatment, and the cough can persist two to three weeks; no treatment shortens it meaningfully. Acute rhinosinusitis resolves within two weeks without antibiotics in roughly 70 to 80 per cent of cases. Cochrane gives antibiotics a number needed to treat of roughly 11 to 15 for cure at seven to fourteen days, against substantial adverse-effect rates, with a number needed to harm of roughly 8 for any adverse effect. Acute sore throat resolves spontaneously in the great majority, and antibiotics shorten it by roughly sixteen hours on average across all comers, per Cochrane — a negligible clinical benefit. Influenza is SELF-LIMITING, with oseltamivir shortening symptoms by roughly a day.

The exception where treatment matters is group A streptococcal pharyngitis in populations at risk of rheumatic fever. Penicillin within nine days reduces first-episode rheumatic fever by roughly 70 to 80 per cent, and Cochrane gives antibiotics for sore throat a relative risk of roughly 0.27 for acute rheumatic fever; it also reduces quinsy and otitis media. In high-rheumatic-fever-incidence populations the calculation is entirely different from high-income primary care, and both must be stated.

**Prevention.**

*Handwashing with soap — STRONG, with large measured effects.* Cochrane reviews of physical interventions find handwashing reduces respiratory infection transmission, and the Karachi cluster-randomised trial found handwashing promotion halved pneumonia incidence in children under five. Soap and water.

*Influenza vaccination — MODERATE.* Laboratory-confirmed influenza reduced by roughly 40 to 60 per cent in seasons with a good match, with hospitalisation and death reduced in older adults. *COVID-19 vaccination — STRONG* for severe disease.

*Masks — MODERATE and CONTESTED, and both positions must be printed.* The 2023 Cochrane review of physical interventions concluded that wearing masks in the community probably makes little or no difference to influenza-like illness, with a pooled relative risk of about 0.95. That conclusion was heavily criticised for pooling heterogeneous trials and for low adherence in the included studies, and Cochrane's own editor-in-chief publicly qualified it. Observational and mechanistic evidence supports source control. This is a genuine and unresolved dispute.

*Avoiding face-touching and self-inoculation — MODERATE*, mechanistically supported. *Ventilation of indoor spaces — MODERATE*, with good mechanistic and modelling support and limited randomised evidence. *Staying home when symptomatic — MODERATE*, with little randomised evidence and strong mechanistic plausibility. *Smoking cessation — MODERATE*. *Reducing day-care group size — WEAK*.

*Vitamin D supplementation — CONTESTED.* The individual-participant meta-analysis published in the BMJ in 2017 found a small protective effect, adjusted odds ratio 0.88, largest in those with baseline 25-hydroxyvitamin D below 25 nmol/L; the subsequent large trials VITAL and D-Health were null for respiratory infection. Both are printed.

*Zinc lozenges — CONTESTED.* Some meta-analyses find cold duration reduced by roughly one to two days with high-dose zinc acetate or gluconate started within 24 hours; others find the evidence too heterogeneous and the trials too small, and adverse taste and nausea are common.

*Vitamin C — WEAK or negative for prevention in the general population*, with one reproducible subgroup finding. Cochrane finds no reduction in cold incidence with routine supplementation, a roughly 8 per cent reduction in duration in adults, and a consistent halving of incidence in people undergoing extreme physical exertion — marathon runners, soldiers, skiers.

*Probiotics — WEAK*; Cochrane suggests a small reduction in episodes at low certainty. *Echinacea, garlic, honey, nasal saline and gargling — WEAK*, with honey having moderate evidence for cough symptom relief in children over one year.

**Treatment.**

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Nothing, meaning watchful waiting with explanation and a safety net | The correct treatment for the great majority. Delayed-prescription strategies reduce antibiotic use by roughly 60 to 80 per cent with no increase in complications or dissatisfaction, per Cochrane | n/a | n/a | **Nothing** |
| Paracetamol or ibuprofen | Fever, headache, sore throat and malaise reduced; they do not shorten the illness | yes, both | yes | a few to a few euro a course |
| Nasal saline irrigation or spray | Modest symptom relief; the UK primary-care trial found nasal irrigation helped while steam did not | n/a | n/a | Near zero home-made |
| Honey, for cough in children over one year | Cochrane: better than no treatment and probably better than diphenhydramine for cough symptoms; comparable to dextromethorphan | no | n/a | a few euro |
| Penicillin or amoxicillin for group A streptococcal pharyngitis | Sore throat shortened by about sixteen hours across all comers; acute rheumatic fever reduced about 70 to 80 per cent, relative risk about 0.27, and quinsy and otitis media reduced | yes; amoxicillin is listed first-choice for pharyngitis | yes | a few to a few euro a course |

| Intervention | Effect size | EML | Off-patent | Cost |
|---|---|---|---|---|
| Antibiotics for acute rhinosinusitis | Number needed to treat 11 to 15 for cure at seven to fourteen days; number needed to harm about 8 for adverse effects; 70 to 80 per cent resolve spontaneously | yes | yes | a few to tens of euro a course |
| Topical or oral decongestant | Short-term relief of nasal blockage; rhinitis medicamentosa with topical use beyond five to seven days; not for young children | partly | yes | a few to tens of euro |
| Zinc lozenges, high dose within 24 hours | Duration reduced by roughly one to two days in some meta-analyses and null in others; taste and nausea common | no | yes | a few to tens of euro a course |
| Oseltamivir, influenza | Symptoms shortened by roughly a day; the mortality benefit in hospitalised patients is observational and contested | yes | yes | a few to tens of euro a course |
| Corticosteroids, a single dose for severe sore throat | Cochrane: complete pain resolution at 24 hours increased, relative risk 2.2, as an adjunct | yes | yes | a few to a few euro |
| Antitussives, dextromethorphan or codeine | Little or no benefit over placebo for acute cough, per Cochrane; codeine is ineffective and not for children | partly | yes | a few to tens of euro |
| Antihistamines as cold remedies | A small short-term effect on rhinorrhoea in adults; no benefit in children, and sedating agents carry harm | yes | yes | a few to tens of euro |
| Antibiotics for the common cold | **No benefit and definite harm**, per Cochrane | — | — | — |
| Vitamin C started after onset | No consistent benefit when started after symptoms begin | no | yes | — |
| Drainage and airway management for quinsy, epiglottitis or abscess | Life-saving in the dangerous minority | n/a | n/a | Surgical |

**Simple means.** This is the condition where simple means are not merely adequate but are the whole of correct care.

Doing nothing, explained well, is the intervention, and it is a conversation. Delayed or no prescription reduces antibiotic use by 60 to 80 per cent with no increase in complications. It costs nothing and it addresses the largest single source of antibiotic overuse in the world.

Handwashing with soap halved childhood pneumonia incidence in the Karachi cluster-randomised trial and reduces respiratory transmission generally. Soap. Rest, fluids and time: the illness resolves in seven to ten days. Paracetamol or ibuprofen costs a few to a few euro both listed and off-patent, and treats the symptoms that matter.

Nasal saline irrigation is home-made from salt, baking soda and boiled or distilled water, and the UK primary-care trial found irrigation helped and steam did not. Near-zero cost, with the same amoebic-infection warning about untreated tap water as in the rhinitis entries.

Honey for cough in children over one year is better than no treatment and probably better than an antihistamine, per Cochrane. A spoon of honey. Not for infants under one year, because of botulism risk. Salt-water gargling has low-quality evidence for symptom relief and costs nothing.

Steam inhalation does not help, and it is the most popular home remedy for the condition. It was found not to help in the UK trial and in Cochrane review, and it carries a real scald risk in children. That is printed.

Penicillin for streptococcal sore throat where rheumatic fever is endemic costs a few to a few euro an oral course, is listed and off-patent, and prevents 70 to 80 per cent of first rheumatic fever episodes. In a population with endemic rheumatic fever, this cheap tablet for a self-limiting illness is one of the highest-value interventions in medicine, while in a high-income

setting the same prescription for the same illness is usually unnecessary. The Centor and McIsaac scores and rapid antigen tests, at a few euro each, help select patients, and in high-incidence settings treating on clinical grounds is the recommended approach.

Recognising the dangerous minority is free and it is the whole of the safety net: drooling, stridor, trismus, unilateral swelling, inability to swallow, a stiff neck or a toxic appearance indicate epiglottitis, quinsy, abscess or Lemierre syndrome. Staying home, covering coughs and ventilating rooms are free and mechanistically sound.

The hard limit, which is unusually mild here. Distinguishing streptococcal from viral pharyngitis benefits from a a few euro rapid antigen test or a throat swab, and the dangerous complications need imaging and surgical access. For the overwhelming majority of upper respiratory infection, nothing is required at all, and the main clinical skill is not treating it.

**Gaps.** GBD gives 27,100 deaths with an uncertainty interval of 6,100 to 77,300 for 2023 — more than a twelvefold range, the widest of any figure in either chapter — so the death count is effectively unknown. No global incidence figure was retrieved, and the roughly 17 billion episodes figure is a model output. Masks: Cochrane concluded little or no difference and the conclusion was heavily criticised and publicly qualified by Cochrane itself; unresolved, politically charged, and both positions printed. Vitamin D: the individual-participant meta-analysis positive at odds ratio 0.88, VITAL and D-Health null; unresolved. Zinc: meta-analyses disagree on whether duration is reduced and by how much. Vitamin C: no prevention benefit in general populations and a consistent halving of incidence in extreme-exertion subgroups, a reproducible and unexplained subgroup finding. Why 25 to 30 per cent of experimentally infected volunteers stay asymptomatic is unexplained. Why psychological stress reproducibly increases susceptibility is not mechanistically settled. No antiviral for rhinovirus exists after seventy years, and no vaccine is feasible given more than 160 serotypes. Antibiotic prescribing rates of 40 to 70 per cent in high-income primary care and over 80 per cent in some low- and middle-income settings for an overwhelmingly viral condition represent the largest gap between evidence and practice in either chapter. The rheumatic-fever calculation inverts the antibiotic decision between high- and low-incidence populations, and guidelines written for one are routinely applied in the other. Post-viral cough lasting weeks has no established mechanism and no effective treatment.

---

# What no longer holds

Each item here is a practice that this chapter's own best evidence contradicts. They are collected because a reference work that scatters them across sixty pages hides them.

**Immunosuppression in idiopathic pulmonary fibrosis.** PANTHER-IPF, testing prednisone with azathioprine and N-acetylcysteine, was stopped early for increased death and hospitalisation, with mortality of 8 against 1 per cent. The standard treatment for decades made the disease worse. This is the heaviest reversal in the chapter, and the reason the diagnostic distinction between idiopathic fibrosis and the immunosuppression-responsive interstitial diseases carries a demonstrated mortality cost.

**Sodium restriction in heart failure.** SODIUM-HF randomised 806 patients to below 1,500 mg of sodium a day and found no reduction in death, cardiovascular hospitalisation or emergency visits, hazard ratio 0.89, p=0.53, with a small quality-of-life improvement. Decades of standard advice rest on physiology rather than on this trial.

**Adaptive servo-ventilation in heart failure.** The SERVE-HF trial tested adaptive servo-ventilation for central sleep apnoea in heart failure with reduced ejection fraction and found increased cardiovascular mortality, and the therapy is now contraindicated in that population. This is the clearest case in either chapter of a device therapy that was withdrawn because the trial found harm rather than absence of benefit.

**Beta blockers after myocardial infarction with preserved ejection fraction.** REDUCE-AMI, with 5,020 patients in 2024, found no benefit of beta blockade after infarction with preserved ejection fraction, hazard ratio 0.96. The classical 20 to 25 per cent mortality benefit comes from the pre-reperfusion trials, and guidelines have not fully absorbed the change.

**Targeted hypothermia after cardiac arrest.** TTM2, with 1,900 patients in 2021, found hypothermia at 33 °C gave no mortality benefit against normothermia with fever avoidance, hazard ratio 1.04. Practice has shifted to fever avoidance, which needs ice packs and fans rather than a tens of thousands of euro cooling device.

**Revascularisation for stable coronary disease, as a way of preventing death or infarction.** COURAGE and ISCHEMIA found no reduction in death or myocardial infarction against optimal medical therapy alone. Intervention relieves angina. It does not do the other thing it is widely believed to do.

**Compression stockings after stroke, and after deep vein thrombosis for post-thrombotic syndrome.** CLOTS-1, with 2,518 stroke patients, found no benefit from thigh-length stockings and increased skin breaks, 5 against 1 per cent. The SOX trial, with 806 patients, found no prevention of post-thrombotic syndrome, 14.2 against 12.7 per cent, against earlier smaller trials reporting roughly a 50 per cent reduction. The same garment remains beneficial in surgical thromboprophylaxis, with a Cochrane odds ratio of about 0.35, so the garment is not the error; the population is.

**House dust mite avoidance in asthma and in allergic rhinitis.** Cochrane found no clear benefit of physical or chemical mite-control measures for either condition. The advice is near-universal.

**Steam inhalation for upper respiratory and sinus symptoms.** Cochrane and the large UK primary-care trial found no benefit, while nasal irrigation did help. Steam is the commoner home remedy and it is the one that does not work, and it carries a scald risk in children.

**Antifungals in chronic rhinosinusitis.** Cochrane found no benefit, against a once-dominant hypothesis.

**Corticosteroids in acute rheumatic carditis.** Cochrane found no clear reduction in cardiac valve damage at one year, relative risk 0.87, against long-standing practice.

**Dornase alfa in non-cystic-fibrosis bronchiectasis.** A randomised trial showed worse FEV1 and more exacerbations. The same drug improves FEV1 by 5 to 6 per cent and reduces exacerbations by about 30 per cent in cystic fibrosis. The pair is a standing warning against extrapolating between superficially similar diseases.

**Antibiotics for the common cold.** No benefit and definite harm, per Cochrane, in a condition that receives an antibiotic prescription in 40 to 70 per cent of high-income primary care consultations and over 80 per cent in some low- and middle-income settings.

**Activity restriction after pneumothorax.** Widely advised and not evidence-based: most episodes occur at rest.

**Intervention for unruptured arteriovenous malformations.** ARUBA, with 223 patients, found intervention worse than medical management, hazard ratio 0.27 favouring medical management.

**Early repair of small abdominal aortic aneurysms.** The UK Small Aneurysm Trial, with 1,090 patients at 4.0 to 5.5 cm, and ADAM, with 1,136 patients, both found no survival advantage from early repair against surveillance. The 5.5 cm threshold is trial-derived rather than arbitrary — and the threshold for women was derived in male cohorts and is not evidence-based.

**Mobilising stroke patients as early and as much as possible.** AVERT, with 2,104 patients, found very early and very high-dose mobilisation was worse than usual early care, odds ratio 0.73 for a favourable outcome. Early mobilisation remains core stroke unit care; “earlier and more” does not follow from it.

**Corticosteroids in tuberculous pleural effusion.** No outcome benefit, and not recommended.

**Immediate angiography after cardiac arrest without ST elevation.** COACT and TOMAHAWK were both null, against prior practice.

**Short-acting beta-agonist monotherapy in asthma.** Associated with increased mortality; the New Zealand fenoterol epidemic and the SMART trial, with 26,355 patients, established it, and GINA no longer recommends reliever-only treatment at any severity.

**Pulmonary vasodilators outside group 1 pulmonary hypertension.** Riociguat in group 3 disease was stopped for increased mortality in RISE-IIP, and sildenafil in pulmonary fibrosis and in heart failure with preserved ejection fraction was null. The harm outside group 1 is widely under-appreciated.

**Recruitment manoeuvres with pressure titration in acute respiratory distress syndrome.** ART, with 1,010 patients, found increased mortality, hazard ratio 1.20.

**Mechanical chest compression devices in cardiac arrest.** LINC and PARAMEDIC found them no better than manual compressions, at tens of thousands of euro a device.

**Advanced wound dressings under compression for venous ulcers.** Cochrane found no dressing type superior to simple low-adherent dressings beneath compression. The market is large and the demonstrated advantage is absent.

One final item belongs here, and it is not a practice but a source. The Management Sciences for Health International Medical Products Price Guide, which several of this chapter’s price figures were drawn from, published its last edition in 2017 and its website was retired after 30 June 2024. Any citation to it must be dated 2017 at the latest and labelled as such. The UNICEF Supply Catalogue is the working substitute used in this chapter, and it returns different indicative prices for the same material number on different pages of the same catalogue, so its figures are printed as indicative and dated rather than as prices.

## Introduction

Three ICD chapters are gathered here. They have nothing in common anatomically. They have one thing in common that matters to this book: they carry the largest burden of disability in the world, almost none of the mortality, and the widest gap between what is known and what is delivered. Fifty-five entries follow, covering sixty-two named conditions.

Diverticular disease is the entry that prompted this book. It gets the longest treatment in this chapter and the reason is not elaborated further.

The clearest cheap cure in the chapter is *Helicobacter pylori* eradication. Two antibiotics and an acid blocker for ten to fourteen days clear the organism in 70 to 94 per cent of courses, depending on the regimen and on local resistance. The drug cost of that course is a few to tens of US dollars at generic prices. What it buys is not symptom relief. It cures the ulcer diathesis, with recurrence falling from about 60 to 70 per cent a year to under 5 per cent. It removes a Group 1 carcinogen responsible for 75 to 90 per cent of non-cardia gastric cancer, a disease that killed about 660,000 people in 2022. And it cures gastric MALT lymphoma outright — a malignancy abolished by an antibiotic course, which is why the cure-status rules in Part 0 name it as the type case for CURABLE.

The two largest burdens in this chapter are low back pain and knee osteoarthritis, and in both of them exercise is the best-supported non-drug treatment. Low back pain is the single largest cause of years lived with disability in the world. The GBD 2021 condition paper gives 619 million prevalent cases in 2020, with a 95 per cent uncertainty interval of 554 to 694 million; 69.0 million years lived with disability (47.9 to 88.9); 8.1 per cent of all-cause YLDs; rank one globally; and a projection of 843 million cases by 2050 (759 to 933). The WHO low back pain fact sheet of 19 June 2023 carries the same 619 million and the same 843 million by 2050. Deaths: zero. The entire burden is disability, which is why the condition dominates the YLD table and is absent from every mortality table.

Against that burden, the trial record on the drugs is poor. Paracetamol was found identical to placebo in PACE, 1,643 patients, with a median seventeen days to recovery in both arms.

Opioids were no better than non-opioid analgesics in SPACE and no better than placebo in OPAL, with worse pain at one year in both. Exercise combined with education reduces recurrence, with a pooled relative risk of about 0.55 to 0.65. In knee and hip osteoarthritis the standardised mean difference for exercise on pain is about 0.4 to 0.6 against about 0.3 to 0.4 for oral NSAIDs, and weight loss adds a dose-response that no drug matches. Several standard treatments in this chapter failed their own trials and are still performed in volume. They are listed at the end of the chapter.

---

## A note on the prices in this chapter

Generic drug costs here are order-of-magnitude and vary by a factor of ten to a hundred between markets. They derive from international generic tender prices, Indian and UK generic prices, and United States retail ranges. Where the source of a price could not be opened, the price carries a dagger.

One source needs naming. The MSH / WHO *International Medical Products Price Guide*, long the standard international reference, is no longer a live product: its last edition is 2017 and its website was retired after 30 June 2024. Any price traceable to it is a 2017 price. The UNICEF Supply Catalogue is the working substitute, and it returns different indicative prices for the same material number on different pages, so its figures are indicative and dated rather than prices.

---

# ICD-11 Chapter 13 — Diseases of the digestive system

---

## Gastro-oesophageal reflux disease

**What it is.** Stomach contents move back up into the oesophagus. The lining is not built for acid, so it burns and may erode. The diagnosis rests on symptoms or on visible mucosal damage at endoscopy.

**Measured.** Global prevalence of at least weekly symptoms is 13.3 per cent of adults, from a systematic review of 102 studies (Eusebi, *Gut* 2018)†. The geographic spread in that review is wide: 18.1 per cent in North America against 8.5 per cent in East Asia†. Prevalence rises with age and is higher above fifty.

GBD does not model reflux disease as a separate cause, so there is no DALY figure for it; the burden enters through Barrett oesophagus and oesophageal adenocarcinoma. Directly attributable deaths are negligible. Mortality enters through adenocarcinoma, for which reflux is the principal risk factor.

**Where it starts.** Obesity is dose-dependent. Each unit of BMI raises risk, and BMI above 30 roughly doubles symptom risk against normal weight (Hampel, *Annals of Internal Medicine* 2005). Hiatal hernia is strongly associated and mechanically direct, through loss of the diaphragmatic pinch, and is present in a large fraction of erosive cases.

Smoking, pregnancy, late large meals and several drug classes — calcium channel blockers, nitrates, anticholinergics — reduce lower oesophageal sphincter tone. Twin studies give a heritability of roughly 31 per cent for reflux symptoms (Mohammed, *Gut* 2003)†.

What is not known is why symptom severity and visible mucosal damage correlate so poorly. Many with severe symptoms have a normal endoscopy, which is non-erosive reflux disease; many with erosions have few symptoms. The determinants of oesophageal pain sensitivity are unexplained, as is why only a small minority progress to Barrett oesophagus.

**Cure status.** CONTROLLABLE. Acid suppression reliably relieves symptoms and heals erosions, but the mechanical defect persists and symptoms return on stopping in the majority. Fundoplication is the nearest thing to a cure and gives durable control in most operated patients, but a substantial minority resume acid suppression within ten years, and the operation carries dysphagia and gas-bloat effects.

**Prevention.** Weight loss: MODERATE. Prospective cohort data show symptom reduction with weight loss, dose-dependently (Jacobson, *NEJM* 2006). Raising the head of the bed and avoiding late meals: WEAK. Smoking cessation: WEAK. Elimination of specific trigger foods — coffee, chocolate, citrus, mint: CONTESTED. Widely advised and poorly supported by trial evidence; the effects appear individual.

**Treatment.** Proton pump inhibitors heal erosive oesophagitis in about 80 to 85 per cent at eight weeks, against about 50 per cent for H2 blockers and about 25 per cent for placebo (Chiba, *Gastroenterology* 1997). Omeprazole is on the WHO EML, section 17.1, with reflux disease among its listed indications; off-patent; roughly US$3 to 25 per patient-year at international generic prices.

H2 receptor antagonists, now famotidine since ranitidine was withdrawn in many markets over NDMA contamination, are less effective than PPIs. Off-patent; a few to tens of US dollars

a year. Alginate and antacid preparations help breakthrough symptoms with no mucosal healing claim. Laparoscopic fundoplication is for PPI-refractory or PPI-intolerant disease with confirmed reflux.

On PPI safety, two bodies of evidence disagree. Observational studies associate long-term use with fracture, kidney disease, enteric infection and B12 deficiency. The COMPASS randomised safety analysis, 17,598 participants over a median three years (Moayyedi, *Gastroenterology* 2019), found no significant excess for any of these except enteric infection. Both are printed. The observational signals are probably substantially confounded.

**Simple means.** Weight loss where overweight is the single most effective non-pharmacological measure. Head-of-bed elevation by about 20 cm and left-lateral sleeping produce a small but measurable reduction in nocturnal acid exposure. Not eating within three hours of lying down; smaller meals; smoking cessation; loosening tight waistbands. None of these requires an industrial supply chain.

**Gaps.** Non-erosive reflux disease is poorly understood and responds less well to acid suppression. Long-term PPI safety remains disputed between observational and randomised evidence. No intervention has been shown to prevent progression to adenocarcinoma. Trigger-food advice is near-universal clinically and near-unsupported evidentially.

---

## Peptic ulcer disease and *Helicobacter pylori*

**What it is.** An open sore in the lining of the stomach or duodenum. Most are caused by *H. pylori* infection or by NSAIDs. The same infection causes gastric cancer.

**Measured.** About 4.4 billion people are infected with *H. pylori*, some 43 to 50 per cent of humanity (Hooi, *Gastroenterology* 2017; Zamani 2018). The geographic gradient is steep: above 70 per cent in parts of Africa, South America and South Asia; below 30 per cent and falling across much of Western Europe, North America and Australia.

Peptic ulcer disease causes some 270,000 to 300,000 deaths a year; GBD 2019 gave 236,000 deaths and about 8 to 9 million DALYs†. Gastric cancer accounted for about 970,000 new cases and about 660,000 deaths in 2022 (GLOBOCAN 2022, IARC). *H. pylori* is responsible for roughly 75 to 90 per cent of non-cardia gastric cancer, and IARC classifies it as a Group 1 carcinogen.

Ulcer incidence and mortality have fallen steeply in high-income countries across four decades, tracking the fall in *H. pylori* prevalence and the rise of acid suppression. The infection is acquired almost entirely in childhood, so adult prevalence reflects childhood conditions decades earlier.

**Where it starts.** *H. pylori* infection is the dominant cause, found in about 90 per cent of duodenal and 70 to 80 per cent of gastric ulcers in populations before widespread eradication. NSAIDs including aspirin raise ulcer complications roughly fourfold and are the main cause in *H. pylori*-negative patients. The two are at least additive and probably synergistic. Smoking raises risk and impairs healing; alcohol is weaker and less consistent.

Lifetime gastric cancer risk in an infected person is about 1 to 3 per cent†. The infection is therefore necessary for most cases and far from sufficient. Transmission is faecal-oral and oral-oral, mostly within households in childhood, and crowding and absent sanitation are the strongest structural determinants.

What is not known is why only 1 to 3 per cent of infected people develop cancer and 10 to 15 per cent† develop ulcers while most stay asymptomatic for life. Host genetics, strain virulence and the rest of the gastric microbiome each explain part, none decisively. Nor is it established whether population-wide eradication alters gastric microbial ecology in ways that matter. Stress and diet, long blamed, are not established causes.

**Cure status.** CURABLE. A ten to fourteen day course of two antibiotics with a PPI eradicates the organism in 70 to 94 per cent of courses depending on regimen and local resistance, and eradication cures the diathesis: ulcer recurrence falls from about 60 to 70 per cent a year to under 5 per cent. An NSAID-caused ulcer is curable by stopping the NSAID and giving acid suppression.

**Prevention.** *H. pylori* eradication to prevent gastric cancer: STRONG. Meta-analyses of randomised trials show roughly a one-third reduction in gastric cancer incidence, pooled relative risk about 0.54 to 0.68 depending on the analysis (Ford, *BMJ* 2014, and Cochrane updates). The Shandong and Linqu County trials in China, with Korean and Japanese studies, are the backbone of that evidence. The effect is larger when eradication precedes established atrophic change, which means earlier in life.

Sanitation and clean water: STRONG as a structural matter. This is what drove the historical collapse in prevalence in high-income countries, demonstrated by ecological and cohort rather than randomised evidence.

Avoiding unnecessary NSAIDs, and co-prescribing a PPI where NSAIDs are needed in at-risk patients: STRONG. PPI co-therapy substantially reduces endoscopic and clinical ulcer complications. Not smoking: MODERATE. No vaccine is in routine use; candidates have shown partial efficacy and none is licensed.

**Treatment.** The eradication regimens are the centre of this entry.

| Regimen | Composition | Duration | Cure rate |
|---|---|---|---|
| Standard triple | PPI + amoxicillin 1 g bd + clarithromycin 500 mg bd | 14 d | 70–85%, falling |
| Bismuth quadruple | PPI + bismuth + tetracycline + metronidazole | 10–14 d | 85–94% |
| Concomitant quadruple | PPI + amoxicillin + clarithromycin + metronidazole | 14 d | 85–90% |
| Levofloxacin triple | PPI + amoxicillin + levofloxacin | 10–14 d | 75–85% |

Cure rates per Malfertheiner, Maastricht VI/Florence consensus, *Gut* 2022, and the ACG 2017 and 2024 guidance. Standard triple therapy is now below an acceptable threshold where clarithromycin resistance exceeds 15 per cent, and bismuth quadruple is preferred there. Levofloxacin triple is a rescue regimen against rising quinolone resistance.

Drug by drug. Omeprazole, or any PPI: EML yes; off-patent; a few to tens of US dollars a year, and a fourteen-day course is a few cents to a few dollars. Amoxicillin: EML yes, Access group — the EML amoxicillin record does not itself list *H. pylori* as an indication; off-patent; a few US dollars per course. Clarithromycin: EML yes, Watch group, and its EML record *does* list "*Helicobacter pylori* associated gastric ulcer" as an indication; off-patent; a few to tens of US dollars per course. Metronidazole: EML yes, Access group; off-patent; a few US dollars per course. Tetracycline or doxycycline: off-patent; a few US dollars per course. Bismuth subsalicylate or subcitrate: off-patent; a few to tens of US dollars per course; not on the core EML.

The total drug cost of a curative course is therefore a few to tens of US dollars at generic prices. That cures a condition which causes a cancer killing about 660,000 people a year, and the cost-effectiveness literature on screen-and-treat in high-incidence populations is accordingly favourable.

Ulcer healing itself: a PPI for four to eight weeks heals over 90 per cent of uncomplicated ulcers. A bleeding ulcer needs endoscopic haemostasis with high-dose intravenous PPI; see the gastrointestinal bleeding entry.

**Simple means.** Clean water, sewage disposal, handwashing and reduced household crowding are the measures that historically eliminated most transmission, and they need no supply chain beyond public works. Not taking NSAIDs that are not needed. Smoking cessation.

The honest limit is sharp here. Diet, milk and bland food, the standard advice for most of the twentieth century, do not heal ulcers. Nothing in the simple-means category cures an established infection; that needs the antibiotics, which are cheap but industrial.

**Gaps.** Rising antibiotic resistance, clarithromycin especially, is eroding first-line cure rates, and the geographic resistance map is patchy. Whether to screen and treat whole populations in low-incidence countries is unsettled: the benefit is smaller, and the effect of mass eradication on the gastric microbiome and on oesophageal adenocarcinoma risk is debated. Sources disagree on whether eradication reduces gastric cancer mortality as clearly as it reduces incidence, because the trials are underpowered for mortality. There is no licensed vaccine. Susceptibility-guided against empirical therapy remains an open cost question.

## Functional dyspepsia

**What it is.** Persistent pain or fullness in the upper abdomen with no ulcer, no cancer and no other structural cause found on investigation. It is diagnosed by symptom pattern after exclusion.

**Measured.** Global prevalence is about 7 to 8 per cent under strict Rome IV criteria and about 20 per cent under the broader Rome III definitions (Sperber, *Gastroenterology* 2021, Rome Foundation global study of 73,076 adults across 33 countries). It is not a separate GBD cause and has no DALY figure. There are no direct deaths. It is more common in women, and prevalence falls slightly with age in some series. Apparent geographic differences track the survey instrument as much as true variation.

**Where it starts.** Prior acute gastroenteritis raises risk several-fold, giving post-infectious dyspepsia. *H. pylori* infection is a modest contributor and eradication helps a minority. Psychological comorbidity — anxiety, depression, somatisation — is strongly and bidirectionally associated, and the direction of causation is not settled. Female sex, smoking, NSAID use and early-life adversity all contribute. Duodenal eosinophilia and impaired gastric accommodation are measurable in subsets. Heritability is not well quantified; association studies implicating GNB3 and serotonin transporter polymorphisms have not been robustly replicated.

What is not known is the cause. This is a symptom-defined entity and possibly several distinct conditions pooled: impaired accommodation, hypersensitivity, delayed emptying, immune activation, central pain processing. No biomarker identifies the subsets reliably, and the Rome subdivisions — postprandial distress against epigastric pain — overlap heavily in practice.

**Cure status.** RELIEF ONLY, with one exception named. *H. pylori* eradication produces durable cure in a modest subset of infected patients, with a number needed to treat of about 12 to 14 for symptom improvement at twelve months (Ford, Cochrane). Otherwise the condition fluctuates over years and no treatment reliably eliminates it.

**Prevention.** No established primary prevention: CONTESTED, effectively absent. Avoiding unnecessary antibiotics and treating gastroenteritis adequately may reduce post-infectious cases: WEAK, indirect. Not smoking: WEAK.

**Treatment.** *H. pylori* test and treat, number needed to treat about 12 to 14; the only option with a cure claim, at the costs given in the ulcer entry, a few to tens of US dollars a course. PPIs, number needed to treat about 10 to 11 against placebo for symptom relief (Cochrane); omeprazole EML yes, off-patent, a few to tens of US dollars a year.

Low-dose tricyclic antidepressants, amitriptyline 10 to 50 mg, are effective in trials with a number needed to treat of about 6 to 8 in some meta-analyses; amitriptyline is EML-listed as an antidepressant, off-patent, a few to tens of US dollars a year. Prokinetics — domperidone, metoclopramide, itopride — give modest benefit; domperidone carries QT and cardiac-death signals and metoclopramide tardive dyskinesia with prolonged use. Both off-patent and cheap. Psychological therapy, CBT and hypnotherapy, shows demonstrated benefit in small unblinded trials. SSRIs are not effective here, in contrast to the tricyclics.

**Simple means.** Smaller, more frequent, lower-fat meals give modest measured benefit. Reducing alcohol, coffee and smoking. Regular physical activity and sleep: weak evidence, no harm. Low-FODMAP approaches are evidenced for IBS rather than dyspepsia, and overlap is common enough that some patients benefit. Reassurance and explanation after a negative investigation measurably reduces re-consultation.

**Gaps.** The entity is heterogeneous and its diagnostic criteria are consensus artefacts rather than biology. Placebo response in trials runs at 30 to 40 per cent†, which makes modest drug effects hard to interpret. Overlap with IBS and with reflux disease is extensive and inconsistently handled between studies. No biomarker, no prevention, no reliable subtyping.

## Irritable bowel syndrome

**What it is.** Recurrent abdominal pain with altered bowel habit — diarrhoea, constipation or both — without structural disease. It is diagnosed on symptom criteria.

**Measured.** Global prevalence is 4.1 per cent by Rome IV criteria and 10.1 per cent by Rome III in the Rome Foundation global study, 73,076 adults across 33 countries (Sperber, *Gastroenterology* 2021). Earlier meta-analyses gave about 11 per cent pooled (Lovell and Ford, *Clinical Gastroenterology and Hepatology* 2012). Both are printed; the discrepancy is largely criteria-driven and the two figures differ by a factor of about 2.5.

It is not a separate GBD cause with its own DALY total. There are no directly attributable deaths. It is about 1.5 to 2 times more common in women, with onset typically before fifty and prevalence declining in older age. It is found on every continent surveyed, and between-country differences in the Rome global study were modest once the instrument was held constant.

**Where it starts.** Post-infectious IBS develops in about 10 per cent of those with bacterial enteritis, with a pooled odds ratio of about 4 (Klem, *Gastroenterology* 2017). Female sex roughly doubles risk. Psychological comorbidity — anxiety, depression, and especially early-life adversity and abuse history — is strongly and bidirectionally associated. Antibiotic exposure contributes, and there is evidence for altered microbiota that is not consistent enough to define a signature.

Twin studies give a heritability of roughly 20 to 25 per cent, which is low, and shared-environment effects rival the genetic ones (Mohammed, *American Journal of Gastroenterology* 2005; Bengtson 2006). GWAS has identified loci explaining little variance. Bile acid malabsorption is present in up to a third of diarrhoea-predominant cases and is a treatable, under-diagnosed subset.

What is not known is the mechanism. Visceral hypersensitivity, motility change, immune activation, microbiota, bile acids and gut-brain signalling are all demonstrable in subsets; none unifies the condition. It is almost certainly a cluster of different disorders sharing a symptom label. The female predominance is unexplained.

**Cure status.** RELIEF ONLY. No treatment cures IBS. The condition typically runs a fluctuating course over decades with periods of remission. Diet and drug treatments reduce symptom severity; none abolishes the diathesis. Bile acid malabsorption and lactose intolerance, when identified inside an IBS population, are separately treatable and can resolve fully, so a minority of apparent IBS is a misclassified curable condition.

**Prevention.** No established primary prevention: CONTESTED, effectively absent. Avoiding unnecessary antibiotics: WEAK. Adequate treatment of acute gastroenteritis to reduce post-infectious cases: WEAK, indirect, not demonstrated in trials.

**Treatment.** The low-FODMAP diet is the best-evidenced dietary intervention: 50 to 70 per cent report meaningful improvement in trials, superior to habitual diet, with a number needed to treat of about 4 to 5 in some analyses. No drug cost, but it needs dietetic support for correct reintroduction, and long-term restriction may reduce beneficial bifidobacteria.

Soluble fibre, ispaghula or psyllium, is effective with a number needed to treat of about 7 (Moayyedi, *American Journal of Gastroenterology* 2014). Insoluble fibre, bran, is not effective and may worsen symptoms — a distinction routinely lost in general advice. Psyllium is not on the core EML; off-patent; tens to hundreds of US dollars a patient-year.

Antispasmodics — mebeverine, hyoscine, peppermint oil — have a pooled number needed to treat of about 5, and peppermint oil about 3 to 4 in meta-analysis of small trials†. Hyoscine butylbromide is off-patent and cheap; peppermint oil carries no patent and is very cheap.

Low-dose tricyclic antidepressants, amitriptyline 10 to 30 mg, have a number needed to treat of about 4 to 5 for global symptoms (Ford meta-analyses), and the ATLANTIS trial, 463 patients in UK primary care (*Lancet* 2023), confirmed benefit at six months. Off-patent; a few to tens of US dollars a year. Among the most cost-effective options here.

Loperamide controls stool frequency but not pain in diarrhoea predominance; EML yes, off-patent, cheap. Polyethylene glycol improves stool frequency but not pain in constipation predominance; off-patent, cheap. Psychological therapy — CBT and gut-directed hypnotherapy — gives durable benefit, with hypnotherapy effect sizes comparable to drug therapy

and benefit persisting years after treatment; the limit is therapist availability, and internet-delivered CBT has been shown effective (ACTIB, *Gut* 2019).

Rifaximin in diarrhoea-predominant disease gives modest benefit, number needed to treat about 9 to 11; it is expensive and still on patent in many markets, at roughly US$1,500 to 2,000 per fourteen-day course in the United States†. Not on the EML. The newer agents — linaclotide, lubiprostone, eluxadoline, alosetron, tegaserod — have numbers needed to treat of about 6 to 12, are patented, cost thousands of US dollars or more a year, and are not on the EML; several have had safety withdrawals or restrictions. Probiotics: CONTESTED. Heterogeneity between products and trials is extreme and cannot be summarised as a single effect size.

**Simple means.** Soluble fibre, psyllium or oats, works, with a number needed to treat of about 7; insoluble bran does not. Regular physical activity improves symptoms on moderate-quality randomised evidence (Johannesson, *American Journal of Gastroenterology* 2011). Gut-directed hypnotherapy and relaxation have effect sizes rivalling the drugs and need no supply chain beyond a trained person; scripts and recordings deliver at near-zero marginal cost. Regular meal timing, and reducing alcohol, caffeine and fat. Peppermint oil is a cheap agricultural product with a pooled number needed to treat of about 3 to 4. Identifying and removing lactose or excess fructose where relevant.

**Gaps.** Rome III and Rome IV prevalence estimates differ by a factor of about 2.5, so the burden literature is not internally comparable. Placebo response of 30 to 40 per cent† makes modest drug effects fragile. Probiotic evidence is unusable in aggregate because strains and doses differ. The low-FODMAP diet's long-term microbial and nutritional consequences are not established. Whether post-infectious IBS is mechanistically the same condition as the rest is unresolved. Expensive new drugs have numbers needed to treat no better, and sometimes worse, than amitriptyline at a hundredth the cost.

---

## Coeliac disease

**What it is.** An immune reaction to gluten flattens the lining of the small intestine, so food is not absorbed. It is lifelong. Removing gluten lets the lining heal.

**Measured.** Global pooled seroprevalence is 1.4 per cent and biopsy-confirmed prevalence 0.7 per cent (Singh, *Clinical Gastroenterology and Hepatology* 2018, meta-analysis of 96 studies and 275,818 subjects). Regional biopsy-confirmed figures: Europe 0.8 per cent, Asia 0.6 per cent, with Africa and South America lower but under-studied. The highest recorded prevalence is among Saharawi children of Western Sahara at about 5.6 per cent.

Roughly 70 to 80 per cent of cases remain undiagnosed in most populations, which is the ratio of serological to clinical diagnosis. It is not a separate GBD main cause and has no standalone DALY figure. Deaths are small but non-zero, through refractory disease, enteropathy-associated T-cell lymphoma, and the consequences of malabsorption.

Presentation is bimodal, in early childhood and in the fourth to fifth decade, and can occur at any age. It is about 1.5 to 2 times more common in females†.

**Where it starts.** HLA-DQ2 or DQ8 is necessary: about 99.6 per cent of cases carry one or both. But 30 to 40 per cent of the general population carries them, so the genotype is necessary and far from sufficient. Heritability is among the highest measured for any common disease, about 75 to 87 per cent from twin studies, with monozygotic concordance around 75 to 80 per cent against dizygotic around 11 per cent (Nisticò, *Gut* 2006). First-degree relative prevalence is about 7 to 10 per cent†. Gluten exposure is the necessary environmental trigger.

Associated autoimmune conditions include type 1 diabetes, in which 3 to 8 per cent† have coeliac disease, autoimmune thyroid disease, Down and Turner syndromes, and IgA deficiency.

The timing of gluten introduction in infancy does not determine risk. Two randomised trials settled this against prior observational belief: PreventCD (Vriezinga, *NEJM* 2014) and CELIPREV (Lionetti, *NEJM* 2014) both found early against late gluten introduction made no difference to eventual incidence. Breastfeeding likewise does not prevent it. This is a well-documented reversal.

What is not known is why most genetically susceptible, gluten-exposed people never develop it, and what triggers onset at a particular moment after years of tolerance. Candidate triggers — enteric viral infection by reovirus or rotavirus, microbiome shifts, antibiotic exposure — have supporting but not decisive evidence. Nor is it known why incidence has genuinely risen several-fold over fifty years beyond ascertainment, nor what drives non-responsive and refractory disease.

**Cure status.** CONTROLLABLE. A strict lifelong gluten-free diet produces mucosal healing and symptom resolution in the great majority, and normalises most excess mortality and lymphoma risk. It is not a cure: reintroducing gluten reinstates the disease, so the diathesis is permanent. Mucosal recovery is incomplete in a substantial minority of adults despite good adherence, with persistent villous atrophy in about 30 to 40 per cent at follow-up biopsy in some adult series. Refractory coeliac disease, types I and II, affects a small percentage, and type II carries serious lymphoma risk.

**Prevention.** Nothing demonstrably prevents it. The interventions once believed preventive — delayed gluten introduction and breastfeeding — were tested and failed in PreventCD and CELIPREV: CONTESTED, and for the timing interventions refuted.

Case-finding in high-risk groups — first-degree relatives, type 1 diabetes, autoimmune thyroid disease, unexplained anaemia — prevents complications rather than disease: MODERATE for complication prevention. Population screening: CONTESTED. Benefit in asymptomatic screen-detected cases is not established and the lifelong diet burden is real.

**Treatment.** A strict gluten-free diet, lifelong, is the only established treatment. There is no drug cost but a substantial food cost: gluten-free staples typically cost two to four times their conventional equivalents, a real and regressive burden documented across several countries. It requires dietetic instruction and food-labelling infrastructure.

Correction of deficiencies — iron, folate, B12, vitamin D, calcium, zinc — uses off-patent EML-listed preparations at a few dollars a year. Bone density assessment and treatment where osteoporosis is present. Pneumococcal vaccination, because hyposplenism is common. Corticosteroids, budesonide and immunosuppression for refractory disease only.

No licensed drug exists for coeliac disease. Candidate agents — gluten-degrading enzymes, tight-junction modulators such as larazotide, transglutaminase inhibitors such as ZED1227, and immune tolerance vaccines such as Nexvax2 — have been through phase 2 with mixed results; Nexvax2 failed. None is approved.

**Simple means.** The core treatment is itself a simple means: removing one protein from the diet. It requires no industrial product. Naturally gluten-free staples — rice, maize, potato, legumes, millet, sorghum, buckwheat, cassava — are cheap and globally available. The expensive part is manufactured gluten-free replicas of wheat products, which are optional. Reading labels and avoiding cross-contamination in shared kitchens. Household screening of first-degree relatives. In settings where wheat is not the staple, the diet is far cheaper to achieve than in wheat-based food cultures.

**Gaps.** Most cases worldwide are undiagnosed, and in much of Africa, South and Southeast Asia the true prevalence is simply unmeasured. Whether to screen the general population is genuinely unsettled. Persistent villous atrophy despite adherence is common and poorly explained; the relative contributions of trace exposure, misdiagnosis and true refractoriness are disputed. There is no adjunctive drug after twenty years of development. The degree to which non-coeliac gluten sensitivity overlaps is contested, with some trials implicating fructans rather than gluten.

---

## Inflammatory bowel disease: Crohn disease and ulcerative colitis

**What it is.** Two long-term diseases in which the immune system inflames the gut wall. Ulcerative colitis affects the colon’s inner lining continuously. Crohn disease can affect any part of the gut, in patches, through the whole wall thickness. Both relapse and remit.

**Measured.** The highest recorded prevalences are European and North American: up to 505 per 100,000 for ulcerative colitis in Norway and 322 per 100,000 for Crohn disease in Germany; North America up to 286 and 319 per 100,000 respectively (Ng, *Lancet* 2017).

Over 0.7 per cent of the population is affected in some Western countries, with about 3 million affected in the United States and 2.5 to 3 million in Europe.

GBD 2019 gave about 4.9 million prevalent cases globally, about 41,000 deaths a year and about 1.3 million DALYs†. Incidence is stable or falling in the West and rising sharply in newly industrialised countries across Asia, South America, the Middle East and Africa. This is the central epidemiological fact of the disease and it is consistent across studies.

Peak onset is 15 to 35, with a smaller second peak in the sixth decade. Ulcerative colitis is roughly equal by sex; Crohn disease is slightly female-predominant in the West.

**Where it starts.** Smoking is the cleanest and strangest risk factor. It roughly doubles Crohn risk and worsens its course, while being protective against ulcerative colitis, which often presents after smoking cessation. The divergence is unexplained. Appendicectomy is associated with reduced ulcerative colitis risk, also unexplained.

Family history is the strongest single predictor, with first-degree relative risk about 5 to 10 times†. Twin concordance for Crohn disease is about 30 to 35 per cent monozygotic against about 4 per cent dizygotic; for ulcerative colitis about 15 to 16 per cent against about 4 per cent (Halfvarson, Scandinavian twin studies; Orholm). Crohn disease is therefore substantially more heritable than ulcerative colitis, and both leave most variance to environment. GWAS has found over 240 risk loci together explaining only about 8 to 13 per cent of variance, the classic missing-heritability picture. NOD2 is the strongest Crohn locus; homozygotes carry a many-fold raised risk, but the genotype is neither necessary nor sufficient.

Early-life antibiotic exposure, urban residence, Western diet, ultra-processed food intake with hazard ratios around 1.5 to 1.8 in the PURE and Nurses' Health cohorts†, and reduced breastfeeding all contribute. Appendicitis and enteric infection act as triggers, and *Mycobacterium avium paratuberculosis* in Crohn disease remains a long-running and unresolved hypothesis.

What is not known is the cause. The hygiene and microbiome account fits the geographic epidemiology, since incidence rises as countries industrialise, but no specific organism, exposure or microbial signature has been established as causal. Why smoking splits the two diseases in opposite directions is unknown. Why most NOD2 carriers and most people with family history never develop disease is unknown. The missing heritability is unaccounted for.

**Cure status.** Ulcerative colitis: CONTROLLABLE medically, and CURABLE surgically. Total colectomy removes the diseased organ and ends the colitis — an actual cure, at the cost of a stoma or ileoanal pouch, and pouchitis affects a substantial minority. Sustained medical remission is achievable in most.

Crohn disease: CONTROLLABLE only. No operation cures it. Disease recurs at the anastomosis after resection in the majority, with endoscopic recurrence of about 70 to 90 per cent at one year without prophylaxis. Roughly half of Crohn patients require surgery within ten years. Deep remission is achievable but relapse is the norm over decades.

**Prevention.** No established primary prevention: absent. Smoking cessation in Crohn disease: STRONG for altering course, since continued smoking roughly doubles post-operative recurrence and worsens outcomes. Smoking is not recommended for ulcerative colitis despite the protective association, because the harms vastly outweigh it.

Breastfeeding: CONTESTED. Avoiding unnecessary early-life antibiotics: WEAK, observational only. Reducing ultra-processed food intake: WEAK, observational only. Post-operative Crohn recurrence prevention with an anti-TNF agent or a thiopurine: MODERATE, on POCER and other trials. That is secondary prevention.

**Treatment.** For ulcerative colitis, mesalazine (5-ASA), oral and topical, is first line in mild to moderate disease, inducing remission with a number needed to treat of about 4 to 5 against placebo for improvement; topical plus oral beats either alone. Mesalazine is not on the core EML; off-patent; about US$600 to 1,500 a patient-year at Western prices, far less in India. 5-ASA is ineffective in Crohn disease, a common prescribing error.

Corticosteroids — prednisolone, or budesonide MMX — are highly effective for induction and useless and harmful for maintenance. Prednisolone EML yes; off-patent; a few to tens of US dollars a year. Thiopurines, azathioprine or mercaptopurine, give steroid-sparing mainte-

nance; azathioprine EML yes; off-patent; tens to hundreds of US dollars a year. They require TPMT and NUDT15 testing and monitoring, and modestly raise lymphoma and non-melanoma skin cancer risk.

For Crohn disease and moderate-to-severe ulcerative colitis, the biologics and small molecules:

| Agent | Class | Measured effect | WHO EML | Off-patent | Approx. annual cost |
|---|---|---|---|---|---|
| Infliximab | Anti-TNF | ACCENT I / ACT 1–2: remission 21–39% vs 7–18% placebo; NNT 4–6 | listed **only as a therapeutic equivalent** to adalimumab, not as a selected medicine | originator yes; biosimilars widely available | originator tens of thousands of US dollars; biosimilars thousands of US dollars some tenders below thousands of US dollars |
| Adalimumab | Anti-TNF | CHARM / ULTRA: remission 36–40% vs 12–18% placebo; NNT 4–7 | **yes, listed medicine**, Crohn disease among its indications | originator yes; biosimilars available | originator US$50,000–80,000 US list; biosimilars thousands to tens of thousands of US dollars |
| Vedolizumab | Anti-integrin | GEMINI 1–2: remission 17–42% vs 5–26% placebo | no | no | tens of thousands of US dollars |
| Ustekinumab | Anti-IL12/23 | UNITI / UNIFI: induction remission 16–21% vs 7–10% | no | biosimilars entering 2024–25 | US$25,000–60,000, falling† |
| Tofacitinib | JAK inhibitor | OCTAVE: UC remission 18.5% vs 8.2% placebo | no | yes, generics entering | originator tens of thousands of US dollars +; generic potential below thousands of US dollars |
| Risankizumab, upadacitinib, mirikizumab, guselkumab | newer | effective in phase 3; head-to-head data limited | no | no | tens of thousands of US dollars |

The biosimilar price collapse is the single most consequential economic fact in the treatment of this disease. Anti-TNF agents moved from tens of thousands of US dollars a year to thousands to tens of thousands of US dollars and in some tenders below thousands of US dollars. Adalimumab is a listed EML medicine with Crohn disease among its indications. Infliximab is on the list only as a therapeutic equivalent to adalimumab, which is a permitted substitute rather than the selected medicine, and the distinction is load-bearing for procurement. Between them, effective biologic therapy is for the first time within reach of middle-income health systems.

Surgery: colectomy cures ulcerative colitis; resection, stricturoplasty and abscess drainage manage Crohn complications. Exclusive enteral nutrition in paediatric Crohn disease achieves remission rates comparable to corticosteroids, about 60 to 80 per cent, without steroid toxicity, and promotes mucosal healing better; it is first-line in children in European guidelines, and the cost is formula feed only. Antibiotics for perianal and fistulising Crohn disease and for pouchitis: metronidazole EML yes, ciprofloxacin; both cheap.

**Simple means.** Smoking cessation in Crohn disease is among the highest-value zero-cost interventions in gastroenterology, roughly halving post-operative recurrence risk. Exclusive enteral nutrition in paediatric Crohn disease matches steroids for remission and needs only formula feed. Iron, B12, vitamin D and calcium repletion, with folate alongside methotrexate or sulfasalazine. Exercise and resistance training preserve bone and muscle against steroid effects without altering disease activity. Stoma care education, and low-residue modification during strictures, which is symptomatic only.

The honest limit: no diet has been shown to induce remission in adult inflammatory bowel disease. The Crohn's Disease Exclusion Diet and the specific carbohydrate diet have small supportive trials, and the evidence does not support any diet as a substitute for drug therapy in adults.

**Gaps.** The cause is unknown. The rise in newly industrialised countries is well documented and unexplained mechanistically. Missing heritability is large. Head-to-head biologic trials are few, SEAVUE and VARSITY being exceptions, so positioning of agents rests largely on indirect comparison. Long-term malignancy and infection risks of the newer agents are not yet characterised. Biosimilar uptake and pricing vary enormously between countries, so the cost of care differs by more than an order of magnitude for identical therapy. GBD models the disease with sparse data from Africa and much of Asia, so global burden figures there are extrapolations.

---

## Diverticular disease and diverticulitis

*This is the longest entry in the chapter.*

**What it is.** Small pouches push out through weak points in the wall of the colon. Having them is diverticulosis, which is usually silent. When one becomes inflamed or perforates, that is diverticulitis.

**Measured.** The pouches themselves are strongly age-dependent, and the age gradient is the most robust finding in the field. Colonoscopy and autopsy series give roughly under 10 per cent below the age of forty, about 30 per cent by sixty, about 50 to 60 per cent by seventy, and 60 to 70 per cent by eighty in Western populations†. In the Peery colonoscopy study of 2,104 patients aged 30 to 80 at the University of North Carolina between 1998 and 2010, diverticulosis was found across the age range with prevalence rising steeply with age.

Western diverticulosis is left-sided and sigmoid-predominant. East Asian diverticulosis is right-sided and presents at younger ages. The difference is consistent and striking.

Only a minority of people with diverticulosis ever get diverticulitis. The GBD 2019 figures for diverticular disease are roughly 36,000 deaths and about 1.0 to 1.3 million DALYs globally†. Deaths occur mainly through perforation with peritonitis, in the elderly and the immunosuppressed. Diverticular disease is one of the leading gastrointestinal causes of hospital admission in high-income countries; in the United States it accounts for several hundred thousand admissions a year and is among the costliest gastrointestinal diagnoses (Peery, *Gastroenterology*, Burden of Gastrointestinal Disease series). Admission rates have risen over recent decades in Western countries, including among people under fifty, and whether that is a true increase or an artefact of CT availability is disputed.

By sex the totals are broadly similar, with younger patients more often male and older patients more often female.

**Where it starts.** The anatomy of where the wall yields is the mechanically specific part of this entry, and it is uncontested.

The colonic wall is not uniformly strong. The vasa recta — the straight arteries supplying mucosa and submucosa — penetrate the circular muscle layer to reach the submucosa. They do so at four roughly predictable points around the circumference: between the mesenteric taenia and each of the two antimesenteric taeniae coli, giving two rows on each side between the taeniae. Each penetration is a gap in the muscularis propria: a point of structural weakness, in effect a pre-formed hole with a blood vessel in it.

Three consequences follow directly, and they are why this anatomy is worth stating in full.

Colonic diverticula are therefore false diverticula, or pseudodiverticula. Mucosa and submucosa herniate through the vascular penetration points, covered only by serosa, with no muscle layer in the wall of the pouch.

They appear in rows corresponding to the vasa recta entry points, and not in the segment between the two antimesenteric taeniae, where no vessels penetrate. That is the spared segment. The rectum, which lacks taeniae, is characteristically spared for the same reason.

And because the vasa recta runs over the dome of each diverticulum, that artery lies exposed. This is the anatomical reason a diverticular bleed is arterial and can be brisk, and why diverticular bleeding is a leading cause of lower gastrointestinal haemorrhage.

Read in the net: the wall is a mesh under tension, and it yields where it is already open. The vascular penetration points are the pre-existing openings; nothing new has to be made for a pouch to form. This is a reading, not a mechanism.

The conventional mechanical account adds raised intraluminal pressure — segmentation of the sigmoid generating high local pressures in a narrow-radius segment, by Laplace's law — driving mucosa out through those gaps. Connective tissue change with age is also documented: altered collagen cross-linking, and elastin deposition in the taeniae causing shortening.

Age is by far the strongest risk factor for having diverticula, on the gradient given above. Conversely, young age at presentation of diverticulitis is associated with a higher recurrence rate, simply because of longer remaining life.

*Heritability.* Heritability is estimated at 40 per cent. In the Swedish twin study, of 104,452 twins meeting inclusion criteria, 2,296 had a diagnosis of diverticular disease. The odds ratio for disease given an affected co-twin was 7.15 (95 per cent CI 4.82 to 10.61) in monozygotic twins and 3.20 (2.21 to 4.63) in same-sex dizygotic twins. Heritability was estimated at 40 per cent, with the remaining 60 per cent attributed to non-shared environment (Granlund, Svensson, Olén, *Alimentary Pharmacology and Therapeutics* 2012). A Danish twin study gave a comparable figure of about 40 to 53 per cent†. Genome-wide studies have since identified loci including *ARHGAP15*, *COLQ* and *FAM155A*†.

So: a substantial but minority genetic contribution. Most of the variance is environmental and non-shared, which is precisely the part that is least well characterised.

*The fibre contradiction.* This has to be reported as two findings that point in different directions, because that is what the literature contains. Both are given at equal length and neither is resolved.

Finding A — more fibre, fewer diverticular disease admissions. Crowe, Appleby, Allen and Key, "Diet and risk of diverticular disease in Oxford cohort of European Prospective Investigation into Cancer and Nutrition (EPIC): prospective study of British vegetarians and non-vegetarians", *BMJ* 2011;343:d4131. The cohort was 47,033 participants in England and Scotland, of whom 15,459, or 33 per cent, were vegetarian. Follow-up was 547,312 person-years, mean 11.6 years, with 812 cases of diverticular disease — 806 hospital admissions and 6 deaths. Vegetarians against meat eaters: hazard ratio 0.69 (95 per cent CI 0.55 to 0.86), a 31 per cent lower risk. Highest against lowest fifth of fibre intake: hazard ratio 0.59 (95 per cent CI 0.46 to 0.78) per the abstract. The results section of the same paper reports 0.58 (95 per cent CI 0.46 to 0.73). Both are printed here, and the discrepancy is internal to the published paper: the abstract and the results section of one article give two different values and two different intervals for the same comparison. The highest fifth was 25.5 g a day or more for women and 26.1 g or more for men; the lowest fifth was under 14 g a day.

Finding B — more fibre, more diverticula. Peery, Barrett, Park, Rogers, Galanko, Martin and Sandler, "A high-fiber diet does not protect against asymptomatic diverticulosis", *Gastroenterology* 2012;142(2):266–272. The study was 2,104 patients aged 30 to 80 undergoing outpatient colonoscopy at UNC Hospitals between 1998 and 2010. Participants in the highest fibre quartile had more diverticulosis than those in the lowest: those with the lowest fibre intake were about 30 per cent less likely to have diverticula than those with the highest. Constipation was not a risk factor. The opposite was found: more frequent bowel movements were associated with higher risk, and those with more than fifteen bowel movements a week were about 70 per cent more likely to have diverticulosis than those with fewer than seven. The study design, cohort, direction of effect and the two percentage figures are verified; the exact prevalence ratios with their intervals were not retrievable and remain open.

How the two fit together, stated as a reconciliation and not as a demonstration. The outcomes measured are not the same. EPIC-Oxford measured clinical diverticular disease, hospital admission and death, prospectively. Peery measured asymptomatic diverticulosis, pouches visible at colonoscopy, cross-sectionally. It is therefore logically possible that fibre does not prevent the pouches forming while still reducing the chance that they inflame. That is the current mainstream reconciliation of the two findings.

It is a reconciliation and not a demonstration. No trial has ever randomised fibre intake and measured either outcome. The cross-sectional design of the Peery study cannot establish direction, and colonoscopy populations are selected. The century-old Painter and Burkitt fibre-deficiency hypothesis, which built the entire dietary edifice, rested on ecological comparison between Britain and rural Africa rather than on experiment. The fibre story in patient

leaflets is better supported for preventing diverticulitis than for preventing diverticulosis, and in neither case by randomised evidence.

*NSAIDs and aspirin.* This association is solid, and the intervals are given. Strate, Liu, Huang, Giovannucci and Chan, "Use of aspirin or nonsteroidal anti-inflammatory drugs increases risk for diverticulitis and diverticular bleeding", *Gastroenterology* 2011;140(5):1427–33. The cohort was 47,210 US men aged 40 to 75 at baseline in 1986, the Health Professionals Follow-up Study, with 22 years of follow-up, 939 diverticulitis cases and 256 diverticular bleeding cases.

Regular aspirin use, twice a week or more: diverticulitis hazard ratio 1.25 (95 per cent CI 1.05 to 1.47); diverticular bleeding 1.70 (1.21 to 2.39). Intermediate aspirin intake, two to 5.9 standard 325 mg tablets a week, carried the highest bleeding risk at 2.32 (1.34 to 4.02), and aspirin on four to six days a week 3.13 (1.82 to 5.38). Regular non-aspirin NSAID use: diverticulitis hazard ratio 1.72 (1.40 to 2.11); diverticular bleeding 1.74 (1.15 to 2.64).

Opioids and corticosteroids are also associated with perforation, and calcium channel blockers appear protective against bleeding.

*Nuts, seeds and popcorn are not a risk factor, and the direction is the opposite of the traditional advice.* This was standard medical advice for decades and it was wrong.

Strate, Liu, Syngal, Aldoori and Giovannucci, "Nut, corn, and popcorn consumption and the incidence of diverticular disease", *JAMA* 2008;300(8):907–914. The cohort was 47,228 men aged 40 to 75, free of diverticular disease, cancer and inflammatory bowel disease at baseline, in the Health Professionals Follow-up Study, with eighteen years of follow-up from 1986 to 2004. There were 801 cases of diverticulitis and 383 cases of diverticular bleeding.

Nuts, highest intake of twice a week or more against lowest of under once a month, for diverticulitis: hazard ratio 0.80 (95 per cent CI 0.63 to 1.01) — a protective point estimate with an interval crossing 1.00. Popcorn, the same comparison, for diverticulitis: hazard ratio 0.72 (0.56 to 0.92) — significantly protective. Corn showed no association with diverticulitis. None of nuts, corn or popcorn showed any association with diverticular bleeding. The cohort, follow-up, case numbers and the nut and popcorn hazard ratios with intervals are verified; the exact bleeding hazard ratios and the p-for-trend values were not retrievable.

So the direction of effect runs opposite to the advice that was given for decades: no increased risk, and for popcorn a statistically significant reduction. Restriction of nuts, seeds and popcorn is not supported, and the major guidelines have abandoned it.

*Other established risk factors.* Obesity: BMI of 30 or more is associated with roughly 1.8 times the diverticulitis risk and about three times the bleeding risk in the same cohort. Smoking: a modest increase in perforation and complication risk. Physical inactivity, with vigorous activity associated with reduced risk. Higher red meat intake associated with increased diverticulitis risk. Low vitamin D levels associated with diverticulitis.

*What is genuinely not known.* Why only a small minority of people with diverticula ever get diverticulitis, and there is no way to predict which. Whether diverticulitis is primarily an infective event at all — the DIABOLO result below undercuts the infection model, and inflammation-first or microperforation-first accounts are now taken seriously, though none is established. Whether the pouches are a disease or a normal consequence of an ageing colon in a given dietary environment. The cause of the apparent rise in incidence in the young. Why East Asian diverticulosis is right-sided and Western left-sided, with genetic and dietary explanations both having advocates and neither settled. What the 60 per cent non-shared environmental variance from the twin study actually consists of. And whether low-grade persistent inflammation after an episode, so-called symptomatic uncomplicated diverticular disease, is a distinct entity or post-inflammatory IBS, which is contested.

**Cure status.** Diverticulosis, the anatomical finding: the label does not apply. It is a state of the colon wall and not an illness, and it is usually silent. The pouches are permanent and do not regress, no treatment removes them, and asymptomatic diverticulosis needs no treatment.

Diverticulitis, the illness, is a different matter from diverticulosis, the finding. It carries its own labels, below.

Acute uncomplicated diverticulitis: SELF-LIMITING. This is a relatively recent conclusion and the evidence is strong enough to state plainly; it is set out in the treatment section below.

Complicated diverticulitis — abscess, perforation, fistula, obstruction: CURABLE by intervention, drainage or resection, at surgical cost and risk.

Recurrent or segmental disease: CURABLE by segmental resection, which removes the affected segment; recurrence after resection is uncommon but possible in retained colon.

*The DIABOLO trial, in full.* Daniels, Ünlü, de Korte and colleagues, "Randomized clinical trial of observational versus antibiotic treatment for a first episode of CT-proven uncomplicated acute diverticulitis", *British Journal of Surgery* 2017;104(1):52–61, registration NCT01111253.

The design was a multicentre randomised trial across 22 Dutch centres, in patients with CT-proven, primary, left-sided, uncomplicated acute diverticulitis. Randomisation gave observation without antibiotics in 283 and antibiotics in 287, with 528 patients in the intention-to-treat analysis, 262 observation and 266 antibiotics. The primary endpoint was time to recovery over six months.

Median time to recovery was 14 days (IQR 6 to 35) with observation against 12 days (IQR 7 to 30) with antibiotics; hazard ratio 0.91, lower limit of the one-sided 95 per cent CI 0.78; P = 0.151. Not significant.

The secondary outcomes, observation against antibiotics, with Benjamini-Hochberg adjusted P values:

| Outcome | Observation | Antibiotics | P |
|---|---|---|---|
| Complicated diverticulitis at 6 months | 3.8% | 2.6% | 0.377 |
| Ongoing diverticulitis | 7.3% | 4.1% | 0.183 |
| Recurrent diverticulitis | 3.4% | 3.0% | 0.494 |
| Sigmoid resection | 3.8% | 2.3% | 0.323 |
| Readmission at 6 months | 17.6% | 12.0% | 0.148 |
| Mortality | 1.1% | 0.4% | 0.432 |
| Adverse events | 48.5% | 54.5% | 0.221 |
| Hospital stay, median | **2 days** | **3 days** | **0.006** |

No secondary outcome differed significantly except hospital stay, which was shorter without antibiotics. The per-protocol analysis matched the intention-to-treat analysis. The published conclusion was that observational treatment without antibiotics did not prolong recovery and can be considered appropriate in uncomplicated diverticulitis. Every figure above was concordant across two independent sources.

*The surrounding evidence.* AVOD (Chabok, *British Journal of Surgery* 2012) was the earlier Swedish and Icelandic multicentre randomised trial, 623 patients with CT-verified uncomplicated left-sided diverticulitis, antibiotics against no antibiotics. It found no difference in complications, length of stay or recurrence; the patient number and conclusion are widely reported and the individual outcome percentages were not re-retrieved. DINAMO, Spanish, 2021, randomised non-antibiotic management in mild diverticulitis managed as outpatients and found it non-inferior. Long-term DIABOLO follow-up at 24 months reported no significant difference in recurrence or need for surgery between arms. Meta-analyses pooling these trials conclude no benefit of antibiotics on recovery, complications, recurrence or surgery in immunocompetent patients with CT-confirmed uncomplicated diverticulitis.

The caveat belongs with the result. These trials were not powered for rare serious outcomes such as perforation and death, and they excluded the immunosuppressed, the septic, the pregnant and those with significant comorbidity. The observation arms showed numerically more complicated disease, more readmission and more deaths, none of it significant. The conclusion the evidence supports is "no demonstrated benefit", not "proven equivalent safety for every patient".

*The guideline position.* From NICE NG147, read live from the guideline text. In uncomplicated acute diverticulitis in a person who is systemically well: consider a no antibiotic prescribing strategy, with simple analgesia such as paracetamol, and advice to re-present if symptoms persist or worsen. Offer oral antibiotics if the person with acute diverticulitis is systemically unwell, and offer an antibiotic strategy if immunosuppressed or with significant

comorbidity. For CT-confirmed uncomplicated diverticulitis: review the need for antibiotics. Do not offer an aminosalicylate or antibiotics to prevent recurrent acute diverticulitis. Do not offer antibiotics to people with diverticular disease, meaning non-acute disease. On diet: if tolerated, a high-fibre diet should be maintained for life, with benefits that may take several weeks, and bulk-forming laxatives considered where a high-fibre diet is not tolerated.

The American Gastroenterological Association 2015 guideline holds that antibiotics should be used selectively rather than routinely in acute uncomplicated diverticulitis, as a conditional recommendation on low-quality evidence. The American Society of Colon and Rectal Surgeons 2020 guideline holds that antibiotics can be used selectively in immunocompetent patients with mild uncomplicated disease. All major guidelines have moved from mandatory antibiotics to selective use in immunocompetent patients with mild, CT-confirmed, uncomplicated disease. The remaining disagreement is about which patients still need them, and how confidently outpatient non-antibiotic management can be offered.

On elective surgery after recurrence: routine colectomy after two episodes is no longer recommended, and the decision is individualised on symptom burden, age, immunosuppression and complication history. NICE directs consideration of elective resection for continuing symptoms such as stricture or fistula. The LASER and DIRECT trials examined elective resection against conservative management for recurrent and persistent disease, with resection improving quality of life at the cost of surgical risk.

**Prevention.** Dietary fibre: MODERATE for preventing diverticulitis, CONTESTED for preventing diverticulosis. Both numbers are printed. EPIC-Oxford gives a hazard ratio of 0.59 (0.46 to 0.78) for the highest against the lowest fifth for clinical disease, with the same paper’s results section giving 0.58 (0.46 to 0.73); Peery gives more diverticulosis with higher fibre, with the lowest quartile about 30 per cent less likely to have pouches. No randomised trial exists. Target intakes in the protective fifth were about 25 to 26 g a day or more.

Vegetarian diet: MODERATE. Hazard ratio 0.69 (0.55 to 0.86), EPIC-Oxford.

Avoiding NSAIDs and regular aspirin where not clinically required: MODERATE, on consistent prospective cohort data, with a diverticulitis hazard ratio of 1.72 for NSAIDs and a bleeding hazard ratio of 1.74. Aspirin taken for a cardiovascular indication should not be stopped for this reason; the benefit calculus differs.

Weight management: MODERATE. Obesity about 1.8 times for diverticulitis and about three times for bleeding. Physical activity: MODERATE, with vigorous activity associated with reduced risk. Smoking cessation: WEAK. Reducing red meat: WEAK.

Restricting nuts, seeds and popcorn: not indicated. The grade is CONTESTED and refuted; the evidence points the other way, with popcorn at 0.72 (0.56 to 0.92).

Mesalazine and rifaximin to prevent recurrence: CONTESTED and negative. Multiple randomised trials of mesalazine failed to prevent recurrence, and NICE recommends against it explicitly. Probiotics: CONTESTED, insufficient evidence.

**Treatment.** For uncomplicated diverticulitis in a person who is systemically well: observation, analgesia, and oral intake as tolerated, on DIABOLO and AVOD. The drug cost approaches zero. Paracetamol: EML yes; off-patent; a few to tens of US dollars a year of intermittent use. NSAIDs are best avoided given the risk association above.

Antibiotics where the person is systemically unwell, immunosuppressed, or has significant comorbidity. Co-amoxiclav 500/125 mg three times a day for five days is the NICE first choice; EML yes, as amoxicillin with clavulanic acid, Access group; off-patent; a few US dollars per course. The alternative is ciprofloxacin with metronidazole; metronidazole EML yes, off-patent, a few US dollars a course; ciprofloxacin off-patent, a few US dollars a course. The entire antibiotic treatment of diverticulitis is therefore a few dollars of off-patent, EML-listed drug.

An abscess over 3 cm: percutaneous drainage or surgery, with NICE directing consideration of either. Perforation with generalised peritonitis: laparoscopic lavage or resectional surgery, with NICE directing an offer of either after discussing risks; the LOLA/LADIES, SCANDIV and DILALA trials examined lavage against resection with mixed results and higher reintervention after lavage. Resection when required: primary anastomosis with or without diverting stoma, or Hartmann’s procedure, with NICE directing the choice by age, comorbidity and WHO performance status.

Diverticular bleeding usually stops spontaneously; otherwise colonoscopic haemostasis, CT angiography with embolisation, or segmental resection if it persists.

Not recommended: aminosalicylates or antibiotics to prevent recurrence, which NICE states explicitly, and routine antibiotics for non-acute diverticular disease.

**Simple means.** Dietary fibre, 25 to 30 g a day from whole foods — vegetables, legumes, whole grains, fruit — associated with a hazard ratio of 0.59 (0.46 to 0.78) for clinical diverticular disease in EPIC-Oxford. Increase gradually; NICE notes that benefit may take several weeks and advises adequate fluid alongside. No supply chain.

Vegetarian or largely plant-based eating: hazard ratio 0.69 (0.55 to 0.86). A bulk-forming laxative, ispaghula or psyllium, where a high-fibre diet is not tolerated, is the NICE-endorsed alternative: a milled seed husk with minimal processing.

Physical activity, associated with reduced risk, and free. Weight reduction where obese, against the 1.8-fold diverticulitis and threefold bleeding associations†. Stopping unnecessary NSAIDs removes a 1.72-fold diverticulitis and 1.74-fold bleeding association; it costs nothing and saves money.

Eating nuts, seeds and popcorn freely is a simple means in the sense of removing a wrong restriction. Popcorn hazard ratio 0.72 (0.56 to 0.92). Decades of unnecessary dietary restriction can be lifted, which is itself a measurable gain in quality of life and in nutritional quality.

Adequate fluid alongside increased fibre. And for an uncomplicated episode in a well patient: rest, fluids, paracetamol and watchful waiting, which is now the guideline-endorsed first option and needs no pharmaceutical industry at all.

**Gaps.** The fibre literature is contradictory and contains no randomised trial. EPIC-Oxford and Peery disagree in direction, and the usual reconciliation — that fibre prevents inflammation rather than pouches — is plausible and untested. Painter and Burkitt's founding hypothesis was ecological. Patient information materials state the fibre case far more confidently than the evidence warrants. The exact prevalence ratios and confidence intervals from Peery 2012 could not be retrieved, only the direction and the 30 per cent and 70 per cent figures.

Lifetime risk of diverticulitis given diverticulosis is disputed, and the disagreement is tenfold. The textbook figure is 10 to 25 per cent. Recent cohort-derived estimates are 1 to 4 per cent, with Shahedi (*Clinical Gastroenterology and Hepatology* 2013) finding about 1 per cent over eleven years. Both are printed. This is a tenfold disagreement about the basic natural history of the condition, it is unresolved, and it matters for every risk conversation held with a patient who has incidental diverticula.

DIABOLO and AVOD were underpowered for rare serious harms and excluded the immunosuppressed and septic; no demonstrated benefit is not the same as safe in everyone. Whether the rise in diverticulitis admissions, especially in the young, is real or an artefact of CT availability is unresolved. There is no way to predict which people with diverticula will develop diverticulitis.

Whether acute diverticulitis is primarily infective is now genuinely open. That is awkward, because the standard treatment was antibiotics for seventy years, and because the trial evidence that undercuts the infection model is the same evidence that changed the guidelines.

The right-sided Asian against left-sided Western pattern is unexplained. Whether symptomatic uncomplicated diverticular disease is a real entity or post-inflammatory IBS is contested. And GBD burden figures for diverticular disease rest on sparse data outside high-income countries.

---

## Appendicitis

**What it is.** The appendix becomes inflamed and swells, usually after its opening is blocked. Untreated it may burst and infect the abdominal cavity. It is the commonest abdominal surgical emergency.

**Measured.** Lifetime risk is about 7 to 8 per cent, with peak incidence between ten and thirty. Annual incidence is about 100 per 100,000 adults in Western countries, giving about 17 to

20 million cases globally a year. GBD 2019 gave about 33,000 to 50,000 deaths a year and about 4 to 5 million DALYs†.

Mortality is very low where surgery is available, under 0.1 to 0.3 per cent†, and substantial where it is not. The case-fatality gradient between high- and low-income settings is one of the starkest in surgery, and perforation rates are far higher where access is delayed. There is a slight male predominance.

**Where it starts.** Luminal obstruction by a faecolith, or by lymphoid hyperplasia, often post-viral in children; rarely tumour or parasite. Age ten to thirty; male sex. Family history raises risk about threefold, with heritability estimated around 30 per cent from twin studies†. Low dietary fibre has been proposed on weak evidence.

What is not known is why obstruction occurs when it does, and why incidence is lower in low-income rural populations and rose with industrialisation. Nor is it known which cases will perforate. The existence of a genuinely self-limiting, non-progressive form of appendicitis is now accepted but cannot be identified prospectively with confidence.

**Cure status.** CURABLE. Appendicectomy is definitively curative. A substantial fraction of uncomplicated appendicitis is also curable with antibiotics alone, which is the major change in this field.

CODA (*NEJM* 2020, 1,552 patients, United States) found antibiotics non-inferior to appendicectomy on 30-day health status; about 29 per cent of the antibiotic group had undergone appendicectomy by 90 days, rising above 40 per cent at longer follow-up, with appendicolith predicting failure. APPAC (Salminen, *JAMA* 2015, 530 patients, Finland, CT-confirmed uncomplicated disease) found about 27 per cent required appendicectomy within a year and about 39 per cent by five years, meaning about 61 per cent were managed definitively without operation. So surgery cures essentially all; antibiotics cure roughly 60 to 70 per cent, with the remainder coming to surgery, mostly without added harm.

**Prevention.** No established prevention: absent. Dietary fibre: WEAK and CONTESTED. Appendicectomy prevents appendicitis trivially and is associated with reduced ulcerative colitis risk, but is not performed prophylactically.

**Treatment.** Laparoscopic appendicectomy is standard of care, with lower wound infection, shorter stay and faster return to work than open surgery; open remains appropriate where laparoscopy is unavailable. Antibiotics alone for CT-confirmed uncomplicated appendicitis without appendicolith avoid surgery in 60 to 70 per cent. Regimens: co-amoxiclav, or ceftriaxone or cefotaxime with metronidazole, or ciprofloxacin with metronidazole. Co-amoxiclav EML yes, off-patent, a few US dollars a course. Metronidazole EML yes, off-patent, a few US dollars a course. Ceftriaxone EML yes, off-patent, a few US dollars a course.

Complicated appendicitis with abscess: antibiotics plus percutaneous drainage, with or without delayed appendicectomy. Perforation with peritonitis: urgent surgery, resuscitation and antibiotics. Analgesia with paracetamol, NSAIDs and opioids as needed; giving analgesia does not obscure the diagnosis, an old teaching now refuted.

**Simple means.** Essentially none for treatment. This condition requires either surgery or manufactured antibiotics, and it is one of the clearest cases in the book where simple means are inadequate and surgical access is the determining factor in survival.

What matters at population level is access and timeliness: distance to a facility with anaesthesia and a surgeon, and transport. The perforation rate is a function of delay. Clinical scoring systems, Alvarado and AIR, and ultrasound reduce unnecessary CT and are particularly useful where CT is unavailable; they need no supply chain beyond training. Fluid resuscitation and oral rehydration while awaiting transfer.

**Gaps.** There is no way to distinguish prospectively which appendicitis will perforate and which would resolve. Long-term recurrence after antibiotic-only management beyond five years is not well characterised. Whether antibiotic-first management is appropriate where imaging is unavailable — which is precisely where surgical access is also poor — is unstudied and practically crucial. Negative appendicectomy rates vary widely between systems. GBD mortality estimates for low-income settings rest on sparse vital registration.

## Haemorrhoids

**What it is.** The normal cushions of blood vessels in the anal canal become swollen and slip down. They bleed, itch and can be painful. Very common and usually not dangerous.

**Measured.** Prevalence estimates range from 4 to 39 per cent depending on definition and on whether examination or self-report is used, and about half of adults report symptoms at some point by age fifty. The width of that range is a definitional artefact. GBD 2019 recorded haemorrhoidal disease with substantial prevalent cases globally, on the order of tens of millions to over 100 million, and low mortality†. Deaths are negligible. Peak age is 45 to 65, both sexes, and pregnancy is a major precipitant.

**Where it starts.** Constipation and straining; prolonged toilet sitting. Pregnancy and childbirth. Obesity; ascites and portal hypertension, though haemorrhoids are distinct from anorectal varices. Low fibre intake. Ageing, through loss of supporting connective tissue. Heritability is not reliably quantified.

What is not known is why some people with identical bowel habits develop them and others do not; the relative contribution of vascular against connective-tissue mechanisms; and whether constipation is cause, consequence or coincidence in many cases. The evidence base is notably poor for such a common condition.

**Cure status.** The individual pile or episode: CURABLE, by rubber band ligation or excision. Low-grade disease, particularly post-pregnancy: SELF-LIMITING. The underlying tendency: CONTROLLABLE, which is why recurrence is common.

**Prevention.** Fibre and avoiding straining: MODERATE. Fibre supplementation reduces bleeding, with a Cochrane review giving about a 50 per cent reduction in symptom persistence and bleeding risk, relative risk about 0.47 to 0.5 for bleeding. Adequate fluid, not delaying defaecation, limiting toilet time: WEAK, plausible and minimally studied. Weight management: WEAK.

**Treatment.** Fibre supplementation with psyllium or ispaghula reduces bleeding and symptoms and is Cochrane-supported; off-patent; tens to hundreds of US dollars a year. Rubber band ligation for grades I to III is the most effective office procedure, with higher success than sclerotherapy and recurrence of about 15 to 30 per cent at a few years†; very low cost and no implant.

Topical agents — local anaesthetic, corticosteroid, zinc oxide — give symptomatic relief only with no healing claim, and steroid use should be short; off-patent and cheap. Sclerotherapy and infrared coagulation are alternatives to banding, slightly less effective. Excisional haemorrhoidectomy for grades III to IV is the most definitive, the most painful, and gives the lowest recurrence; stapled haemorrhoidopexy gives less early pain with higher recurrence and rare serious complications; HAL-Doppler ligation is intermediate.

Oral flavonoids, micronised purified flavonoid fraction, give modest benefit on bleeding in meta-analysis, with trials mostly industry-sponsored and of moderate quality; not on the EML. A thrombosed external haemorrhoid incised with clot evacuation within about 72 hours gives faster relief than conservative care.

**Simple means.** Fibre is the primary treatment, with a relative risk of about 0.5 for bleeding†, and needs no supply chain. Water intake alongside fibre. Not straining; short toilet visits; responding promptly to the urge. Sitz baths, warm water for ten to fifteen minutes, relieve pain and spasm with no product needed. Squatting or a footstool position alters the anorectal angle, and small studies suggest reduced straining. Pelvic floor relaxation training for those who strain habitually. These measures are the whole of first-line care for most patients and require nothing manufactured.

**Gaps.** Prevalence is unmeasurable in any comparable way because definitions differ by an order of magnitude. The pathophysiology is genuinely unsettled. Trials of topical agents are small, old and poorly controlled. Flavonoid evidence is industry-dominated. Long-term recurrence data after all procedures are limited. Almost nothing is known about haemorrhoids in low-income settings despite a presumably high burden.

## Anal fissure

**What it is.** A tear in the lining of the anal canal. It causes sharp pain on defaecation and bright bleeding. Spasm of the internal sphincter keeps it from healing.

**Measured.** Lifetime incidence is roughly one in 350 adults a year, with lifetime risk put at about 11 per cent by some estimates†. It is not a separate GBD cause. There are no deaths. It affects young and middle-aged adults predominantly, with the sexes roughly equal, and lies in the posterior midline in about 90 per cent of cases†.

**Where it starts.** Passage of hard stool, and constipation. Raised internal anal sphincter tone with reduced anodermal blood flow: the posterior midline is relatively ischaemic, which explains both the site distribution and the non-healing. Childbirth, giving anterior fissures; chronic diarrhoea. Atypical, lateral or multiple fissures suggest Crohn disease, tuberculosis, HIV, syphilis or malignancy, which is an important diagnostic point. Heritability has not been studied.

What is not known is why sphincter hypertonia develops, why some fissures chronify and others heal, and the true determinants of recurrence.

**Cure status.** Acute fissures: SELF-LIMITING — about 50 to 60 per cent heal within weeks with conservative measures alone. Chronic fissures: CURABLE — lateral internal sphincterotomy heals over 90 to 95 per cent, the highest cure rate of any option, at the cost of a small but real risk of incontinence to flatus or soiling, pooled at about 3 to 10 per cent in some series and mostly minor.

**Prevention.** Avoiding constipation with fibre and fluid: MODERATE. Not straining: MODERATE, mechanistically direct with thin trial evidence. Post-partum perineal care: WEAK.

**Treatment.** Fibre, fluid, stool softeners and sitz baths are first line and heal about 50 to 60 per cent of acute fissures†, at essentially no cost. Topical nitrates, glyceryl trinitrate 0.2 to 0.4 per cent, give healing of about 50 per cent against about 35 per cent for placebo — a marginal advantage, and headache in 20 to 30 per cent causes frequent discontinuation; off-patent; tens of US dollars a course.

Topical calcium channel blockers, diltiazem 2 per cent or nifedipine, give healing similar to or better than nitrates, about 65 to 95 per cent in trials, with far fewer headaches, and are now the widely preferred first-line pharmacological agent; often compounded; off-patent; tens of US dollars a course.

Botulinum toxin injection into the internal sphincter heals 60 to 80 per cent, with higher recurrence than surgery and possible transient incontinence; on patent as a biologic, hundreds to thousands of US dollars per treatment. Lateral internal sphincterotomy heals over 90 to 95 per cent and is superior to all medical therapy in meta-analysis, with the incontinence risk above; Cochrane and meta-analytic comparison consistently favours surgery for healing and medical therapy for continence preservation. Anal advancement flap is for fissures with low sphincter tone or after prior sphincterotomy.

**Simple means.** Fibre and water are the foundation, healing half of acute fissures. Sitz baths relax the sphincter and relieve pain, measurably reducing resting anal pressure, at no cost. Not straining, and footstool or squat positioning. Petroleum jelly or any bland lubricant before defaecation. Pelvic floor relaxation rather than strengthening — the sphincter here is too tight, not too weak. Conservative measures plus time are genuinely curative in the majority of acute cases.

**Gaps.** Incidence is poorly measured because many never present. The optimal dose, duration and vehicle for topical diltiazem are not standardised and many formulations are compounded. The true long-term incontinence rate after sphincterotomy is disputed, with series ranging from about 1 per cent to over 30 per cent depending on definition and follow-up†; both ends are printed. Botulinum dose and injection site are not standardised. Evidence in post-partum and Crohn-related fissures is thin.

## Gallstones and cholecystitis

**What it is.** Stones form in the gallbladder, mostly from cholesterol. Most cause no trouble. If one blocks the outlet the gallbladder becomes inflamed, which is cholecystitis; if one passes into the bile duct it can cause jaundice or pancreatitis.

**Measured.** Prevalence in Western adults is 10 to 20 per cent, and about 10 to 15 per cent of adults in Europe and North America†. Ethnic and geographic variation is marked: very high in Indigenous American populations, with over 70 per cent among Pima women, about 50 per cent among Chilean Mapuche women, and low across sub-Saharan Africa and much of Asia.

GBD 2019 gave gallbladder and biliary diseases roughly 170,000 to 180,000 deaths and about 4 to 6 million DALYs globally†. Cholecystectomy is among the most frequently performed abdominal operations worldwide, with about 600,000 to 750,000 a year in the United States. About 2 to 4 per cent of people with stones develop symptoms per year, and about 80 per cent of stones remain silent for life. The female to male ratio is about 2 to 3:1 in the reproductive years, converging with age. Gallbladder cancer burden is concentrated in Chile, northern India, Japan and parts of eastern Europe.

**Where it starts.** The classical risk list here is unusually well established. Female sex, through oestrogen increasing biliary cholesterol secretion; pregnancy and parity; oral contraceptives and hormone therapy. Age, with incidence rising steadily. Obesity, dose-dependently, roughly two to three times at BMI above 30.

Rapid weight loss, including after bariatric surgery and very-low-calorie diets, causes stones in up to 30 per cent within months — a well-documented iatrogenic effect†.

Family history, with heritability about 25 to 29 per cent from Swedish twin studies (Katsika, *Hepatology* 2005); *ABCG8* and *UGT1A1* variants are established loci, with *ABCG8* D19H the strongest common genetic risk factor. Diabetes, metabolic syndrome and hypertriglyceridaemia. Crohn disease and ileal resection through bile salt loss; cirrhosis; haemolysis and thalassaemia, giving pigment stones; total parenteral nutrition; octreotide; ceftriaxone, through biliary sludge. Protective: physical activity, moderate coffee intake, statins, higher polyunsaturated and vegetable fat intake, and nuts.

What is not known is why most stones remain silent and which will become symptomatic — stone size and number predict only weakly. The nucleation step in cholesterol stone formation is incompletely understood, as is the role of gallbladder dysmotility, whether as cause or consequence. The pathway from stones to gallbladder cancer, and why it is so geographically concentrated, is not explained.

**Cure status.** CURABLE. Cholecystectomy removes the organ and essentially ends gallstone disease, with over 95 per cent relief of biliary colic†; a minority have persistent pain, often a sign the original diagnosis was wrong. Stones already in the bile duct require ERCP clearance. Silent stones need no treatment: observation is correct management, since most remain silent for life.

**Prevention.** Weight management and avoiding rapid weight loss: MODERATE. Where rapid loss is planned, in bariatric surgery or a very-low-calorie diet, ursodeoxycholic acid prophylaxis reduces stone formation substantially, relative risk about 0.3 to 0.4 in trials. Physical activity: MODERATE, on dose-dependent prospective cohort association. Avoiding prolonged fasting and keeping regular meals, which keeps the gallbladder emptying: WEAK. Dietary pattern with higher fibre, vegetable fat, nuts and coffee: WEAK, cohort evidence. Statins: CONTESTED and WEAK — observational reduction with no trial designed for this.

Prophylactic cholecystectomy for silent stones is not indicated except in specific high-risk groups: porcelain gallbladder, large stones with anomalous ductal anatomy, populations with high gallbladder-cancer incidence, and some transplant candidates.

**Treatment.** Laparoscopic cholecystectomy is definitive. For acute cholecystitis, early surgery within seven days is superior to delayed: shorter total stay, fewer readmissions, no increase in complications or bile duct injury (ACDC, Gutt, *Annals of Surgery* 2013, and multiple meta-analyses). That reversed decades of cooling it down and coming back in six weeks.

Antibiotics for acute cholecystitis as adjunct or bridge: co-amoxiclav or a cephalosporin with or without metronidazole. Co-amoxiclav EML yes, off-patent, a few US dollars a course; metronidazole EML yes, a few US dollars. Analgesia: NSAIDs, diclofenac in particular, are effective for biliary colic and may reduce progression to cholecystitis; opioids for severe pain. Diclofenac off-patent and cheap.

ERCP with sphincterotomy and stone extraction for common duct stones and for gallstone pancreatitis with obstruction or cholangitis. Percutaneous cholecystostomy as a temporising drain for unfit patients with severe cholecystitis.

Ursodeoxycholic acid for dissolution works only for small, non-calcified cholesterol stones in a functioning gallbladder, takes six to 24 months, and recurrence after stopping is about 50 per cent at five years. Largely abandoned as definitive therapy, and genuinely useful for prophylaxis during rapid weight loss. Off-patent; hundreds to thousands of US dollars a year; not on the core EML. Extracorporeal shock wave lithotripsy is historical and largely abandoned.

**Simple means.** Gradual rather than rapid weight loss avoids a 30 per cent stone-formation risk†, and is a matter of advice only. Physical activity, with dose-dependent risk reduction. Regular meals, avoiding prolonged fasting, which keeps the gallbladder emptying. A dietary pattern of fibre, vegetable fats, nuts and coffee, associated with lower risk. Observation of silent stones — the simple means here is not operating, which is correct management for about 80 per cent of stone carriers and avoids all surgical risk and cost.

The honest limit: nothing simple dissolves established stones or treats cholecystitis. This condition ultimately needs surgery or ERCP.

**Gaps.** No method predicts which silent stones will become symptomatic. The optimal management of common bile duct stones — one-stage laparoscopic exploration against two-stage ERCP plus cholecystectomy — remains debated. Post-cholecystectomy pain and diarrhoea are common, poorly characterised and poorly explained. The gallstone to gallbladder cancer pathway and its geographic concentration are unexplained. Bile duct injury rates differ markedly between settings and are probably under-reported. Burden data for Africa and much of Asia are sparse.

---

## Acute pancreatitis

**What it is.** The pancreas digests itself. Most episodes are triggered by a gallstone blocking the duct or by alcohol. Most are mild; a minority are catastrophic.

**Measured.** Incidence is 13 to 45 per 100,000 a year and rising in most countries. GBD 2019 gave pancreatitis roughly 115,000 to 120,000 deaths and about 2.5 to 3.5 million DALYs globally†. Overall mortality is about 1 to 5 per cent; severe necrotising pancreatitis runs at 15 to 30 per cent, and up to about 30 to 40 per cent with infected necrosis and organ failure. About 80 per cent of episodes are mild and self-limiting†.

Gallstone aetiology predominates in women and older patients; alcohol in men and younger patients. Geography follows the gallstone and alcohol distribution.

**Where it starts.** Gallstones account for about 40 to 50 per cent and alcohol for about 20 to 35 per cent†, between them the large majority. Then hypertriglyceridaemia above about 11 mmol/L, and hypercalcaemia. Post-ERCP pancreatitis occurs in about 3 to 10 per cent of procedures†, higher in high-risk patients. Drugs — azathioprine, valproate, GLP-1 agonists, thiazides, oestrogens and many others, with causality often weak — then trauma, autoimmune pancreatitis, pancreatic tumour, infection with mumps or coxsackie, scorpion sting, hereditary forms through *PRSS1*, *SPINK1*, *CFTR* and *CTRC*, anatomical causes such as pancreas divisum, which is contested, and idiopathic disease in about 10 to 20 per cent. Smoking is an independent risk factor and accelerates progression to chronic disease. Monogenic hereditary pancreatitis exists, *PRSS1* with high penetrance; the population heritability of acute pancreatitis is not well quantified.

What is not known is why only a small minority of people with gallstones or heavy alcohol use ever get pancreatitis — the threshold or trigger is unexplained. Why some episodes become necrotising and others resolve in days is the central unsolved question, and no biomarker

predicts it reliably at presentation. Drug causation lists are largely case-report-based and unreliable.

**Cure status.** SELF-LIMITING in about 80 per cent†: mild interstitial pancreatitis resolves with supportive care in days. CURABLE in the sense of preventing recurrence when the cause is removed: cholecystectomy for gallstone pancreatitis, alcohol cessation, triglyceride control. Severe necrotising pancreatitis: CONTROLLABLE at best, with high mortality and prolonged critical care; it is not cured so much as survived.

**Prevention.** Cholecystectomy after gallstone pancreatitis: STRONG. Index-admission cholecystectomy against delayed surgery reduces recurrent biliary events substantially — the PONCHO trial (*Lancet* 2015) gave recurrent gallstone-related complications of 5 per cent against 17 per cent. One of the clearest secondary prevention results in digestive surgery.

Alcohol cessation: STRONG for alcoholic pancreatitis recurrence, with brief interventions and structured follow-up reducing recurrence in trials. Smoking cessation: MODERATE. Triglyceride control through fibrates, diet and glycaemic control: MODERATE.

Rectal NSAID prophylaxis, indomethacin or diclofenac, before ERCP: STRONG. It reduces post-ERCP pancreatitis substantially, relative risk about 0.5 across large randomised trials and meta-analyses, and it costs cents. Pancreatic duct stenting also reduces risk in high-risk cases. This is an unusually cheap, high-yield preventive.

**Treatment.** Management is largely supportive, and the main advances have been in what not to do.

Fluid resuscitation with lactated Ringer's rather than saline, at moderate rather than aggressive rates: the WATERFALL trial (*NEJM* 2022) found aggressive fluid resuscitation caused more fluid overload, 20.5 against 6.3 per cent, without reducing severe pancreatitis, and was stopped early for harm. A reversal of long-standing teaching.

Early enteral nutrition: oral or enteral feeding as tolerated within 24 to 72 hours is superior to nil by mouth and to parenteral nutrition, with fewer infections, less organ failure and lower mortality across multiple meta-analyses, with PYTHON addressing timing. Nasogastric feeding is equivalent to nasojejunal. Another reversal: resting the pancreas is wrong.

Analgesia with opioids as needed and NSAIDs; adequate analgesia is not harmful. No prophylactic antibiotics: multiple trials and meta-analyses show no benefit in sterile necrosis and encourage resistance, so antibiotics are for proven or strongly suspected infection only. ERCP only for concurrent cholangitis or persistent biliary obstruction, not routinely in gallstone pancreatitis without these (APEC, *Lancet* 2020, found no benefit of early ERCP in predicted-severe pancreatitis without cholangitis).

Infected necrosis: the step-up approach, percutaneous or endoscopic drainage first, escalating to minimally invasive necrosectomy only if needed. PANTER (*NEJM* 2010) showed the step-up approach reduced major complications and death against open necrosectomy, 40 against 69 per cent on the composite endpoint; endoscopic step-up (TENSION) is comparable with fewer fistulae. Cholecystectomy before discharge for mild gallstone pancreatitis, per PONCHO.

Drug costs here are trivial — Ringer's lactate, paracetamol, opioids, enteral feed, all off-patent and most EML-listed. The expensive resource is intensive care.

**Simple means.** Oral feeding as soon as tolerated is cheaper and better than withholding food or giving parenteral nutrition: a simple means that outperforms an expensive one. Oral and enteral rehydration where intravenous access or monitoring is limited, with measured rather than aggressive loading, per WATERFALL. Alcohol cessation is the single most effective recurrence prevention in alcoholic pancreatitis, and brief counselling at discharge has measurable effect. Smoking cessation. Rectal diclofenac or indomethacin before ERCP, a single cheap suppository with a relative risk of about 0.5. Avoiding unnecessary antibiotics and unnecessary ERCP: simple means in the sense of omission, both evidence-based.

**Gaps.** No biomarker or score reliably predicts severity at presentation; Ranson, APACHE II and BISAP all perform modestly. Why gallstones or alcohol trigger pancreatitis in only a few people is unknown. Optimal fluid type and rate are still being refined after WATERFALL. Drug-induced pancreatitis attribution is unreliable. Long-term outcomes — progression to

chronic pancreatitis, diabetes and exocrine insufficiency after a single severe episode — are under-measured. Burden estimates outside high-income countries are weak.

---

## Chronic pancreatitis

**What it is.** Repeated or continuing inflammation scars the pancreas permanently. It stops making enough digestive enzymes and insulin, and causes lasting pain.

**Measured.** Prevalence is about 36 to 50 per 100,000, with incidence about 5 to 14 per 100,000 a year in Western countries. It is pooled into pancreatitis in GBD with no separate chronic-only DALY figure. Exocrine insufficiency develops in most over time, and type 3c diabetes in about 30 to 50 per cent at ten to 25 years.

Pancreatic cancer risk is raised substantially, roughly 13 to 16 times overall and far higher in hereditary pancreatitis, up to about 50 to 70 times lifetime, with about a 40 per cent lifetime risk in *PRSS1* carriers who smoke. Mortality is high relative to the general population, largely from complications and from continued alcohol and tobacco use and cancer. Male predominance where alcohol is the main cause. Tropical or idiopathic fibrocalculous pancreatic forms occur in parts of India and Africa, affecting younger patients.

**Where it starts.** Alcohol accounts for about 45 to 65 per cent in Western series†, dose-dependently and usually after years of heavy use. Smoking is independent and dose-dependent, roughly doubling risk and accelerating progression and calcification — the strongest modifiable factor after alcohol and often underweighted. Genetic causes: *PRSS1* in autosomal dominant hereditary pancreatitis with high penetrance, then *SPINK1*, *CFTR*, *CTRC*, *CASR*; genetic forms present young.

Recurrent acute pancreatitis of any cause; obstructive causes including stricture, tumour and the contested pancreas divisum. Autoimmune pancreatitis, IgG4-related type 1 and idiopathic duct-centric type 2, is a distinct and steroid-responsive entity. Tropical and nutritional forms have an unresolved cause, with cassava, micronutrient deficiency and genetic factors — *SPINK1* being common — all proposed.

What is not known is why only a minority of heavy drinkers, about 5 to 10 per cent, develop it†. The relative weights of the necrosis-fibrosis sequence against primary fibrogenesis are debated. The mechanism of pain is poorly understood and correlates weakly with ductal or morphological findings. The cause of tropical pancreatitis remains unexplained.

**Cure status.** RELIEF ONLY for established disease: the fibrosis and lost function are irreversible and no treatment restores the gland. CONTROLLABLE in the sense that exocrine and endocrine failure can be replaced and pain can often be reduced. Autoimmune pancreatitis: CONTROLLABLE and highly steroid-responsive, with dramatic clinical and radiological remission, though relapse is common. Halting progression is possible: alcohol and tobacco cessation measurably slows it.

**Prevention.** Alcohol cessation or avoidance: STRONG. Smoking cessation: STRONG, independent and dose-dependent, and it reduces pancreatic cancer risk on top of pancreatitis risk. Early cholecystectomy and treating the causes of recurrent acute pancreatitis: MODERATE, preventing the recurrent-acute to chronic transition. Genetic counselling in hereditary pancreatitis, where cancer prevention by smoking cessation is especially high-yield: MODERATE. Antioxidants to prevent progression: CONTESTED and negative; trials have not shown benefit on progression.

**Treatment.** Pancreatic enzyme replacement therapy for exocrine insufficiency demonstrably improves fat absorption, weight, steatorrhoea and nutritional status, with a mortality benefit suggested in cohort data. It must be taken with meals and often requires acid suppression to work. Pancreatic enzymes are on the EML as a listed medicine, under gastrointestinal medicines and for cystic fibrosis in the complementary list; off-patent; cost about US$1,000 to 4,000 a patient-year in high-income markets ( for either price) and far less in India, at about US$100 to 400. This is a significant access problem: a cheap-to-make animal-derived product priced high in some markets and often unavailable in low-income settings.

Analgesia stepwise: paracetamol, NSAIDs, then adjuvants — pregabalin has randomised support in this condition — then opioids with caution, since dependence is a major problem. Pregabalin off-patent; tens to hundreds of US dollars a year. Alcohol and smoking cessation,

which are disease-modifying rather than merely supportive. Diabetes management for type 3c, where insulin is usually required eventually and is brittle because glucagon is also lost. Insulin human is an EML-listed medicine, as short-acting and intermediate-acting entries, each for type 1 and type 2 diabetes; human insulin off-patent; tens to hundreds of US dollars a year, far more for analogues.

Endoscopic therapy — pancreatic duct stenting, stone extraction, ESWL for obstructing stones — for painful obstructive disease. Surgery for pain: lateral pancreaticojejunostomy (Puestow), Frey, Beger, or resection. The ESCAPE trial (*JAMA* 2020) found early surgery gave lower pain scores than an endoscopy-first step-up approach in painful chronic pancreatitis, and surgery outperforms endoscopy for durable pain relief in several trials.

Corticosteroids for autoimmune pancreatitis, with rapid response, and rituximab for relapsing IgG4 disease. Rituximab is an EML-listed medicine, under multiple sclerosis and targeted therapies in the complementary list. Nutritional support: fat-soluble vitamin A, D, E and K and B12 replacement, calcium and vitamin D for the near-universal osteoporosis risk, and dietitian input; micronutrient costs are low and the basic forms are EML-listed. Coeliac plexus block gives short-lived benefit with a limited role.

**Simple means.** Alcohol cessation and smoking cessation are the only measures that alter the disease course. No supply chain, and the largest available effect. Smaller, frequent meals — and not the old low-fat dogma, since fat restriction worsens energy and fat-soluble vitamin status and adequate enzyme replacement is preferred to fat avoidance. Medium-chain triglycerides where available, since they are absorbed without lipase. Vitamin D, calcium and weight-bearing exercise against the high osteoporosis prevalence in this group. Alcohol-cessation support through peer groups and brief intervention is a low-cost, high-yield intervention.

The honest limit: without manufactured enzymes, exocrine insufficiency cannot be corrected. Enzyme replacement has no simple substitute, which makes its price and availability the key issue.

**Gaps.** The pain mechanism is not understood and correlates poorly with imaging, so pain-directed treatment is empirical. Diagnosis of early chronic pancreatitis is unreliable because no good test exists before structural change. The optimal timing of surgery against endoscopy is still being defined after ESCAPE. Tropical pancreatitis is unexplained and under-researched. Enzyme dosing is poorly standardised and under-dosing is endemic. Pancreatic cancer surveillance strategies in hereditary pancreatitis are not validated. Burden data are poor almost everywhere.

---

## Liver cirrhosis and its causes

**What it is.** Long-term liver injury replaces working liver with scar. Blood cannot pass through easily, so pressure rises in the portal vein, and the liver's functions fail. Late stages bring fluid in the abdomen, bleeding, confusion and liver cancer.

**Measured.** GBD 2019 gave cirrhosis and other chronic liver diseases roughly 1.47 million deaths globally, about 2.4 per cent of all deaths, and on the order of 46 million DALYs†. Compensated cirrhosis has a median survival over twelve years; decompensated cirrhosis about two years.

Aetiological shares, GBD 2019 global: hepatitis B about 24 per cent, hepatitis C about 27 per cent, alcohol about 27 per cent, metabolic fatty liver disease about 8 to 9 per cent, other about 12 per cent†. These shares are shifting fast, with viral hepatitis falling under treatment and vaccination while alcohol and metabolic disease rise.

Hepatitis B dominates in East Asia and sub-Saharan Africa; hepatitis C in Egypt, Pakistan and parts of eastern Europe; alcohol in Europe and the Americas; metabolic disease is rising everywhere. Male deaths are roughly double female. Peak deaths fall in middle age, making this a major cause of premature working-age mortality. Hepatocellular carcinoma accounts for about 800,000 to 900,000 new cases a year globally, mostly on a background of cirrhosis (GLOBOCAN 2022).

**Where it starts.** The causes are mostly known, measurable and in large part preventable, which is the central fact about cirrhosis.

Chronic hepatitis B: about 254 million people living with chronic infection on the WHO 2024 estimate†. Note that the two live WHO fact sheets disagree: the hepatitis B fact sheet of 28 July 2026 gives 240 million for 2024, while the STI fact sheet of 10 September 2025 gives 254 million for 2022. Both are printed. Vertical and early-childhood transmission dominate in high-prevalence areas.

Chronic hepatitis C: about 50 million people chronically infected†, through injection drug use, unsafe injections and unscreened blood products.

Alcohol is dose-dependent with no safe threshold for liver injury established; risk rises steeply above about 30 g a day in men and about 20 g in women, with wide individual variation, and only about 10 to 20 per cent of heavy drinkers develop cirrhosis†. Metabolic fatty liver disease, through obesity, type 2 diabetes and metabolic syndrome, is now a leading and rising cause.

Others: haemochromatosis with *HFE* C282Y homozygosity, Wilson disease, alpha-1 antitrypsin deficiency, autoimmune hepatitis, primary biliary cholangitis, primary sclerosing cholangitis, Budd-Chiari syndrome, cardiac and congestive causes, drug-induced injury, schistosomiasis giving periportal fibrosis rather than true cirrhosis, and hepatitis D, which markedly accelerates hepatitis B cirrhosis.

Co-factors multiply risk rather than add to it: obesity and diabetes markedly accelerate both alcohol and viral fibrosis; alcohol with hepatitis C is more than additive; smoking; aflatoxin, which is synergistic with hepatitis B for hepatocellular carcinoma; and HIV co-infection. *PNPLA3* I148M is the strongest common genetic modifier for both alcohol-related and metabolic liver disease, with *TM6SF2*, *MBOAT7* and the protective *HSD17B13* also established. These explain why only a minority of exposed people progress, but only partly.

What is not known is why only 10 to 20 per cent of heavy drinkers and a minority of those with steatosis progress to cirrhosis. Fibrosis progression rate cannot be predicted in an individual. The determinants of regression after cause removal are not well characterised. Why decompensation occurs when it does, and the mechanism of acute-on-chronic liver failure, are incompletely understood.

**Cure status.** This needs splitting, because the answer differs sharply by cause and stage.

The cause, named case by case: hepatitis C is CURABLE, over 95 per cent with direct-acting antivirals. Hepatitis B is CONTROLLABLE, suppressed and rarely cured. Alcohol-related disease is CONTROLLABLE by abstinence. Haemochromatosis and Wilson disease are CONTROLLABLE, by venesection and chelation. Autoimmune hepatitis is CONTROLLABLE by immunosuppression.

Established cirrhosis: CONTROLLABLE, with real reversibility when the cause is removed early. Fibrosis itself is partly reversible, and this is well demonstrated: removing the cause produces measurable fibrosis regression, including from cirrhosis, in a substantial proportion, documented after hepatitis C cure, hepatitis B suppression, alcohol abstinence and weight loss in metabolic steatohepatitis, with clinical outcomes improving correspondingly.

Decompensated cirrhosis: CONTROLLABLE at best; CURABLE only by transplantation, which is a genuine cure but supply-limited and geographically concentrated.

**Prevention.** Cirrhosis is one of the most preventable major causes of death.

Hepatitis B vaccination: STRONG. A birth dose plus schedule prevents chronic infection with about 90 to 95 per cent efficacy, and Taiwan’s programme produced a documented fall in childhood hepatocellular carcinoma; birth-dose coverage remains the key gap in Africa. Among the most cost-effective interventions in medicine. Hepatitis B antiviral prophylaxis in pregnancy with a birth-dose vaccine and immunoglobulin: STRONG for preventing vertical transmission.

Hepatitis C treatment as prevention, blood-product screening, safe injection practice, needle and syringe programmes, and opioid agonist therapy: STRONG. Alcohol policy — taxation, availability restriction, marketing limits: STRONG at population level, and alcohol taxation is among the best-evidenced population health measures. Individual alcohol reduction or abstinence: STRONG.

Weight management and diabetes control: MODERATE for metabolic cirrhosis. Aflatoxin reduction through grain storage and drying: MODERATE, and synergistic with hepatitis B.

Coffee consumption: MODERATE, observational only, consistently associated with lower cirrhosis incidence and mortality across many cohorts and dose-dependently. Avoiding unnecessary hepatotoxic drugs, and paracetamol dose limits: MODERATE.

**Treatment.** Treating the cause first. Hepatitis C with direct-acting antivirals gives a sustained virological response above 95 per cent with eight to twelve weeks of sofosbuvir-velpatasvir or glecaprevir-pibrentasvir, including in cirrhosis. Generic regimens now cost as little as US$40 to 90 per curative course in low- and middle-income countries under licensing agreements, against tens of thousands of US dollars originator list prices at launch. Sofosbuvir and daclatasvir are EML-listed. This is the largest price collapse for a curative drug in modern medicine.

Hepatitis B with nucleos(t)ide analogues, tenofovir disoproxil or entecavir, suppresses viral replication and reduces fibrosis progression and hepatocellular carcinoma risk substantially, usually lifelong. EML yes; off-patent; tens of US dollars a patient-year for generic tenofovir. Extremely cheap for the benefit delivered.

Alcohol-related liver disease: abstinence is the treatment with the largest effect on survival. Pharmacotherapy for alcohol use disorder — baclofen has the best evidence in cirrhosis, with acamprosate and naltrexone, the latter avoided in advanced liver disease. All off-patent; tens to hundreds of US dollars a year. Metabolic steatohepatitis: weight loss, with resmetirom the first approved drug, expensive at tens of thousands of US dollars a year list, and GLP-1 agonists showing benefit. Autoimmune hepatitis: prednisolone with azathioprine, effective and cheap, both off-patent. Haemochromatosis: venesection, nearly free. Wilson disease: penicillamine, trientine, zinc. Primary biliary cholangitis: ursodeoxycholic acid, then obeticholic acid or fibrates.

Managing the complications. Non-selective beta-blockers, propranolol or carvedilol, for portal hypertension and variceal prophylaxis; off-patent, EML-listed, a few dollars a year. Ascites: salt restriction, spironolactone with furosemide, large-volume paracentesis with albumin, and TIPS for refractory cases. Spironolactone is an EML-listed medicine under diuretics and heart failure; furosemide EML-listed; both off-patent, tens of US dollars a year. Albumin is expensive and supply-constrained.

Spontaneous bacterial peritonitis: a third-generation cephalosporin, with secondary prophylaxis using norfloxacin or ciprofloxacin; cheap and off-patent. Hepatocellular carcinoma surveillance: six-monthly ultrasound with or without alpha-fetoprotein in cirrhosis, improving survival through earlier-stage detection on cohort-based and debated evidence. Transplantation is definitive for end-stage disease, with cost and availability the binding constraints and most of the world having no access. Vaccination against hepatitis A and B, pneumococcus, influenza and COVID-19, and avoidance of alcohol and NSAIDs in cirrhosis.

**Simple means.** Alcohol abstinence is the largest single survival effect available in alcohol-related cirrhosis, including in decompensated disease, where abstinence can restore compensation. No supply chain. Salt restriction, about 2 g sodium a day, for ascites, reducing diuretic need and paracentesis frequency; free, and often more effective than it is given credit for.

Adequate protein and energy intake with a late-evening snack. Malnutrition and sarcopenia are independent predictors of death in cirrhosis, and a bedtime carbohydrate and protein snack measurably improves nitrogen balance by shortening the overnight fast. Protein restriction is wrong and harmful, and is an abandoned practice still encountered.

Weight loss and exercise in metabolic disease. Coffee, with a dose-dependent association with lower progression and mortality, cheap and widely available. Resistance exercise against sarcopenia. Avoiding NSAIDs, aminoglycosides and alcohol, and checking for hepatotoxic herbal remedies. Hepatitis B birth-dose vaccination: a single cheap injection within 24 hours of birth prevents a lifetime of liver disease, and it is the highest-value simple intervention here, though it does require a cold chain.

**Gaps.** Fibrosis progression in an individual cannot be predicted. The extent and durability of cirrhosis regression after cause removal is not fully characterised, and cirrhosis may be too coarse a category. Non-invasive fibrosis tests, FIB-4 and elastography, perform moderately and cut-offs differ between populations and aetiologies. Acute-on-chronic liver failure definitions differ between EASL and APASL, so the literature is not comparable. GBD aetiological attribution relies on modelling and the alcohol against metabolic split is uncertain.

Transplant access is grossly unequal and largely unmeasured globally. The magnitude of the hepatocellular carcinoma surveillance benefit is disputed.

---

## Metabolic dysfunction-associated steatotic liver disease

*The nomenclature changed in the 2023 multi-society Delphi consensus: MASLD replaced NAFLD and MASH replaced NASH. The definitions are not identical — MASLD requires at least one cardiometabolic criterion — so prevalence figures are not strictly interchangeable across the 2023 boundary.*

**What it is.** Fat builds up in the liver in people who do not drink heavily. In some it causes inflammation and scarring. It travels with obesity, diabetes and metabolic syndrome.

**Measured.** Global prevalence is about 30 to 32 per cent of adults, up from about 25 per cent a decade earlier (Younossi and subsequent meta-analyses)†. It is the most common liver disease in the world. Regionally: Latin America and the Middle East and North Africa highest at about 35 to 45 per cent, Africa lowest measured at about 13 to 15 per cent, Europe about 25 to 30 per cent, Asia about 30 per cent†.

Steatohepatitis affects about 5 to 7 per cent of the general population and about 20 to 25 per cent of those with the fatty liver. In type 2 diabetes, prevalence is about 55 to 70 per cent. GBD attributes about 8 to 9 per cent of cirrhosis deaths to it†, which almost certainly understates it: related cirrhosis is frequently reclassified as cryptogenic, and this is the fastest-growing indication for liver transplant in several countries.

Cardiovascular disease, not liver disease, is the leading cause of death in this condition. That is the key clinical fact. Prevalence rises with age but is now common in children and adolescents, affecting about 10 per cent of children and about 35 per cent of obese children†.

**Where it starts.** Obesity, especially visceral adiposity, dose-dependently, is the dominant driver. Type 2 diabetes and insulin resistance are both cause and consequence. Metabolic syndrome components: hypertension and dyslipidaemia with high triglycerides and low HDL. Dietary factors: high fructose and sugar-sweetened beverage intake, ultra-processed food, excess energy, with fructose having specific mechanistic support through de novo lipogenesis. Sarcopenia and physical inactivity, independent of BMI.

Lean disease occurs in about 10 to 20 per cent of cases† — normal BMI with metabolic dysfunction, more common in Asian populations, and not benign. *PNPLA3* I148M is the strongest common variant, raising both risk and fibrosis progression, with *TM6SF2*, *MBOAT7*, *GCKR* and the protective *HSD17B13*. Heritability is estimated at about 20 to 50 per cent depending on method and on whether steatosis or fibrosis is the trait, from twin and familial studies. Obstructive sleep apnoea, polycystic ovary syndrome, hypothyroidism and hypopituitarism also contribute.

What is not known is why only about 20 to 25 per cent of those with steatosis progress to steatohepatitis, and only a fraction of those to cirrhosis. The determinants of progression are the central unknown, and there is no reliable way to identify progressors prospectively. Whether steatosis itself is harmful or merely a marker is debated. The reason cardiovascular risk dominates is not fully explained. Lean disease is poorly understood. And whether this condition causes cardiovascular disease or shares its causes is unresolved, which matters greatly for how it should be treated.

**Cure status.** CONTROLLABLE by weight loss, and the dose-response is one of the best quantified relationships in hepatology. From Vilar-Gomez (*Gastroenterology* 2015, 293 patients with biopsy-paired histology after twelve months of lifestyle intervention): 5 per cent or more weight loss improves steatosis; 7 per cent or more gives steatohepatitis resolution in about 64 to 65 per cent; 10 per cent or more gives resolution in about 90 per cent, fibrosis regression in about 45 per cent, and NAS reduction in close to 100 per cent. Bariatric surgery produces resolution in about 80 to 85 per cent and fibrosis regression in about 30 to 70 per cent at five years (Lassailly, *Gastroenterology* 2020).

So: a condition that can be put into remission by weight loss and stays in remission while the loss is sustained, and sustained loss is achieved by a minority.

**Prevention.** Weight management: STRONG, on the dose-response above. Physical activity: STRONG, and partly independent of weight loss — exercise reduces hepatic fat even without weight change, by about 20 to 30 per cent relative reduction across multiple randomised trials; both aerobic and resistance training work, and resistance training achieves it at lower energy expenditure. Reducing sugar-sweetened beverages and fructose: MODERATE, with randomised trials in adolescents showing liver fat reduction. Mediterranean dietary pattern: MODERATE, reducing liver fat independent of weight loss in randomised trials. Reducing ultra-processed food: MODERATE. Coffee: MODERATE, observational, dose-dependent and consistent. Avoiding alcohol: MODERATE, since even moderate alcohol adds risk here, and the older notion that modest alcohol was protective is not supported. Diabetes prevention and control: STRONG.

**Treatment.** Weight loss by diet and exercise is first line, with the effect sizes above and no drug cost; 7 to 10 per cent loss is the therapeutic target.

GLP-1 receptor agonists: semaglutide gave steatohepatitis resolution of about 59 per cent against 17 per cent placebo at 72 weeks (Newsome, *NEJM* 2021, phase 2), confirmed in phase 3 (ESSENCE, 2024–25) with resolution about 63 against 34 per cent and fibrosis improvement about 37 against 22 per cent†. On patent; about US$9,000 to 16,000 a year US list, less in Europe; semaglutide was added to the EML in 2025 for diabetes†. Generic liraglutide is beginning to appear; tirzepatide is similar or better.

Resmetirom, a thyroid hormone receptor beta agonist, is the first drug approved specifically for steatohepatitis with F2 to F3 fibrosis (US FDA, March 2024). MAESTRO-NASH gave resolution of 26 to 30 per cent against 10 per cent placebo, and fibrosis improvement 24 to 26 against 14 per cent. On patent; tens of thousands of US dollars a year list. Not on the EML.

Pioglitazone gives resolution of about 34 to 47 per cent against about 21 per cent placebo (PIVENS and others)†, at the cost of weight gain, fluid retention and fracture risk. Off-patent; tens to hundreds of US dollars a year — by far the cheapest effective pharmacotherapy, and underused. Not on the core EML.

Vitamin E, 800 IU a day, gave improvement in about 43 per cent against 19 per cent placebo in non-diabetic patients (PIVENS, *NEJM* 2010). Off-patent; tens of US dollars a year; concerns about prostate cancer and haemorrhagic stroke at high dose limit enthusiasm.

Bariatric or metabolic surgery is the most effective durable intervention for those with severe obesity, with resolution in about 80 to 85 per cent. SGLT2 inhibitors reduce liver fat, and their cardiovascular and renal benefits make them attractive in comorbid diabetes; increasingly off-patent.

Statins do not treat the liver disease but are safe in it and indicated for the dominant cardiovascular risk. They are under-prescribed because of unfounded fear of hepatotoxicity. Off-patent, EML-listed, tens of US dollars a year. Arguably the highest-yield drug here, by addressing the actual cause of death. Treating the full cardiometabolic package — blood pressure, lipids, glycaemia — is the mortality-relevant intervention.

**Simple means.** This is a condition where simple means are not merely adjunctive but curative. Weight loss of 7 to 10 per cent gives steatohepatitis resolution in 64 to 90 per cent and fibrosis regression in about 45 per cent†, with no product required. Exercise without weight loss reduces hepatic fat by about 20 to 30 per cent†, and resistance training is effective at lower energy cost and feasible for those unable to do aerobic work. Eliminating sugar-sweetened drinks, with randomised demonstration of liver fat reduction. Mediterranean-pattern eating — olive oil, legumes, fish, vegetables, nuts, whole grains — reduces liver fat independent of weight loss. Coffee, two to three cups a day, with a dose-dependent association with less fibrosis. Avoiding alcohol. Sleep apnoea treatment and adequate sleep.

The comparison with the drugs is worth setting down plainly: 10 per cent weight loss resolves steatohepatitis in about 90 per cent, against about 26 to 30 per cent for a drug costing tens of thousands of US dollars a year. The limiting factor is adherence and food environment, not efficacy.

**Gaps.** There is no reliable way to identify who will progress. Non-invasive tests — FIB-4, elastography, ELF — have moderate accuracy and were largely validated in secondary care, so they perform worse in population screening. Whether to screen at all, and whom, is

unsettled, and major guidelines differ. The 2023 renaming means prevalence and outcome data are not strictly comparable across the boundary. Lean disease is poorly characterised. Long-term outcome data for resmetirom and the GLP-1 agonists on hard endpoints — decompensation, death — are not yet available. African prevalence data are sparse. The causal against shared-risk relationship with cardiovascular disease is unresolved.

---

## Alcohol-related liver disease

**What it is.** Drinking damages the liver in stages: fat, then inflammation, then scarring. Severe alcoholic hepatitis can kill within weeks. Stopping drinking is the one thing that reliably changes the outcome.

**Measured.** Alcohol accounts for roughly 27 per cent of global cirrhosis deaths (GBD 2019)†, and a higher share in Europe and the Americas, over 50 per cent in several European countries. Alcohol consumption is attributed about 2.6 million deaths a year across all causes (WHO Global Status Report on Alcohol and Health, 2024), of which liver disease is a major component†.

Severe alcoholic hepatitis carries a 28-day mortality of about 20 to 30 per cent, and about 30 to 50 per cent at six months in those with high Maddrey or MELD scores. About 90 per cent of heavy drinkers develop steatosis; 10 to 35 per cent develop alcoholic hepatitis; and only about 10 to 20 per cent develop cirrhosis. Mortality peaks in middle age, with a male to female ratio of roughly 2 to 3:1 for deaths, though women develop disease at lower intakes. Rates are rising in many countries, with a documented acceleration during and after the COVID-19 pandemic, especially in young adults and women.

**Where it starts.** Cumulative alcohol dose is the necessary cause. Risk rises steeply above about 30 g a day in men and about 20 g in women, and duration matters as much as daily amount. Female sex: women develop disease at lower intake and shorter duration, attributed to body water distribution and lower gastric alcohol dehydrogenase — a consistent and important difference. Drinking pattern: daily drinking, and drinking outside meals, carry higher risk than the same total taken with food.

Obesity and diabetes are strongly synergistic, multiplying alcohol's hepatic risk rather than adding to it. Smoking. Viral hepatitis co-infection, more than additive. *PNPLA3* I148M is the strongest genetic modifier, with *TM6SF2*, *MBOAT7* and the protective *HSD17B13*; alcohol dependence itself has substantial heritability, about 50 per cent, and liver-disease susceptibility given equal exposure is partly genetic but mostly unexplained.

What is not known is why only 10 to 20 per cent of heavy drinkers get cirrhosis, the single largest unexplained feature. Why alcoholic hepatitis strikes some and not others, and why it can occur after a period of relative abstinence, is unknown. Why corticosteroid response is so variable, and why the microbiome and gut-permeability axis matters in some patients, is unresolved.

**Cure status.** CONTROLLABLE, with substantial reversibility determined almost entirely by abstinence. Steatosis reverses within weeks of abstinence. Alcoholic hepatitis is survivable, and abstinence transforms long-term survival. Compensated cirrhosis with abstinence gives a five-year survival of about 85 to 90 per cent, against about 30 to 60 per cent with continued drinking; decompensated cirrhosis with abstinence gives over 60 per cent at five years against about 30 per cent with continued drinking. Few interventions in medicine produce a survival difference of this size. Decompensated disease can re-compensate with abstinence, sometimes removing the need for transplant.

Transplantation is CURABLE, and early transplantation in carefully selected severe alcoholic hepatitis non-responders gives about 70 to 80 per cent six-month survival against about 25 to 30 per cent without (Mathurin, *NEJM* 2011, and subsequent series).

**Prevention.** Population alcohol policy: STRONG. Taxation and minimum unit pricing have measurable effects on liver mortality — Scotland's minimum unit pricing was associated with reduced alcohol-specific deaths, and the Russian and Baltic tax and availability changes produced large documented mortality shifts. Among the best-evidenced population health interventions available.

Individual abstinence or reduction: STRONG. Weight management: MODERATE, given the synergy with obesity. Hepatitis B vaccination and hepatitis C treatment in drinkers: STRONG, removing a multiplicative co-factor. Screening and brief intervention in primary care: MODERATE, reducing consumption modestly but at population scale. Smoking cessation: MODERATE.

**Treatment.** Abstinence has by far the largest effect; everything else is secondary.

Treatment of alcohol use disorder is liver treatment, and it is under-delivered. Integrated hepatology and addiction clinics improve both abstinence and survival. Baclofen is the best-evidenced agent in cirrhosis and safe in liver disease; off-patent; tens to hundreds of US dollars a year. Acamprosate is effective for abstinence maintenance; off-patent; hundreds of US dollars a year. Naltrexone is effective but avoided in advanced liver disease; off-patent. Disulfiram is hepatotoxic and generally avoided here. Psychosocial treatment — CBT, motivational interviewing, twelve-step and mutual aid — all has demonstrated effect at minimal material cost.

Severe alcoholic hepatitis with Maddrey discriminant function of 32 or more, or MELD above 20: corticosteroids, prednisolone 40 mg a day for 28 days. STOPAH (Thursz, *NEJM* 2015, 1,103 patients) found prednisolone reduced 28-day mortality, odds ratio 0.72 (95 per cent CI 0.52 to 1.01, p = 0.06) — borderline on the primary analysis and significant after adjustment — with no benefit at 90 days or one year, while pentoxifylline showed no benefit at all. So the benefit is short-term and modest, and infection risk rises. The Lille score at day 7 identifies non-responders, in whom steroids should stop. Prednisolone EML yes; off-patent; a few to tens of US dollars a year. Pentoxifylline is abandoned on the STOPAH evidence.

N-acetylcysteine added to steroids shows some survival benefit at one month in trials; cheap, off-patent, EML-listed. Nutrition: energy intake below about 21.5 kcal/kg a day predicts mortality in alcoholic hepatitis, and enteral feeding is used where intake is inadequate. Thiamine and B vitamins to prevent Wernicke encephalopathy; cheap, essential, EML-listed, given before glucose. Management of cirrhosis complications as in the cirrhosis entry. Early liver transplantation for selected severe alcoholic hepatitis non-responders and for abstinent cirrhotic patients; the six-month rule is no longer evidence-based as an absolute requirement.

**Simple means.** Abstinence is the largest single survival intervention and requires no product; mutual-aid groups are free and have measurable effect. Nutrition is critical and routinely neglected: malnutrition is near-universal in alcoholic hepatitis and independently predicts death, and adequate energy at about 35 kcal/kg a day with protein at 1.2 to 1.5 g/kg a day, including a late-evening snack, is the target. Protein restriction is harmful and must not be used.

Thiamine costs pennies per dose and prevents an irreversible neurological catastrophe. Weight management removes the synergistic multiplier. Smoking cessation. Brief interventions and peer support are low-cost, scalable and evidence-based. At population level, alcohol taxation and availability restriction need no clinical infrastructure at all and have the largest measured population effect.

**Gaps.** Why most heavy drinkers escape cirrhosis is unknown. Corticosteroid benefit in alcoholic hepatitis is real but small and short-lived, and STOPAH's borderline primary result is interpreted differently by different guideline bodies — a genuine disagreement between sources. No effective therapy exists for steroid non-responders except transplant. Transplant selection criteria for alcohol-related disease vary enormously between centres and countries, and the ethical debate is unresolved. GBD attribution between alcohol and metabolic disease is uncertain where both are present, which is increasingly common. Alcohol-related liver mortality data in many countries are compromised by under-reporting on death certificates.

---

## Hepatic encephalopathy

**What it is.** When the liver fails, toxins the gut produces — chiefly ammonia — reach the brain. The person becomes confused, drowsy and eventually comatose. It comes and goes, often with a trigger.

**Measured.** Overt hepatic encephalopathy occurs in about 30 to 40 per cent of people with cirrhosis at some point. Minimal or covert encephalopathy affects about 20 to 80 per cent of cirrhotic patients depending on the test used, and the fourfold range reflects the absence of a standard test. After a first overt episode, one-year survival without transplant is about 40 to 50 per cent. It is not a separate GBD cause; the burden sits inside cirrhosis. Recurrence within a year is the norm without prophylaxis, at about 40 to 50 per cent. It is a major driver of hospital admission, carer burden, driving incapacity and loss of employment in cirrhosis.

**Where it starts.** Underlying cirrhosis with portosystemic shunting is the necessary substrate. It also occurs after TIPS insertion, in about 10 to 50 per cent†, and in acute liver failure.

The precipitants are identifiable in most episodes, and this is the practically important part. Infection, especially spontaneous bacterial peritonitis, is the commonest. Gastrointestinal bleeding. Constipation. Dehydration and electrolyte disturbance, especially hypokalaemia and hyponatraemia, and over-diuresis. Renal impairment. Sedatives, opioids and benzodiazepines. Alcohol binge, and non-adherence to lactulose. Dietary protein excess is a weak and largely historical precipitant, and the old practice of protein restriction causes more harm than it prevents. Sarcopenia is an independent risk factor, because muscle metabolises ammonia and muscle loss worsens encephalopathy.

What is not known: ammonia correlates poorly with grade in individuals, so the full mechanism is clearly not ammonia alone — inflammation, manganese, GABAergic tone, bile acids and the microbiome all contribute without a settled model. Why some cirrhotic patients with heavy shunting never develop it is unexplained. Whether minimal encephalopathy should be screened for and treated routinely is unresolved, partly because no reference test exists.

**Cure status.** With the cirrhosis in place: CONTROLLABLE. Individual episodes are highly reversible — treating the precipitant and giving lactulose resolves most — but the underlying predisposition persists as long as the cirrhosis does, so recurrence is expected without prophylaxis. After liver transplantation: CURABLE, though some cognitive deficit may persist.

**Prevention.** Lactulose for secondary prophylaxis: STRONG. After a first episode, lactulose reduces recurrence substantially, with a randomised trial giving recurrence of about 20 per cent against about 47 per cent placebo (Sharma, *Gastroenterology* 2009). Rifaximin added to lactulose: STRONG. Bass (*NEJM* 2010, 299 patients) gave breakthrough encephalopathy of 22 against 46 per cent, hazard ratio 0.42 (95 per cent CI 0.28 to 0.64), and hospitalisation 13.6 against 22.6 per cent over six months.

Preventing and promptly treating precipitants: STRONG — peritonitis prophylaxis, variceal prophylaxis, avoiding over-diuresis, treating constipation, avoiding sedatives. Avoiding benzodiazepines and opioids in cirrhosis: STRONG. Maintaining muscle mass and nutrition: MODERATE, plausible and supported by observational data. Primary prophylaxis in those who have never had an episode: CONTESTED, and not standard.

**Treatment.** Identify and treat the precipitant — culture and treat infection, stop bleeding, correct electrolytes and hypokalaemia, rehydrate, stop sedatives, relieve constipation. That is the single most important step.

Lactulose is first line, titrated to two or three soft stools daily, resolving most episodes and preventing recurrence at 20 against 47 per cent. EML yes; off-patent; tens to hundreds of US dollars a patient-year. Cheap, effective, universally available. Over-dosing causes dehydration and can precipitate encephalopathy, a common iatrogenic trap.

Rifaximin is added for recurrence prevention, hazard ratio 0.42 for breakthrough episodes. Not on the EML; on patent in many markets; about US$2,500 to 15,000 a patient-year in high-income markets, though Indian generics are a small fraction of that. The cost differential between lactulose and rifaximin is one of the starkest in hepatology for a modest incremental benefit.

Lactulose enemas where the oral route is unavailable. L-ornithine L-aspartate reduces ammonia with benefit shown in some trials, mainly used outside the United States and United Kingdom, at modest cost. Branched-chain amino acid supplementation improves manifestations in meta-analysis and is expensive relative to food. Neomycin and metronidazole are historical alternatives limited by toxicity. Correct hyponatraemia cautiously, avoiding overrapid correction. Reduce or occlude large portosystemic shunts by embolisation in refractory

cases, or reduce TIPS diameter. Liver transplantation is definitive. Albumin has some evidence for benefit in overt encephalopathy, and is expensive and supply-limited.

**Simple means.** Adequate dietary protein, not restriction, is the most important correction in this entry. A randomised trial (Córdoba, *Journal of Hepatology* 2004) showed protein restriction produced no benefit and increased protein breakdown, and guidelines now recommend 1.2 to 1.5 g/kg a day of protein and about 35 kcal/kg a day of energy in cirrhosis, even during encephalopathy. Decades of low-protein diets were actively harmful.

Vegetable and dairy protein may be better tolerated than meat protein. Frequent small meals with a late-evening snack shortens the overnight fast, improves nitrogen balance and reduces muscle breakdown, at no cost. Preventing constipation with fibre and adequate fluid removes a precipitant at no cost; lactulose is the pharmacological version of the same thing. Resistance exercise to maintain muscle mass is mechanistically direct, since muscle is the main alternative site of ammonia disposal when the liver fails. Avoiding alcohol, sedatives and benzodiazepines. Zinc replacement where deficient, which is common in cirrhosis and involved in the urea cycle; cheap.

Carer education to recognise early signs — day-night reversal, altered handwriting — and to seek help early costs nothing and has a measurable effect on admission severity. Driving advice: minimal encephalopathy impairs driving measurably, and this is a safety intervention requiring only a conversation.

**Gaps.** There is no reference standard for diagnosing minimal or covert encephalopathy, so prevalence ranges fourfold and screening cannot be evaluated properly. Ammonia levels correlate poorly with severity and should not guide management, yet frequently do. Whether minimal encephalopathy should be treated is unresolved. Rifaximin's cost-effectiveness is contested and varies hugely by market price. The mechanism is incompletely understood beyond ammonia. Long-term cognitive outcomes after repeated episodes, including after transplant, are under-studied.

---

## Hernias: inguinal and hiatal

**What it is.** A hernia is tissue pushing through a weak point. An inguinal hernia pushes bowel or fat through the groin wall. A hiatal hernia lets the stomach slide up through the diaphragm into the chest.

**Measured.** For inguinal hernia, lifetime risk is about 27 to 30 per cent in men and about 3 to 6 per cent in women, one of the largest sex differences in surgical disease. Over 20 million inguinal hernia repairs are performed worldwide each year, making it the commonest general surgical operation. GBD 2019 gave inguinal, femoral and abdominal hernia roughly 32,000 to 59,000 deaths and about 2 to 3 million DALYs globally, mostly from obstruction and strangulation where surgical access is lacking. Age distribution is bimodal: infancy, then rising steadily after fifty. The untreated burden is concentrated in low-income settings, with large unmet surgical need in sub-Saharan Africa, where giant and strangulated hernias are common and strangulation mortality is substantial.

For hiatal hernia, prevalence is highly method-dependent: about 10 to 20 per cent of adults by endoscopy, higher with careful measurement and with age, and present in the majority of patients with erosive oesophagitis. It is not a separate GBD cause. Type I, sliding, accounts for over 95 per cent†; types II to IV, paraoesophageal, are uncommon but carry volvulus and strangulation risk.

**Where it starts.** For inguinal hernia: male sex, about eight to ten times the risk; age; a patent processus vaginalis, which is congenital and the basis of paediatric and many indirect adult hernias. Family history raises risk several-fold, with heritability estimated at about 57 per cent in Swedish twin data†. Connective tissue disorders — Ehlers-Danlos, Marfan — and altered collagen type I to III ratio; smoking, which impairs collagen. Raised intra-abdominal pressure from chronic cough or COPD, constipation and straining, prostatism, ascites, heavy manual work and pregnancy.

Low BMI is a risk factor, not high — a counter-intuitive and well-replicated finding for inguinal hernia specifically, since obesity is a risk factor for incisional and hiatal hernia but appears

protective for inguinal. Prior appendicectomy or open prostatectomy; collagen-degrading enzyme activity.

For hiatal hernia: age, through diaphragmatic and phreno-oesophageal ligament laxity; obesity, dose-dependently; raised intra-abdominal pressure; pregnancy; kyphoscoliosis; prior oesophageal surgery; congenital factors. There is some familial clustering and heritability is not well quantified.

What is not known is why the collagen and connective-tissue changes occur; why the male excess is so extreme beyond the processus vaginalis explanation; and which asymptomatic hernias will strangulate. For hiatal hernia, why some develop it and others with identical BMI and age do not, and the precise relationship between hernia size and reflux severity.

**Cure status.** Inguinal hernia: CURABLE by surgical repair, with mesh repair recurrence of about 1 to 5 per cent and tissue (Shouldice) repair about 1 to 15 per cent depending on operator and technique. Hernias never resolve spontaneously in adults; the only exception is some paediatric umbilical hernias, which commonly close by themselves. Watchful waiting is legitimate for minimally symptomatic hernias in men: randomised trials (Fitzgibbons, *JAMA* 2006; O'Dwyer) showed low rates of acute strangulation, about 0.2 to 0.5 per cent a year, though the majority eventually cross over to surgery, about 70 per cent at seven to ten years.

Hiatal hernia: CONTROLLABLE for type I, managed as reflux with acid suppression and weight loss, and not routinely repaired. CURABLE by surgical repair with fundoplication, indicated for large or paraoesophageal hernias, those with obstructive symptoms, volvulus risk or refractory reflux. Radiological recurrence after large hiatal hernia repair is 15 to 60 per cent, which tempers the cure claim.

**Prevention.** For inguinal hernia, little is demonstrably preventable: WEAK, effectively absent. Smoking cessation: WEAK, on the collagen mechanism and observational data. Treating chronic cough, constipation and prostatism: WEAK, mechanistically direct with trial evidence absent. Avoiding very heavy lifting: CONTESTED — an occupational association exists but causation and threshold are unclear, and advice to avoid lifting after repair is not evidence-based. Mesh prophylaxis during open aortic or stoma surgery reduces incisional, not inguinal, hernia: MODERATE for that specific setting.

For hiatal hernia, weight management: MODERATE. Avoiding chronic straining: WEAK.

**Treatment.** For inguinal hernia, mesh repair is the standard. Lichtenstein open mesh and laparoscopic TAPP or TEP are both effective: laparoscopic repair gives less chronic pain and faster return to work with a longer learning curve and higher cost, while open mesh under local anaesthesia is cheap, safe and suitable for almost any setting. Recurrence is about 1 to 5 per cent either way.

Mesh cost matters here. Commercial polypropylene mesh costs tens to hundreds of US dollars. Sterilised mosquito-net mesh has been shown non-inferior to commercial mesh in randomised trials in Uganda and India (Löfgren, *NEJM* 2016, 302 patients: no difference in recurrence or infection at one year) at roughly US$1 or less. One of the most important cost findings in global surgery.

Tissue repair, Shouldice, where mesh is unavailable or declined, gives excellent results in specialist hands. Local anaesthetic repair enables high-volume, low-cost surgery without a general anaesthetic service; lidocaine EML yes, off-patent, pennies. Watchful waiting for minimally symptomatic hernias in men. Emergency repair for strangulation or obstruction, which is the time-critical presentation. Trusses are largely obsolete with no evidence of benefit and may obscure strangulation; not recommended.

For hiatal hernia, PPI and weight loss for type I with reflux symptoms: omeprazole EML yes, off-patent, a few to tens of US dollars a year. Laparoscopic repair with fundoplication for large or paraoesophageal hernias, obstruction or refractory symptoms, with mesh use at the hiatus controversial because of erosion risk. Emergency repair for gastric volvulus.

**Simple means.** Mosquito-net mesh is the headline simple means here: a near-free, locally available material shown non-inferior to commercial mesh, which removes the main consumable cost barrier to hernia repair in low-income settings. Repair under local anaesthesia needs no anaesthetic machine, no oxygen and no ventilator, and enables task-shared, high-volume camps.

Weight loss for hiatal hernia and reflux; head-of-bed elevation; avoiding late meals. Treating constipation and cough to reduce straining. Smoking cessation. Watchful waiting — the simple means of not operating on an asymptomatic hernia, which is evidence-based.

The honest limit: an inguinal hernia cannot be cured without an operation. No exercise, belt, truss or diet repairs it. The simple-means question here is about making surgery cheap and accessible, not about avoiding it.

**Gaps.** Unmet surgical need for hernia in low-income countries is large and poorly quantified. Chronic post-operative inguinal pain affects about 10 to 12 per cent to some degree and about 0.5 to 6 per cent severely†; its mechanism and prevention are not well understood and it is the main remaining problem with mesh repair. Mesh-related litigation and concern have outrun the evidence for inguinal mesh specifically, confusing patients. Optimal management of large paraoesophageal hernias and whether to use mesh at the hiatus are unresolved. Watchful waiting in women is not studied, and femoral hernias strangulate more readily. Hiatal hernia prevalence is method-dependent and essentially unknown at population level.

---

## Bowel obstruction

**What it is.** Something blocks the bowel, so contents cannot pass. The bowel above swells, vomiting starts, nothing comes out. If the blood supply is cut off, the bowel dies.

**Measured.** Obstruction accounts for about 15 per cent of emergency admissions for abdominal pain, and small bowel obstruction is the commonest emergency small bowel diagnosis. Adhesions cause about 60 to 75 per cent of small bowel obstruction in high-income countries, with hernia and malignancy most of the rest. Large bowel obstruction is about 60 per cent malignant†, mostly colorectal cancer, then volvulus and diverticular stricture.

GBD does not model bowel obstruction as a single cause; the burden is distributed across hernia, neoplasm, intestinal infection and other digestive diseases. Mortality is about 3 to 10 per cent overall, rising steeply with strangulation, delay, age and comorbidity, and up to about 30 per cent with bowel resection for ischaemia.

The geographic difference is marked. In much of sub-Saharan Africa and South Asia, hernia and sigmoid volvulus predominate over adhesions, and presentation is later, so case-fatality is far higher. Adhesive obstruction is a disease of populations that have had abdominal surgery. In children, intussusception with a peak at three to twelve months, and congenital atresias; intussusception is a specific, treatable cause with a non-surgical cure.

**Where it starts.** Prior abdominal or pelvic surgery, giving adhesions. Risk rises with open surgery, with lower abdominal and pelvic surgery, and with peritonitis; about 5 to 10 per cent of patients after major abdominal surgery will have an adhesive obstruction admission over the following decades. Hernia, external — inguinal, femoral, incisional — or internal. Malignancy: colorectal, ovarian, gastric, peritoneal carcinomatosis. Volvulus: sigmoid, with high-fibre diet, redundant sigmoid, chronic constipation, institutionalisation, Chagas disease and altitude; or caecal. Crohn strictures, diverticular strictures, radiation enteritis. Gallstone ileus, bezoar, foreign body, intussusception, ascariasis — a major cause in endemic areas, particularly in children — and abdominal tuberculosis, important in endemic settings.

What is not known is why adhesion formation varies so much between individuals after identical surgery, and why some adhesions obstruct and others never do. There is no reliable way to predict who needs surgery and who will settle; clinical and CT signs of ischaemia have moderate accuracy at best. The failure of adhesion-prevention products to deliver clear clinical benefit is unexplained.

**Cure status.** This depends on cause and on whether the bowel is viable, so each stratum is named.

Adhesive small bowel obstruction without strangulation: SELF-LIMITING — about 65 to 80 per cent resolve with non-operative management, nasogastric decompression, intravenous fluids and correction of electrolytes. Strangulation or ischaemia: CURABLE only by urgent surgery, and delay is lethal. Hernia-related obstruction: CURABLE by repair. Resectable malignant obstruction: CURABLE. Unresectable malignant obstruction: RELIEF ONLY, by stent, defunctioning stoma or palliative measures. Sigmoid volvulus: CURABLE — endoscopic decompression relieves it in over 80 per cent, but recurrence is 40 to 60 per cent

without subsequent sigmoid resection, so definitive cure requires surgery. Intussusception in children: CURABLE non-operatively, with air or hydrostatic enema reduction succeeding in about 80 to 90 per cent.

**Prevention.** Minimally invasive rather than open surgery: MODERATE, with substantially fewer subsequent adhesive obstructions. Elective hernia repair: STRONG for preventing hernia-related obstruction and strangulation, which is the main preventable cause in low-income settings. Colorectal cancer screening: STRONG for preventing malignant obstruction, by preventing or down-staging the cancer. Sigmoid resection after a first volvulus: STRONG, against 40 to 60 per cent recurrence otherwise. Mass deworming in endemic areas: STRONG for ascaris-related obstruction in children. Adhesion barriers — hyaluronate and carboxymethylcellulose film, icodextrin — reduce adhesion formation on second look but are CONTESTED for reducing clinically important obstruction; the hard outcome evidence is weak and they add cost. Avoiding unnecessary laparotomy: MODERATE.

**Treatment.** Resuscitation first: intravenous fluids and correction of hypokalaemia, hyponatraemia and metabolic alkalosis. Sodium chloride and potassium chloride, EML-listed, pennies. Nasogastric decompression relieves vomiting and reduces aspiration risk: a plastic tube, essentially free.

A non-operative trial for adhesive obstruction without ischaemia, typically 48 to 72 hours, resolves 65 to 80 per cent†. Water-soluble contrast, gastrografin or diatrizoate, is both diagnostic and therapeutic: contrast reaching the colon within 24 hours predicts resolution, and it reduces the need for surgery and shortens hospital stay in meta-analyses of adhesive obstruction. Cheap, off-patent, and a genuinely useful, underused intervention.

Surgery for strangulation, perforation, closed-loop obstruction, failure of non-operative management, or an obstructing hernia: adhesiolysis, resection and anastomosis, or stoma. Sigmoid volvulus: endoscopic or rigid sigmoidoscopic decompression with a flatus tube, then elective sigmoid resection. Malignant large bowel obstruction: a self-expanding metal stent as a bridge to surgery or as palliation, or a defunctioning stoma, or resection. Intussusception: air or hydrostatic enema reduction under imaging, with surgery if it fails or if there is perforation or ischaemia. Palliation of malignant and inoperable obstruction: dexamethasone, octreotide, anti-emetics, hyoscine butylbromide, venting gastrostomy; dexamethasone and hyoscine are EML-listed and cheap, and octreotide is expensive. Antibiotics only for perforation, peritonitis or strangulation, not routinely.

**Simple means.** A nasogastric tube with intravenous — or where necessary oral or rectal — rehydration is the mainstay for the 65 to 80 per cent who resolve without surgery. A tube and salt water. Oral rehydration solution where intravenous fluids are unavailable, with the caveat that in complete obstruction with vomiting oral intake is unsafe, so this applies to partial obstruction and to resuscitation en route; the solution itself is sugar and salt in clean water, EML-listed, at an indicative UNICEF price of US$4.80 per carton of 100 sachets, about US$0.048 a sachet, read 19 October 2026.

Water-soluble contrast is cheap and both predicts and promotes resolution. Rectal tube decompression for sigmoid volvulus — a rigid sigmoidoscope and a flatus tube — relieves a life-threatening condition immediately with no electricity or imaging required: one of the highest-yield simple procedures in emergency surgery. Elective hernia repair with mosquito-net mesh under local anaesthetic prevents the commonest obstruction in low-resource settings. Deworming with a single albendazole dose, EML-listed, prevents ascaris obstruction. Early presentation and transport is the dominant determinant of survival, and that is a logistics problem rather than a technology problem.

The honest limit: strangulated bowel requires an operation, and nothing simple substitutes.

**Gaps.** There is no reliable predictor of which adhesive obstruction will need surgery or which bowel is ischaemic; CT accuracy is moderate and clinical judgement remains decisive. The optimal duration of non-operative management is not established, whether 48 hours, 72 hours or longer. Adhesion barrier products have soft outcome evidence and uncertain cost-effectiveness. The global burden of bowel obstruction is not separately modelled in GBD, so the true mortality is unknown and probably substantially underestimated where surgical access is poor. Evidence on stent against surgery for malignant obstruction is mixed. Paediatric data outside high-income settings are sparse.

## Constipation

**What it is.** Stools are infrequent, hard or difficult to pass. Common at all ages, and especially in older people and in pregnancy. Usually no disease is found.

**Measured.** Global prevalence is about 14 per cent of adults (Suares and Ford, *American Journal of Gastroenterology* 2011, meta-analysis), with a range of 2 to 27 per cent across studies by definition. Rome IV functional constipation gives about 11.7 per cent globally (Rome Foundation global study, Sperber 2021). It is not a separate GBD main cause and has no standalone DALY figure. Deaths are rare but non-zero, through faecal impaction, stercoral perforation and complications in frail elderly patients.

Prevalence is about twice as high in women and rises sharply with age, affecting about 30 to 40 per cent of those over 65 and far more in institutional care†. In children it is about 10 to 15 per cent, a very common paediatric presentation, about 95 per cent of it functional†. It is a major driver of laxative expenditure and of emergency admissions in the elderly.

**Where it starts.** Female sex, older age, low physical activity, low dietary fibre, low fluid intake, low socioeconomic status. Drugs are a leading and under-recognised cause: opioids most clearly and dose-dependently, then anticholinergics, calcium channel blockers such as verapamil, iron, calcium, aluminium antacids, tricyclics, antipsychotics, diuretics and 5-HT3 antagonists. Pregnancy, through progesterone, iron and mechanical factors.

Secondary causes to exclude: hypothyroidism, hypercalcaemia, diabetes, Parkinson disease, multiple sclerosis, spinal cord lesions, Hirschsprung disease in children, and colorectal cancer, especially with new onset over fifty, bleeding or weight loss.

Pelvic floor dyssynergia, or dyssynergic defaecation, is a distinct mechanical subtype in up to a third of referred cases, in which the pelvic floor fails to relax. It matters because it responds to biofeedback and not to laxatives. Slow-transit constipation is a distinct minority subtype. Behavioural causes include withholding in children, often after a painful stool, and poor toilet access. Heritability is modest; twin studies suggest a genetic contribution that is not well quantified.

What is not known is the cause of most functional constipation. Whether low fibre and low fluid intake are causes or consequences is not firmly established, and the fluid evidence is particularly weak. The role of the microbiome is unresolved. Why women are affected twice as often is unexplained.

**Cure status.** CONTROLLABLE for most functional constipation — treatable and manageable, usually indefinitely, rather than cured. CURABLE in specific situations: when a drug cause is removed; when a secondary cause such as hypothyroidism or hypercalcaemia is treated; when dyssynergic defaecation is corrected by biofeedback, which produces durable cure in that subtype; and in children, who recover fully with treatment and time. RELIEF ONLY for refractory slow-transit constipation, where even colectomy gives mixed results.

**Prevention.** Dietary fibre: MODERATE. It increases stool frequency and softens stool, with modest effect sizes, and it does not help all subtypes — it can worsen slow-transit and dyssynergic constipation. Physical activity: WEAK, with consistent association and modest trial evidence. Avoiding constipating drugs, or co-prescribing against them, especially routine laxative co-prescription with opioids: STRONG. That is the clearest preventive action available. Adequate fluid: WEAK — the evidence is much weaker than the advice. Toilet access, privacy and unhurried time, and responding to the urge: MODERATE in institutional settings, where it is often the dominant factor. In children, avoiding the pain-withholding cycle by treating painful fissures and stools promptly: MODERATE.

**Treatment.** The proportion of dyssynergic defaecation cured durably by biofeedback, and of children who recover fully, is not given here. Fibre supplementation with psyllium or ispaghula is the best-evidenced bulk agent, increasing frequency and improving consistency; off-patent; tens to hundreds of US dollars a year. Bran is less well tolerated and less effective than psyllium.

Osmotic laxatives: polyethylene glycol, macrogol, is first line and superior to lactulose in Cochrane review, giving greater stool frequency, less abdominal pain and fewer adverse effects. Off-patent; tens to hundreds of US dollars a year; EML status. Effective, safe long-term, and safe in children and pregnancy. Lactulose is effective, cheaper in some markets,

and causes more bloating; EML; tens to hundreds of US dollars a year. Magnesium salts are cheap and effective, with caution in renal impairment.

Stimulant laxatives, senna and bisacodyl, are effective in randomised trials — bisacodyl and sodium picosulfate both have good trial support — and the old fear of damaging the bowel and causing dependence is not supported by evidence and has led to undertreatment. Senna is off-patent, EML, tens of US dollars a year: among the cheapest effective options. Suppositories and enemas — glycerol, bisacodyl, phosphate — for impaction and for rectal evacuation disorders; cheap.

Biofeedback and pelvic floor retraining for dyssynergic defaecation is superior to laxatives in randomised trials for that subtype, with about 70 to 80 per cent success and durable benefit at one to two years (Chiarioni, *Gastroenterology* 2006 and others). No drug and no device beyond basic equipment; the limiting factor is trained therapists. Identifying this subtype is the single most valuable diagnostic step in refractory constipation.

Prucalopride, a 5-HT4 agonist, is effective for refractory constipation and now off-patent in several markets, at hundreds to thousands of US dollars a year and falling. Secretagogues — linaclotide, lubiprostone, plecanatide — are effective, on patent, at thousands of US dollars or more a year, and not on the EML. Peripherally acting mu-opioid receptor antagonists — naloxegol, methylnaltrexone, naldemedine — work for opioid-induced constipation where laxatives fail and are expensive, at thousands to tens of thousands of US dollars a year; for opioid constipation, tapering the opioid has the best risk-benefit profile. Manual disimpaction and bowel regimens in institutional care. Surgery, subtotal colectomy with ileorectal anastomosis, is a last resort for proven isolated slow-transit constipation with a normal pelvic floor, with mixed outcomes and critical patient selection. In children: disimpaction then maintenance macrogol, with toilet training, behavioural support and demystification; prolonged maintenance over months is necessary and premature stopping causes relapse.

**Simple means.** This condition is managed overwhelmingly by simple means.

Dietary fibre from fruit, vegetables, legumes and whole grains. Kiwifruit, two a day, prunes and psyllium all have randomised trial support, and prunes outperformed psyllium in a head-to-head trial (Attaluri, *Alimentary Pharmacology and Therapeutics* 2011), with kiwifruit having repeated positive trials†. These are foods.

Physical activity, walking in particular, is effective in the elderly and in pregnancy. A toileting routine — using the urge, after a meal to exploit the gastrocolic reflex, unhurried, with privacy. In care homes this single change often outperforms drugs. A footstool or squat position raises the knees and straightens the anorectal angle, measurably reducing straining and defaecation time in small studies; a box costs nothing. Pelvic floor relaxation and biofeedback is the treatment of choice for dyssynergic defaecation, outperforming laxatives, and requires a trained person rather than a product. Abdominal massage has modest evidence in neurogenic and institutional constipation.

On fluid, the honest version. Increasing fluid intake above normal has little evidence of benefit in people who are not dehydrated. The benefit is in correcting dehydration, which is common in the frail elderly, and fluid matters when fibre is increased. The blanket advice to drink more water is weakly supported.

Reviewing and stopping constipating drugs is free, and often the whole answer.

**Gaps.** Definitions vary enough that prevalence spans 2 to 27 per cent. The fluid-intake evidence does not match the universality of the advice. Fibre's effect is modest and subtype-dependent, and it harms some patients. Dyssynergic defaecation is under-diagnosed because anorectal physiology testing is unavailable in most settings, so a curable subtype is routinely treated with ineffective laxatives. Long-term safety data for the expensive secretagogues are limited, and they have not been shown superior to cheap osmotic and stimulant laxatives head-to-head. Evidence for abdominal massage and positional change is thin despite plausibility. Paediatric relapse rates are high and the optimal maintenance duration is not established.

## Lactose intolerance

**What it is.** After weaning, most people stop making much lactase, the enzyme that digests milk sugar. Undigested lactose ferments in the colon, causing wind, pain and diarrhoea. It is the normal human condition, not a disease.

**Measured.** Global lactase non-persistence runs at about 65 to 70 per cent of adults, the majority of humanity†. The geographic and ancestral gradient is strong and well mapped: East Asia about 90 to 100 per cent non-persistent; sub-Saharan Africa about 70 to 90 per cent, but low in pastoralist groups such as the Tutsi, Fulani, Beja and Maasai, where persistence is common; Southern Europe and the Middle East about 50 to 70 per cent; Northern Europe about 5 to 20 per cent non-persistent, meaning 80 to 95 per cent persistent; and Northwest European ancestry has the lowest non-persistence in the world, about 5 to 10 per cent in parts of Scandinavia, Ireland and Britain.

Symptomatic intolerance is much less common than non-persistence, since many non-persistent people tolerate moderate lactose. That is the key distinction in the field. It is not a GBD cause, with no deaths and no DALY figure. Lactase activity declines after weaning, typically from age two to five onward in non-persistent individuals, with symptoms usually emerging in later childhood or adulthood.

**Where it starts.** Primary lactase non-persistence is genetically determined and is the ancestral, default human state. It is regulated by variants in the *MCM6* enhancer upstream of *LCT*, notably −13910C>T in Europeans and −14010G>C, −13907C>G and −13915T>G in African and Middle Eastern pastoralist populations. Lactase persistence is the derived trait, under one of the strongest signals of recent positive selection in the human genome, arising independently several times alongside dairying. Heritability of lactase persistence is essentially monogenic, determined by these regulatory variants — among the clearest genotype-phenotype relationships in human nutrition.

Secondary lactase deficiency is transient, from mucosal injury: gastroenteritis, especially rotavirus in infants, coeliac disease, Crohn disease, giardiasis, small bowel bacterial overgrowth, chemotherapy, radiation. It is reversible when the underlying condition heals. Congenital lactase deficiency is a very rare autosomal recessive condition from *LCT* mutations, concentrated in Finland, presenting with severe neonatal diarrhoea and life-threatening without a lactose-free diet.

What is not known is why symptom severity correlates so poorly with measured lactase activity and breath hydrogen. Colonic microbiota adaptation explains part of it — the colon can adapt to ferment lactose with fewer symptoms over weeks of continued exposure — but the determinants of individual tolerance are not predictable. Visceral hypersensitivity and overlap with IBS confound diagnosis substantially: in blinded challenge studies, many people who self-identify as lactose intolerant do not react to lactose.

**Cure status.** Primary lactase non-persistence: CONTROLLABLE. It is a permanent genetic state and is not curable, and it is also not a disease: it is fully managed by dose adjustment, and most non-persistent people can consume useful amounts of dairy. Secondary lactase deficiency: SELF-LIMITING, resolving when the mucosa heals. Congenital lactase deficiency: CONTROLLABLE, on lifelong strict avoidance.

**Prevention.** Primary non-persistence is not preventable, since it is the genetic default: not applicable. Preventing secondary deficiency: MODERATE — rotavirus vaccination prevents a major cause of transient infantile lactase deficiency, and treating coeliac disease and giardiasis resolves it. Continued regular small lactose exposure to maintain colonic adaptation and tolerance: MODERATE, demonstrated in trials, and avoidance tends to reduce tolerance. Complete dairy avoidance is not a desirable goal: it risks calcium and vitamin D inadequacy and is unnecessary for the great majority.

**Treatment.** Dose reduction rather than elimination. Most lactase non-persistent adults tolerate about 12 to 15 g of lactose, roughly 240 ml or one cup of milk, in a single sitting with few or no symptoms, and more when spread through the day and taken with other food. That is the central practical finding and it is routinely overlooked.

Fermented dairy: yoghurt with live cultures is substantially better tolerated because bacterial beta-galactosidase digests lactose in the gut, and hard aged cheeses — cheddar, parme-

san, Swiss — contain almost no lactose, under 0.5 g a portion. Butter is nearly lactose-free. These require no manufacturing beyond traditional dairying.

Lactase enzyme supplements, beta-galactosidase taken with the meal, are effective and dose-dependent, with benefit confirmed in trials though variable between products. Off-patent or sold as a food supplement; tens to hundreds of US dollars a year depending on use; not on the EML. Lactose-free, lactase-treated milk and dairy is fully effective, costs more than ordinary milk, and requires industrial processing.

Calcium and vitamin D adequacy is essential if dairy is reduced, through non-dairy calcium sources — fortified plant milks, tinned fish with bones, tofu set with calcium, dark green leaves, sesame — or supplements. Calcium carbonate and vitamin D are cheap and EML-listed; a few to tens of US dollars a year. Treat the underlying cause in secondary deficiency. And reconsider the diagnosis: a substantial proportion of self-diagnosed lactose intolerance is IBS, fructan sensitivity or nocebo, with blinded challenge the arbiter where it matters.

**Simple means.** This condition is almost entirely managed by simple means, and dairying cultures worked them out long before the biochemistry was known.

Spreading lactose through the day and taking it with meals raises tolerance substantially, and is free. Yoghurt and fermented milk: traditional fermentation reduces lactose and supplies bacterial lactase, available anywhere milk is. Aged hard cheese is effectively lactose-free by the nature of cheesemaking. Gradual reintroduction to build colonic adaptation: regular small doses over two to three weeks measurably improve tolerance. Non-dairy calcium sources: fish with bones, calcium-set tofu, sesame, leafy greens.

Breastfeeding should be continued during infant gastroenteritis and not withheld for lactose intolerance; for older infants, continued feeding with lactose-containing milk is generally appropriate, since routine lactose-free formula is not required in most acute diarrhoea on WHO and standard guidance. Oral rehydration solution for the diarrhoea of secondary deficiency, at an indicative UNICEF price of about US$0.048 a sachet, October 2026.

The honest note: the simple means here is largely not treating it as a disease. The commercial lactose-free product category addresses a problem that dose adjustment and traditional fermentation already solve for most people.

**Gaps.** Symptom reporting correlates poorly with objective lactase status and with blinded challenge, so self-reported prevalence is unreliable and probably substantially overstates true intolerance. Breath hydrogen testing has imperfect sensitivity and specificity and no agreed protocol. The overlap with IBS and with fructan sensitivity is unresolved and clinically consequential. The long-term bone health consequences of unnecessary dairy avoidance are plausible and under-measured. Data from Africa and Asia on symptomatic as opposed to genetic intolerance are sparse. The degree and durability of colonic adaptation varies between individuals for unknown reasons.

---

## Dental caries and periodontal disease

**What it is.** In caries, bacteria ferment sugar into acid that dissolves tooth enamel, making holes. In periodontal disease, chronic inflammation of the gums and the bone holding the teeth loosens them and eventually loses them.

**Measured.** These are among the most prevalent diseases of any kind on earth, and the single largest block of untreated disease in the GBD.

Untreated caries in permanent teeth affects about 2.0 to 2.5 billion people and is consistently ranked first for prevalence of any condition in GBD. The WHO oral health fact sheet of 17 March 2025 names untreated caries in permanent teeth as the most common health condition on GBD 2021 data, but gives no prevalence figure for it anywhere on the page. Untreated caries in deciduous teeth affects about 510 to 530 million children.

Severe periodontitis affects about 1.0 to 1.1 billion people, about 19 to 20 per cent of adults globally; the WHO page gives more than 1 billion cases, with no year. Total edentulism affects about 350 to 400 million people, concentrated in older age; the WHO page gives edentulism prevalence of about 7 per cent among people aged 20 and over and 23 per cent among those aged 60 and over, with no year.

Oral conditions together affect about 3.5 billion people and cause roughly 18 to 19 million DALYs globally (WHO Global Oral Health Status Report 2022); the WHO oral health fact sheet gives nearly 3.7 billion people with oral diseases, with no year given. GBD 2023 Table 1 places oral disorders eleventh among YLD causes at 23.9 million (95 per cent UI 14.5 to 35.1). Separately, the WHO page gives about 1 billion people affected by oro-dental trauma with about 20 per cent prevalence in children up to twelve, which is a different metric and easily confused with the periodontal figure.

Deaths are negligible directly, though dental sepsis, Ludwig angina and noma cause some, especially in children in poor settings. Noma has a case fatality of about 90 per cent untreated and was added to the WHO neglected tropical diseases list in 2023; the WHO oral health page gives about 140,000 new noma cases a year, from 1998 estimates, fatal in 90 per cent of untreated cases, mostly in children aged two to six.

Caries begins in early childhood, with early childhood caries affecting a large share of preschool children in many countries; periodontitis prevalence rises with age, with severe disease peaking in the sixth and seventh decades. These are the diseases where socioeconomic gradients are steepest and least disguised. The burden is high everywhere, but the *untreated* burden is concentrated in low- and middle-income countries and in poor populations within rich countries. Oral disease is largely excluded from universal health coverage in most countries, so out-of-pocket payment dominates.

**Where it starts.** For caries, free sugars are the necessary dietary cause. Both amount and frequency of intake matter, and frequency may matter more. The dose-response is continuous with no threshold, which is the basis of the WHO recommendation of under 10 per cent, and conditionally under 5 per cent, of energy from free sugars. Historical evidence — Vipeholm, Hopewood House, wartime sugar rationing — and modern cohorts agree.

Then the cariogenic biofilm: *Streptococcus mutans*, *Lactobacillus*, *Actinomyces*, *Scardovia*. Fluoride exposure is protective. Saliva flow and buffering capacity matter, and xerostomia — from anticholinergics and antidepressants, Sjögren syndrome, or head and neck radiotherapy — is a strong risk factor. Enamel defects: molar incisor hypomineralisation, fluorosis, hypoplasia from early-life illness or preterm birth; tooth morphology and crowding. Socioeconomic deprivation is one of the strongest predictors, operating through diet, fluoride access and dental care access. Bottle-feeding with sweetened drinks and nocturnal bottle use cause early childhood caries. Twin studies estimate heritability of about 40 to 60 per cent for caries experience, much of it operating through saliva composition, enamel formation and taste preference, while the environmental cause, sugar, remains necessary.

For periodontal disease, a dysbiotic subgingival biofilm: *Porphyromonas gingivalis*, *Tannerella forsythia*, *Treponema denticola*, *Aggregatibacter actinomycetemcomitans*. Smoking is the strongest modifiable risk factor, roughly two to six times the risk, dose-dependently, and it impairs treatment response. Diabetes is bidirectional: it roughly doubles to triples periodontitis risk, and periodontitis worsens glycaemic control. Heritability is about 50 per cent for chronic and severe periodontitis from twin studies (Michalowicz). Then age, male sex, obesity, stress, poor oral hygiene, rheumatoid arthritis, immunosuppression and HIV, and specific neutrophil defects for the aggressive forms.

What is not known, for both conditions, is why individuals with similar sugar intake, hygiene and plaque differ so much in disease experience. Host susceptibility is clearly decisive and not predictable. Which specific microbial configurations tip into disease, and whether the dysbiosis is cause or consequence, is unresolved. The causal direction and magnitude of the periodontitis-cardiovascular and periodontitis-adverse pregnancy associations are contested: the associations are robust, but randomised periodontal treatment has not been shown to reduce cardiovascular events or preterm birth, which argues against simple causation or against treatment adequacy.

**Cure status.** Five strata, each with its own label.

Non-cavitated, white-spot caries lesion: CURABLE. Early white-spot lesions remineralise with fluoride and reduced sugar frequency, which is a genuine reversal of the lesion.

Cavitated caries lesion: CONTROLLABLE. The lost tooth substance does not regenerate. Restoration replaces it rather than removing the disease, and the restored tooth enters a repeat-restoration cycle.

The caries disease process: CONTROLLABLE. It is held by fluoride, sugar control and plaque control, and resumes when those stop.

Gingivitis: CURABLE, fully, by plaque control.

Periodontitis: CONTROLLABLE, not curable. Lost attachment and bone do not regenerate, except for limited regeneration in specific defect geometries. Treatment arrests progression and can produce substantial pocket reduction, but the condition requires lifelong maintenance, and without maintenance progression resumes.

**Prevention.** This is the area where prevention is strongest and most neglected.

Fluoride toothpaste at 1,000 to 1,500 ppm, twice daily: STRONG. Cochrane gives about a 24 per cent reduction in caries increment against non-fluoride toothpaste, as a prevented fraction, with greater effect at higher concentration and higher baseline risk. The WHO oral health fact sheet gives the same 1,000 to 1,500 ppm range. The single most cost-effective caries intervention in existence.

Water fluoridation: STRONG for effect, with a magnitude that is now smaller. Older studies showed about a 35 per cent caries reduction in children. The 2024 Cochrane update found that studies conducted since 1975 — that is, since fluoride toothpaste became widespread — show a much smaller benefit, on the order of 0.24 fewer decayed, missing or filled deciduous teeth, a reduction that is real and modest. Both figures are printed. This is an honest revision: fluoridation's marginal benefit has fallen because toothpaste now delivers most of the effect. It remains equitable, reaching those who do not brush, and cheap, and the debate about it is now about marginal benefit rather than about whether fluoride works.

Reducing free sugars to under 10 per cent, ideally under 5 per cent, of energy: STRONG on dose-response evidence. Sugar-sweetened beverage taxation has demonstrated consumption reductions in Mexico, the United Kingdom and elsewhere: MODERATE at population level.

Fluoride varnish, two to four times a year in children: STRONG, with about a 43 per cent reduction in caries increment in permanent teeth as a Cochrane prevented fraction. Pit and fissure sealants: STRONG, substantially reducing occlusal caries in permanent molars against no sealant. Silver diamine fluoride: STRONG for arresting existing caries, with about 60 to 80 per cent arrest rates, applied in seconds with no drilling, no electricity and no anaesthetic. Supervised toothbrushing programmes in schools and nurseries: STRONG and highly cost-effective in deprived populations. Not putting sugary drinks in infant bottles, and no nocturnal bottle: STRONG.

For periodontal disease: smoking cessation: STRONG. Daily plaque removal, brushing with interdental cleaning: STRONG for gingivitis prevention. Diabetes control: MODERATE. Professional maintenance after treatment: STRONG. Xylitol, chlorhexidine and probiotics: CONTESTED.

**Treatment.** For caries: fluoride in toothpaste, varnish, gel or mouthrinse, for prevention and for remineralising early lesions. Sodium fluoride and fluoride toothpaste are on the WHO EML; off-patent; toothpaste a few to tens of US dollars a year — the cheapest effective intervention in this entire chapter.

Silver diamine fluoride at 38 per cent arrests caries without drilling, with 60 to 80 per cent arrest, and stains the lesion black; a few to a few US dollars per application. Transformative for settings without dental chairs, electricity or anaesthesia, and for young children and the frail elderly.

Atraumatic restorative treatment uses hand instruments and glass ionomer cement, with no electricity and no drill; survival rates for single-surface restorations are good, above about 85 per cent at two to three years, and it is WHO-endorsed for low-resource settings.

Conventional restoration uses amalgam, which is durable and cheap and being phased down under the Minamata Convention, or composite or glass ionomer. The Minamata phase-down creates a real access problem, because composite needs more equipment, skill and time. The Hall technique for primary molars seals a stainless steel crown over the carious tooth without removing decay or giving anaesthetic, with high success in trials and excellent results for children. Pulpotomy, root canal treatment or extraction for pulpal involvement.

Analgesia and antibiotics for dental abscess — but antibiotics do not treat the cause, and drainage or extraction is required. Amoxicillin EML yes, with periapical abscess without sinus a listed indication; off-patent; about US$1 to 3 a course, and the indicative UNICEF price for amoxicillin 250 mg dispersible tablets is US$0.054 per tablet, October 2026. Metronidazole EML yes.

For periodontal disease: subgingival instrumentation, scaling and root planing, is the foundation of treatment, producing pocket depth reduction of about 1 to 2 mm with attachment gain, with greater effect in deeper pockets†. It requires instruments and training, not electricity. Oral hygiene instruction and plaque control, without which instrumentation fails. Smoking cessation, which improves treatment response measurably. Periodontal maintenance every three to six months prevents recurrence, and the evidence for maintenance is as strong as for the initial treatment. Adjunctive systemic antibiotics, amoxicillin with metronidazole, give modest additional benefit in severe and aggressive disease, with routine use discouraged for resistance reasons. Periodontal surgery and regenerative procedures for residual deep pockets and specific defects.

Periodontal treatment improves glycaemic control in diabetes: HbA1c reduction of roughly 0.3 to 0.4 percentage points at three to six months in meta-analyses, comparable to adding a second oral hypoglycaemic agent. A genuine cross-disease benefit. Dentures, bridges and implants for tooth replacement are the expensive end, and where most dental expenditure in rich countries actually goes.

**Simple means.** This is the chapter's clearest example of simple means doing nearly all the work.

Brushing twice daily with fluoride toothpaste gives about a 24 per cent caries reduction (Cochrane) at a few to tens of US dollars a year, and needs a brush, paste and water. The highest benefit-to-cost ratio here. Not rinsing after brushing — spit, don't rinse — retains fluoride, costs nothing and gives measurable additional benefit. Reducing sugar frequency, not just amount: fewer sugar exposures a day, free. Water instead of sugary drinks.

Interdental cleaning with floss or interdental brushes, and interdental brushes are more effective than floss where spaces allow. Silver diamine fluoride: pennies, seconds, no drill, no power, 60 to 80 per cent arrest. Atraumatic restorative treatment with hand instruments and glass ionomer only. Chewing sugar-free gum after meals, for saliva stimulation, gives modest benefit. A chewing stick, miswak or neem, gives plaque removal comparable to a toothbrush in several comparative studies and is used by hundreds of millions: a twig. Supervised school toothbrushing needs only brushes, paste and a sink. Breastfeeding rather than a bottle with sweetened fluids, and no bottle in bed. Smoking cessation for periodontitis, the largest single modifiable effect. Scaling with hand instruments, effective without electricity.

The honest statement: a cavitated tooth needs restoration or extraction, which needs a trained operator and instruments. But the disease is preventable almost entirely by a brush, fluoride paste and less sugar — which makes the global burden of 2 to 2.5 billion untreated caries a failure of distribution and policy, not of knowledge.

**Gaps.** Oral health is excluded from most universal health coverage schemes and from most health surveys, so burden data are weaker than the prevalence figures suggest, and are largely based on clinical examination with varying diagnostic thresholds. The WHO oral health fact sheet names untreated caries the most common health condition on earth and prints no number for it. The 2024 Cochrane revision of water fluoridation's effect size is contested in its interpretation, and the contemporary marginal benefit is genuinely uncertain. Whether periodontal treatment reduces cardiovascular events or adverse pregnancy outcomes is unresolved: the observational association is strong and the randomised evidence is null or inconclusive. The Minamata amalgam phase-down's effect on access and on caries outcomes in poor settings is unquantified. Noma is still barely counted. Dental workforce distribution is extremely unequal, and the evidence base for task-sharing — silver diamine fluoride, atraumatic restorative treatment, the Hall technique — while promising, is thinner than it should be. Caries heritability estimates vary widely between twin studies.

## Oesophageal varices

**What it is.** When the liver is scarred, blood backs up and forces open veins at the lower end of the oesophagus. These thin-walled veins can burst and bleed catastrophically.

**Measured.** Varices are present in about 30 to 40 per cent of people with compensated cirrhosis and about 60 to 85 per cent with decompensated cirrhosis†. Incidence of new varices is about 5 to 8 per cent a year in cirrhotic patients without them, with about 10 to 12 per cent a year progressing from small to large varices†. Bleeding risk is about 10 to 15 per cent a year overall†, higher with large varices, red wale marks and Child-Pugh C.

Six-week mortality after a variceal bleed is about 15 to 25 per cent, down from about 40 to 50 per cent several decades ago — a genuine improvement attributable to a defined care bundle. Rebleeding without secondary prophylaxis is about 60 per cent within one to two years; with combination prophylaxis about 15 to 25 per cent. It is not a separate GBD cause and is counted within cirrhosis. Geography follows cirrhosis, concentrated where hepatitis B, hepatitis C and alcohol burden is high. In schistosomiasis-endemic areas, varices occur with preserved liver function, a distinct and more survivable pattern.

**Where it starts.** Portal hypertension is the necessary cause. Varices form when the hepatic venous pressure gradient exceeds 10 mmHg, and bleed above 12 mmHg. These thresholds are well established and quantitative.

Cirrhosis of any cause, and also non-cirrhotic portal hypertension: schistosomiasis, globally a major cause, portal vein thrombosis, Budd-Chiari syndrome, idiopathic non-cirrhotic portal hypertension, congenital hepatic fibrosis. Risk factors for bleeding specifically: large variceal size, red wale marks or cherry-red spots on endoscopy, Child-Pugh class B or C, gradient above 12 mmHg, continued alcohol use, bacterial infection as a recognised trigger, and raised intra-abdominal pressure from tense ascites.

What is not known is why some patients with high portal pressure never bleed and others bleed at modest gradients. Variceal wall tension depends on size, wall thickness and pressure in ways not measurable clinically. The gradient is the best predictor but is invasive and rarely measured outside specialist centres, so prediction in practice is crude. Why non-selective beta-blocker response varies so much between individuals is unexplained.

**Cure status.** CONTROLLABLE. Varices themselves can be obliterated by repeated endoscopic band ligation, and bleeding can be prevented and treated effectively, but the underlying portal hypertension persists, so varices recur unless portal pressure falls. CURABLE indirectly, by removing the cause: hepatitis C cure, hepatitis B suppression or alcohol abstinence can lower portal pressure enough that varices regress, and this is documented. CURABLE definitively by liver transplantation. TIPS decompresses the portal system effectively at the cost of encephalopathy in a substantial minority.

**Prevention.** Three distinct levels, which must be kept separate.

Preventing varices forming, pre-primary prophylaxis: CONTESTED. Beta-blockers do not prevent the development of varices in patients who do not yet have them (Groszmann, *NEJM* 2005) — a clear negative trial. Treating the underlying liver disease is what works.

Preventing a first bleed, primary prophylaxis, for medium and large varices: STRONG. Non-selective beta-blockers — propranolol, nadolol, and carvedilol, now preferred because it lowers the gradient more — reduce first bleeding from about 25 per cent to about 15 per cent, relative risk about 0.5 to 0.6 in meta-analyses. Endoscopic band ligation is comparably effective, with the choice depending on availability, tolerance and patient preference. Carvedilol has been shown to reduce decompensation and improve survival in compensated cirrhosis with clinically significant portal hypertension (PREDESCI, *Lancet* 2019, and individual-patient meta-analyses).

Preventing rebleeding, secondary prophylaxis: STRONG. A non-selective beta-blocker combined with band ligation is superior to either alone, reducing rebleeding from about 60 per cent to about 15 to 25 per cent.

Antibiotic prophylaxis during acute bleeding: STRONG. It reduces infection, rebleeding and mortality, with ceftriaxone or norfloxacin. One of the clearest mortality benefits in the bundle. Alcohol abstinence and treating viral hepatitis: STRONG. Screening endoscopy at cirrhosis

diagnosis, or non-invasive triage: Baveno VII allows avoiding endoscopy where liver stiffness is below 20 kPa and platelets above 150,000, a useful resource-sparing rule.

**Treatment.** Acute variceal bleeding is a defined bundle, each element evidence-based.

Resuscitation with restrictive transfusion, to a haemoglobin target of 7 to 8 g/dL and not higher. Villanueva (*NEJM* 2013, 921 patients) found restrictive transfusion reduced mortality, hazard ratio 0.55, and rebleeding against liberal transfusion, with the benefit particularly clear in cirrhosis. Over-transfusion raises portal pressure and worsens bleeding — an important counter-intuitive point.

A vasoactive drug immediately, before endoscopy, for two to five days: terlipressin, somatostatin or octreotide, which reduce bleeding and improve haemostasis. Terlipressin EML yes; off-patent; tens to hundreds of US dollars a course; cheaper and more available than octreotide in many countries, and carrying hyponatraemia and ischaemic risks. Octreotide off-patent; hundreds of US dollars a course.

Antibiotic prophylaxis with ceftriaxone 1 g daily or norfloxacin reduces mortality. Ceftriaxone EML yes; off-patent; a few US dollars a course. Extremely cheap for a mortality benefit.

Endoscopic band ligation within twelve hours is the definitive haemostatic procedure and is superior to sclerotherapy, with less stricture and fewer complications; banding is now standard and sclerotherapy is reserved for where banding is unavailable. A proton pump inhibitor as a short course after banding reduces ulceration.

Early or pre-emptive TIPS within 72 hours in high-risk patients — Child-Pugh C, or B with active bleeding — improved survival against standard therapy (García-Pagán, *NEJM* 2010), and is under-used relative to the evidence. Balloon tamponade with a Sengstaken-Blakemore or Minnesota tube is a mechanical rescue bridge for uncontrolled bleeding: cheap, but requiring airway protection and carrying necrosis and aspiration risk if used beyond 24 hours. Self-expanding oesophageal metal stents are an alternative bridge with fewer complications. Lactulose to prevent post-bleed encephalopathy, since blood in the gut is a potent precipitant. And avoid over-resuscitation with saline, which raises portal pressure and worsens ascites.

Gastric varices differ: cyanoacrylate glue injection or balloon-occluded retrograde transvenous obliteration rather than banding, with TIPS for IGV1.

Longer term: a beta-blocker, carvedilol preferred, with a band ligation programme until varices are obliterated, then surveillance. Treating the underlying liver disease is the only intervention that lowers portal pressure durably. Transplantation for end-stage disease.

**Simple means.** Propranolol or carvedilol is the single most important preventive drug: off-patent, EML-listed, a few to tens of US dollars a patient-year, and requiring only a pulse check to titrate, to a heart rate reduction of about 25 per cent or 55 to 60 bpm. No endoscopy and no monitoring equipment. That is the key fact for low-resource settings: primary prophylaxis with a cheap oral tablet achieves much of what an endoscopy programme achieves.

Ceftriaxone during a bleed, at a few US dollars reduces mortality. Restrictive transfusion is a simple means in the sense of withholding an expensive resource, which improves survival and conserves blood supply. Balloon tamponade is a rubber tube that buys hours of life where no endoscopy exists. Alcohol abstinence lowers portal pressure. Salt restriction for ascites reduces intra-abdominal pressure. Avoiding NSAIDs, for bleeding risk, and avoiding over-transfusion. Recognition and transport is the main determinant of survival where endoscopy is distant.

The honest limit: active variceal bleeding needs endoscopy, or at minimum tamponade. There is no simple substitute for haemostasis.

**Gaps.** The hepatic venous pressure gradient, the best predictor of bleeding and treatment response, is measured in very few centres, so risk stratification in practice is coarse. Non-invasive substitutes — elastography, platelet count, the Baveno criteria — are validated mainly in high-income cohorts and perform less well in hepatitis B and in schistosomiasis-related portal hypertension. Carvedilol's superiority is established for gradient reduction, and long-term head-to-head outcome data against propranolol plus banding are limited. Early TIPS is under-used and access is extremely unequal. Gastric variceal management rests on weaker evidence than oesophageal. Terlipressin availability and price vary enormously and it

is unavailable in some markets, including, historically, the United States. Burden is invisible in GBD because it sits inside cirrhosis.

---

## Gastrointestinal bleeding

**What it is.** Bleeding anywhere from the gullet to the anus. Upper bleeding shows as vomited blood or black tarry stool; lower bleeding as fresh blood. It ranges from trivial to immediately fatal.

**Measured.** Upper gastrointestinal bleeding incidence is about 40 to 150 per 100,000 a year and falling in most high-income countries as *H. pylori* prevalence and ulcer disease decline. Lower gastrointestinal bleeding is about 20 to 35 per 100,000 a year and rising with ageing and anticoagulant and antiplatelet use.

Mortality from upper gastrointestinal bleeding is about 2 to 10 per cent in modern series, and notably most deaths are from comorbidity and multi-organ failure rather than exsanguination. Variceal bleeding mortality is higher, about 15 to 25 per cent at six weeks†.

GBD 2019 gave peptic ulcer disease, the main upper gastrointestinal bleeding cause, about 236,000 deaths†. Bleeding as such is not a separate GBD cause and its burden is distributed across ulcer, cirrhosis, neoplasm, haemorrhoid and diverticular categories. Incidence rises steeply with age, and the median patient is now elderly with multiple comorbidities and on antithrombotic drugs; that demographic shift is the dominant trend in the field. Male predominance for ulcer bleeding.

**Where it starts.** Upper gastrointestinal causes: peptic ulcer at about 30 to 50 per cent and falling; oesophageal and gastric varices at about 10 to 20 per cent†; Mallory-Weiss tear; oesophagitis; gastroduodenal erosions; malignancy; Dieulafoy lesion; angiodysplasia; and aorto-enteric fistula, which is rare and lethal.

Lower gastrointestinal causes: diverticular bleeding at about 20 to 40 per cent†, the commonest, and arterial, from the vasa recta over the dome of a diverticulum, as described in the diverticular entry; then angiodysplasia, haemorrhoids, ischaemic colitis, colorectal neoplasm, post-polypectomy bleeding, inflammatory bowel disease, infectious colitis and radiation proctitis.

Risk factors. NSAIDs and aspirin raise ulcer bleeding risk roughly fourfold, dose-dependently; and for diverticular bleeding specifically, regular aspirin gives a hazard ratio of 1.70 (95 per cent CI 1.21 to 2.39) and non-aspirin NSAIDs 1.74 (1.15 to 2.64) (Strate 2011). *H. pylori*, whose eradication reduces rebleeding dramatically. Anticoagulants — warfarin and the direct oral anticoagulants — and antiplatelets, with dual therapy multiplying risk; among the direct oral anticoagulants, rivaroxaban and high-dose dabigatran carry higher gastrointestinal bleeding risk than apixaban, which is relevant to drug choice. SSRIs, through platelet serotonin depletion; corticosteroids with NSAIDs. Cirrhosis and portal hypertension; chronic kidney disease, through uraemic platelet dysfunction and angiodysplasia; aortic stenosis, in Heyde syndrome; prior bleeding; older age.

What is not known is which ulcers or diverticula will bleed. Why angiodysplasia forms and recurs is poorly understood, and it is the most frustrating recurrent cause. Optimal timing of antithrombotic resumption after bleeding is genuinely uncertain, trading rebleeding against thrombosis. The reason most deaths are non-haemorrhagic is understood in outline, through comorbidity and the stress of bleeding, but not well modelled.

**Cure status.** Four strata.

The individual bleeding episode, treated: CURABLE — endoscopic haemostasis with acid suppression stops bleeding and heals the lesion.

The episode without intervention: SELF-LIMITING. About 80 per cent of upper gastrointestinal bleeds and about 75 to 85 per cent of lower bleeds stop spontaneously.

The cause, where removable: CURABLE. *H. pylori* eradication cures the bleeding ulcer diathesis, with rebleeding falling from about 20 to 25 per cent a year to about 1 to 2 per cent — one of the highest-value cheap cures in acute medicine. Stopping an NSAID cures NSAID-related bleeding. Resecting a bleeding diverticular segment or tumour is curative.

Angiodysplasia, and portal hypertensive bleeding while the liver disease persists: RELIEF ONLY, and recurrent.

**Prevention.** *H. pylori* test and eradicate after a bleeding ulcer: STRONG. It reduces rebleeding from about 20 to 25 per cent a year to about 1 to 2 per cent, is superior to maintenance acid suppression, and costs a few to tens of US dollars once rather than indefinitely. Among the clearest cost-effective preventives in this book.

PPI co-prescription with NSAIDs or aspirin in at-risk patients: STRONG, substantially reducing ulcer complications; omeprazole EML yes, a few to tens of US dollars a year. Avoiding unnecessary NSAIDs: STRONG. Choosing apixaban over rivaroxaban or dabigatran where gastrointestinal bleeding risk is high: MODERATE. Avoiding unnecessary dual antiplatelet therapy and shortening its duration: MODERATE. Variceal prophylaxis with non-selective beta-blockers and banding: STRONG. Antibiotic prophylaxis in cirrhotic patients with bleeding: STRONG, reducing mortality.

Stress ulcer prophylaxis in intensive care: indicated for specific high-risk patients, on mechanical ventilation or with coagulopathy, but CONTESTED for routine use. The SUP-ICU trial (*NEJM* 2018) found pantoprazole reduced clinically important gastrointestinal bleeding without a mortality benefit, and there is a pneumonia and *C. difficile* trade-off. Overprescription is endemic.

**Treatment.** Resuscitation with restrictive transfusion, to a haemoglobin target of 7 to 8 g/dL. Villanueva (*NEJM* 2013) found a restrictive strategy reduced mortality, hazard ratio 0.55, and rebleeding. Over-transfusion is harmful, especially in variceal bleeding.

Risk stratification: a Glasgow-Blatchford score of 0 to 1 identifies patients safe for outpatient management, which is a major resource saving and is validated. Clinical scores need no technology.

High-dose intravenous PPI after endoscopic haemostasis of a high-risk ulcer reduces rebleeding, the need for surgery and mortality in high-risk lesions. Pre-endoscopy PPI reduces high-risk stigmata without reducing mortality. Omeprazole and pantoprazole EML yes — verified for omeprazole, which lists gastrointestinal bleeding as an indication; off-patent; a course costs a few dollars.

Endoscopy within 24 hours with haemostasis: injection plus a second modality, clips or thermal coagulation, since injection alone is inadequate. Over-the-scope clips and haemostatic powders for refractory bleeding. Very early endoscopy, under six hours, does not improve outcomes over 24 hours in high-risk patients (Lau, *NEJM* 2020) — a useful negative finding. Band ligation, vasoactive drugs and antibiotics for variceal bleeding, as in the varices entry.

*H. pylori* testing and eradication, noting that testing during acute bleeding has high false-negative rates, so retest or treat empirically after recovery. A frequently missed step with large consequences.

Tranexamic acid: do not use. The HALT-IT trial (*Lancet* 2020, 12,009 patients) found tranexamic acid did not reduce death from gastrointestinal bleeding and increased venous thromboembolic events, 0.8 against 0.4 per cent, and seizures. A clear, large, negative trial that reversed widespread practice, and worth stating plainly because the drug is cheap and was used freely.

Interventional radiology embolisation for refractory bleeding, and surgery as a last resort. For lower gastrointestinal bleeding: resuscitation, CT angiography for localisation in active bleeding, colonoscopy with clipping, adrenaline or thermal therapy, embolisation, segmental resection. Reversal of anticoagulation where appropriate — vitamin K and prothrombin complex concentrate for warfarin; idarucizumab for dabigatran and andexanet alfa for factor Xa inhibitors, both very expensive and of debated net benefit. Resume antithrombotics early once haemostasis is secure, since the thrombotic risk of prolonged interruption generally exceeds the rebleeding risk. Capsule endoscopy and enteroscopy for small bowel or obscure bleeding, with thalidomide and octreotide having evidence in refractory angiodysplasia. Iron replacement, oral or intravenous, for the resulting anaemia; oral ferrous salts EML yes, off-patent, about US$2 to 15 a year, with an indicative UNICEF price for iron 60 mg tablets of US$1.43 on one catalogue page and US$1.60 on another per bottle of 100, about US$0.0143 to 0.0160 a tablet, October 2026.

**Simple means.** Restrictive transfusion: withholding blood improves survival and conserves a scarce resource — the clearest do-less intervention here. Glasgow-Blatchford scoring is pen and paper and safely identifies patients needing no admission. Stopping NSAIDs and unnecessary antithrombotics. *H. pylori* eradication at a few to tens of US dollars once converts a recurrent life-threatening condition into a cured one: the highest-value intervention in this entry. Oral rehydration and oral iron for stable patients with slow blood loss, at cents, and adequate for most chronic occult bleeding. Positioning and airway protection, and a nasogastric tube where needed. Not giving tranexamic acid — a cheap drug whose omission is now evidence-based (HALT-IT). Early recognition and transport, the dominant survival determinant where endoscopy is distant.

The honest limit: major acute bleeding needs endoscopy, transfusion capability and sometimes surgery or radiology. Simple means cover prevention, triage, resuscitation and the chronic anaemia, not haemostasis.

**Gaps.** Gastrointestinal bleeding is not a GBD cause, so global burden is genuinely unknown and almost certainly underestimated where endoscopy is unavailable; the case-fatality difference between settings is largely unmeasured. Optimal timing of antithrombotic resumption after bleeding is uncertain and guidelines differ. Management of obscure small bowel bleeding and recurrent angiodysplasia rests on weak evidence. The role of direct-oral-anticoagulant reversal agents is debated relative to their very high cost. Stress ulcer prophylaxis indications remain contested. *H. pylori* testing during acute bleeding is unreliable and the failure to retest is a known, unquantified care gap. Risk scores are validated mainly in high-income populations.

# ICD-11 Chapter 15 — Diseases of the musculoskeletal system or connective tissue

---

## A note on the headline figure for this chapter

The WHO musculoskeletal health fact sheet, printed 14 July 2022 on GBD 2019 data, contradicts itself, and both numbers are printed here because neither can be ruled out from the page.

The headline figure is approximately 1.71 billion people with musculoskeletal conditions. The page also gives condition-by-condition prevalent cases: low back pain 570 million, osteoarthritis 528 million, fractures 440 million, neck pain 222 million, amputations 180 million, gout 54 million, rheumatoid arthritis 18 million, and other musculoskeletal conditions 453 million. Those component figures total about 2.5 billion.

The page never states that people can have more than one condition, so the headline of 1.71 billion and the component total of about 2.5 billion stand unreconciled on the same page. The gap is about 800 million people. If comorbidity is the explanation, the page does not say so. Both figures are printed, and the discrepancy is named.

The same page gives musculoskeletal YLDs of about 149 million, which it calls 17 per cent of all YLDs worldwide, and regional totals of 441 million for high-income countries, 427 million for the Western Pacific and 369 million for South-East Asia. It also notes that about two-thirds of adults needing rehabilitation have musculoskeletal conditions.

Note also that the fact sheet's low back pain prevalence of 570 million (GBD 2019) differs from the 619 million on the WHO low back pain fact sheet (2020 data) and in the GBD 2021 condition paper. Both are printed in their entries. They are different GBD cycles, which is the likely explanation, and no page states it.

---

### Low back pain

*The single largest cause of years lived with disability in the world. The figures are given in full.*

**What it is.** Pain in the lower back, with or without pain running down the leg. In the great majority no specific structural cause is identifiable, and imaging findings correlate poorly with pain. It is usually episodic and recurrent.

**Measured.** Low back pain is the leading cause of years lived with disability globally and has been since GBD began measuring it. The authoritative condition-specific analysis is Ferreira, de Luca, Haile, Steinmetz, Culbreth and colleagues, "Global, regional, and national burden of low back pain, 1990–2020, its attributable risk factors, and projections to 2050: a systematic analysis of the Global Burden of Disease Study 2021", *Lancet Rheumatology* 2023;5(6):e316–e329.

Prevalent cases in 2020: 619 million (95 per cent UI 554 to 694) people globally.

Years lived with disability in 2020: 69.0 million (95 per cent UI 47.9 to 88.9), up from 43.4 million (30.5 to 57.9) in 1990.

Low back pain accounted for 8.1 per cent of all-cause YLDs in 2020, up from 7.7 per cent in 1990, and is ranked first among all causes of YLDs.

Age-standardised prevalence in 2020: 7,460 per 100,000 (6,690 to 8,370), a 10.4 per cent decrease (−10.9 to −10.0) from 8,330 per 100,000 in 1990. The age-standardised rate is falling while absolute numbers rise, and the increase is driven by population growth and ageing. Age-standardised YLD rate in 2020: 832 per 100,000 (578 to 1,070), down 10.5 per cent since 1990.

Projection to 2050: 843 million cases (759 to 933), a 36.4 per cent increase (29.9 to 43.2) over 2020.

Deaths: none. Low back pain causes no direct mortality, and its entire burden is disability. That is why it dominates YLD rankings while being absent from every death ranking.

Prevalence is higher in females at every age, with the gap widening after 75: age-standardised prevalence 9,330 per 100,000 (8,370 to 10,500) in females against 5,520 (4,930 to 6,190) in males. Prevalence and YLDs rise with age, peaking around 85, with the highest YLD rate in the 80 to 84 age group at 2,440 per 100,000 (1,470 to 3,490). The older belief that low back pain peaks in middle age and declines is not supported; burden continues rising into old age.

Attributable burden in 2020: 38.8 per cent (28.7 to 47.0) of low back pain YLDs were attributed to the three modelled risk factors — occupational ergonomic factors at 22.0 per cent, smoking at 12.5 per cent, and high BMI at 11.5 per cent. The remaining 61 per cent or so is not attributable to any modelled risk factor.

The WHO low back pain fact sheet, printed 19 June 2023, carries 619 million people affected in 2020, and 843 million cases by 2050; it names low back pain the single leading cause of disability worldwide, puts non-specific low back pain at about 90 per cent of cases, and defines episodes as acute under six weeks, sub-acute six to twelve weeks and chronic over twelve weeks. The page also contradicts itself on the age of greatest prevalence: its Key Facts say prevalence increases with age up to 80 years, while its body says prevalence and disability are greatest among people aged 80 to 85. Both are printed. The GBD 2021 condition paper's peak around 85, and highest YLD rate at 80 to 84, is consistent with the body rather than with the Key Facts.

Geography: highest age-standardised prevalence in Central and Eastern Europe and North Africa and the Middle East, lowest in parts of Asia and Africa, though measurement differences contribute; the largest absolute burden is in Asia by population. Low back pain is also the leading cause of work absence and early retirement in most countries studied, with direct and indirect economic cost estimated in the hundreds of billions of dollars a year in the United States alone.

GBD 2023 Table 1 confirms the rank and gives low back pain 70.4 million YLDs (95 per cent UI 49.7 to 95.1), rank one, and 70.4 million DALYs, rank nine. Both the GBD 2021 figure of 69.0 million and the GBD 2023 figure of 70.4 million are printed, with their cycles named.

**Where it starts.** Occupational ergonomic exposure accounts for 22.0 per cent of attributable YLDs: heavy lifting, awkward and sustained postures, whole-body vibration in drivers and operators. Smoking accounts for 12.5 per cent, dose-dependently. High BMI accounts for 11.5 per cent, dose-dependently. A previous episode of low back pain is the strongest single predictor of a future episode.

Psychosocial factors are powerful and consistently outperform structural findings in predicting chronicity and disability: depression, anxiety, fear-avoidance beliefs, pain catastrophising, job dissatisfaction, low social support, and low expectation of recovery. These predict who moves from acute to chronic disability far better than any imaging finding. That is the single most robust and most clinically ignored finding in the field.

Heritability is substantial. Twin studies estimate about 30 to 45 per cent for low back pain generally and about 65 to 75 per cent for lumbar disc degeneration on imaging (Sambrook, *Arthritis and Rheumatism* 1999; Battié). Genetic factors explain more of disc degeneration

than occupational loading does — a reversal of the traditional wear-and-tear model. GWAS has found loci including *SOX5*, *CHST3* and *SPOCK2*.

Imaging findings are common in people without pain, and this is the crucial negative finding. In asymptomatic adults, disc degeneration is present in about 37 per cent at age 20 and about 96 per cent at 80; disc bulges in about 30 per cent at 20 and about 84 per cent at 80; disc protrusions in about 29 per cent at 20 and about 43 per cent at 80 (Brinjikji, *AJNR* 2015, systematic review of imaging in asymptomatic populations). Degenerative findings are therefore largely age-normal, and their presence does not establish them as the cause of pain. This underpins the recommendation against routine imaging.

Specific identifiable causes account for only about 5 to 10 per cent†: vertebral fracture, malignancy, infection, axial spondyloarthritis, cauda equina syndrome. Radicular pain or sciatica from disc herniation is a distinct, identifiable minority.

What is not known is the cause of pain in the 90 to 95 per cent labelled non-specific†. That is the central fact: the world's leading cause of disability has no established pathoanatomical explanation in most cases. Which structures generate the pain — disc, facet joint, muscle, nerve, central sensitisation — cannot be reliably determined in the individual. Why identical imaging produces pain in one person and not another is unexplained. Why age-standardised rates are falling is not explained. Whether the condition is primarily nociceptive, neuropathic or nociplastic in most chronic cases is unresolved.

**Cure status.** Acute episodes: SELF-LIMITING. Chronic low back pain, beyond twelve weeks: RELIEF ONLY. Both halves matter.

Acute low back pain largely resolves: substantial improvement in pain and disability occurs within about six weeks in most people, with the steepest improvement in the first two weeks. But recurrence is the rule and not the exception, with roughly 60 to 70 per cent having a recurrence within twelve months†. The older claim that 90 per cent recover within six weeks is misleading, because it conflates improvement with cure and ignores recurrence.

Chronic low back pain is RELIEF ONLY. No treatment reliably cures it. All established treatments — exercise, psychological therapy, manual therapy, drugs, surgery — produce small to moderate average effects on pain and function, typically 5 to 15 points on a 100-point scale against control, often not sustained beyond six to twelve months. That is the evidence base, and it is stated plainly rather than disguised.

Sciatica from disc herniation is largely SELF-LIMITING: most resolve over weeks to months as the herniation resorbs, and surgery accelerates relief while one- and two-year outcomes converge with conservative management (SPORT and others).

CURABLE only for the small specific fraction: infection, by antibiotics; tumour; fracture stabilisation; cauda equina decompression.

**Prevention.** One clear winner, and a number of popular measures that do not work.

Exercise: STRONG, and the only consistently effective prevention. Exercise alone, or exercise with education, reduces the risk of a low back pain episode by roughly 35 to 45 per cent, pooled relative risk about 0.55 to 0.65 for exercise plus education (Steffens, *JAMA Internal Medicine* 2016, systematic review and meta-analysis of 23 trials). The effect wanes when exercise stops, so it requires continuation. No particular exercise type is clearly superior.

Education alone: WEAK, effectively ineffective. Education without exercise does not prevent episodes. Back belts and lumbar supports: CONTESTED and ineffective for prevention, with no demonstrated benefit in trials. Shoe insoles: ineffective for prevention.

Ergonomic interventions and lifting training alone: WEAK and CONTESTED. "Lift with your knees" training in isolation has repeatedly failed to prevent back pain in trials, which is surprising given the occupational attributable fraction. Comprehensive workplace programmes that include exercise and organisational change do better.

Smoking cessation: MODERATE, on the 12.5 per cent attributable fraction. Weight management: MODERATE, on the 11.5 per cent attributable fraction. Reducing occupational heavy lifting, vibration and awkward posture exposure: MODERATE — the 22.0 per cent attributable fraction makes this important at population level, though individual-level trial evidence for specific interventions is weak. Avoiding bed rest and staying active during an episode: STRONG for preventing chronicity. Addressing fear-avoidance and catastrophis-

ing early: MODERATE for preventing progression to chronic disability. Mattress firmness: WEAK, with medium-firm performing slightly better than firm in limited trials.

**Treatment.** Ordered by evidence. The evidence favours non-drug treatment, and this has been the consistent direction of guidelines — NICE NG59, the American College of Physicians, the *Lancet* Low Back Pain series of 2018 — for a decade.

Non-pharmacological, first line. Exercise therapy is the best-supported treatment for chronic low back pain, with a moderate effect on pain and function against no treatment, and no single type — motor control, Pilates, yoga, aerobic, strengthening, McKenzie, aquatic — clearly superior, so patient preference and adherence should drive the choice. Effect sizes are modest, roughly 10 to 15 points out of 100 for pain in the better trials. The cost is a therapist's time, or free if self-directed.

Education, reassurance and advice to remain active reduces disability and healthcare use; bed rest is harmful. Cognitive behavioural therapy, mindfulness-based stress reduction and cognitive functional therapy are effective for chronic low back pain, with effects comparable to or exceeding drug therapy and better maintained. The RESTORE trial (*Lancet* 2023, 492 patients) found cognitive functional therapy produced clinically meaningful improvements in activity limitation against usual care, sustained at 52 weeks — among the larger effects demonstrated for any intervention in chronic low back pain.

Multidisciplinary biopsychosocial rehabilitation, for chronic disabling pain, is better than usual care and than physical treatment alone on pain and disability (Cochrane), and is resource-intensive. Manual therapy and spinal manipulation give a small short-term benefit comparable to other active treatments, reasonable as an adjunct to exercise rather than a stand-alone long-term strategy. Massage, acupuncture and heat give small short-term benefits at low risk; acupuncture's effect over sham is small and contested.

Pharmacological, and the comparative evidence against the drugs is the important part.

NSAIDs are the first-line drug. The effect against placebo is small: roughly 6 to 10 points on a 100-point pain scale, with a number needed to treat of about 6 to 9 for meaningful relief, plus gastrointestinal, renal and cardiovascular risks. Off-patent, EML-listed, a few to tens of US dollars a patient-year.

Paracetamol is not effective for low back pain. The PACE trial (Williams, *Lancet* 2014, 1,643 patients with acute low back pain) found paracetamol no better than placebo for time to recovery, with a median of 17 days in both groups, and no better for pain, disability, function, sleep or quality of life. A clear, large, negative trial that changed guidelines, and paracetamol was subsequently removed as a recommended first-line agent for low back pain in NICE NG59. It is still widely prescribed.

Muscle relaxants, short-term for acute pain, give a small benefit with sedation; benzodiazepines are not recommended. Duloxetine gives modest benefit in chronic low back pain; off-patent, tens to hundreds of US dollars a year.

Opioids are not recommended. The SPACE trial (Krebs, *JAMA* 2018, 240 patients with chronic back, hip or knee pain) found opioids were not superior to non-opioid analgesics for pain-related function over twelve months, and pain intensity was significantly worse in the opioid group, with more adverse effects. The OPAL trial (*Lancet* 2023, 347 patients with acute low back or neck pain) found opioids no better than placebo at six weeks, with worse pain at one year and more opioid misuse risk. Two good trials, both negative. Opioids should not be used for low back pain.

Gabapentinoids are not effective for non-radicular low back pain, and the evidence for sciatica is also negative; they are widely misprescribed. Systemic corticosteroids are not effective for non-radicular low back pain. Antibiotics for Modic changes is a contested and currently unsupported approach.

Interventional and surgical. Epidural corticosteroid injection gives short-term relief of radicular pain only, with no benefit for non-specific low back pain and no effect on long-term outcome or surgery rates. Radiofrequency denervation of facet joints is contested; the large MINT trials (*JAMA* 2017) found no clinically important benefit added to exercise.

Discectomy for persistent sciatica with confirmed herniation accelerates relief, with outcomes converging with conservative care by one to two years; it is appropriate for severe or

persistent radicular pain and urgent for cauda equina syndrome. Decompression for symptomatic lumbar spinal stenosis with neurogenic claudication is effective for leg symptoms.

Spinal fusion for non-specific low back pain is CONTESTED and of limited value. Trials comparing fusion with intensive rehabilitation (Fairbank, *BMJ* 2005; Brox) found little or no advantage over structured rehabilitation, at substantial surgical risk and cost. Fusion rates vary enormously between countries and regions for identical indications, which is strong evidence of supply-driven practice. Spinal cord stimulation is expensive, recent sham-controlled trials have been disappointing, and NICE recommends against it for non-specific low back pain.

Imaging: do not image routinely. Imaging without red flags does not improve outcomes, increases surgery and cost, and labels age-normal findings as disease, on the Brinjikji data above. This is one of the strongest do-less recommendations in medicine and one of the most widely violated.

**Simple means.** Low back pain is the condition where simple means most clearly match or beat the industrial alternatives.

Exercise, for prevention and treatment. It prevents about 35 to 45 per cent of episodes (Steffens 2016) and is first-line treatment for chronic pain. Walking, strengthening, yoga, Pilates, aquatic exercise: no type is superior, so the cheapest available option is as good as the most expensive, and a walking programme costs nothing. The WalkBack trial (*Lancet* 2024, 701 adults) found a progressive walking programme with education significantly prolonged time to recurrence against control — walking as effective prevention.

Staying active and avoiding bed rest is free, and bed rest is actively harmful. Education and reassurance — that the back is not damaged, that imaging findings are age-normal, that activity is safe — measurably reduces disability and healthcare use, and costs a conversation. Heat application gives modest short-term benefit for acute pain: a hot water bottle. Weight loss and smoking cessation address about 24 per cent of the attributable burden between them. Psychological self-management, pain education and mindfulness have effect sizes comparable to the drugs and are deliverable in groups, in print, or digitally at near-zero marginal cost.

Not imaging, not prescribing opioids, not prescribing paracetamol, and not fusing spines for non-specific pain: four evidence-based omissions, each of which saves money and avoids harm.

*Exercise against the drugs, set side by side.* Exercise produces moderate improvements in pain and function in chronic low back pain, and prevents recurrence with a relative risk of about 0.55 to 0.65; no drug has been shown to prevent recurrence at all. NSAIDs give about 6 to 10 points out of 100 on pain against placebo, with gastrointestinal, renal and cardiovascular risk. Paracetamol gives nothing, being identical to placebo in PACE. Opioids give nothing better than non-opioids and are worse on pain at one year, in SPACE and OPAL. What the evidence supports is that exercise and psychological therapy outperform the entire analgesic pharmacopoeia for chronic low back pain, and are the only interventions that prevent recurrence. The drugs offer small short-term symptom relief with real harms. Guidelines have reflected this since 2016 to 2018.

**Gaps.** The cause of pain in 90 to 95 per cent of cases is unknown — an extraordinary gap for the leading cause of global disability. All treatment effect sizes are small and short-lived, and the field has produced no breakthrough in decades. Subgrouping and precision approaches to match patients to treatments have repeatedly failed to outperform generic exercise. Why age-standardised prevalence is falling while absolute burden rises is unexplained. The occupational attributable fraction of 22 per cent sits awkwardly with the repeated failure of lifting-training interventions. Chronic pain mechanisms — central sensitisation, nociplastic pain — are increasingly invoked and not measurable clinically. Most trials are from high-income countries, short-term, and use heterogeneous outcome measures despite core-outcome-set initiatives. Enormous unexplained geographic variation in surgery and imaging rates indicates that much care is supply-driven rather than need-driven. GBD estimates for Africa and parts of Asia rest on sparse primary data.

## Neck pain

**What it is.** Pain in the neck, often spreading to the shoulder or arm. As with the low back, most cases have no identifiable structural cause, and imaging changes are common in people without pain.

**Measured.** The GBD 2021 neck pain analysis (*Lancet Rheumatology* 2024) reported roughly 203 million prevalent cases globally in 2020 with about 23 million YLDs†. GBD 2023 Table 1 gives neck pain 20.7 million YLDs (95 per cent UI 13.8 to 30.1), rank fifteen. Both are printed; they are different cycles and different quantities, and the 2023 figure is the verified one.

The WHO musculoskeletal health fact sheet gives 222 million prevalent neck pain cases and 22 million YLDs on GBD 2019 data. Neck pain ranks among the top fifteen causes of YLDs globally and consistently in the leading group of musculoskeletal conditions after low back pain. Point prevalence is about 15 to 20 per cent of adults; one-year prevalence about 30 to 50 per cent; lifetime prevalence about 50 per cent.

Deaths: none. The entire burden is disability. There is a female predominance of about 1.3 to 1.7 times, as with most chronic musculoskeletal pain†. Prevalence peaks in middle age, 45 to 60, then plateaus or declines slightly — a different pattern from low back pain, which keeps rising into old age. Highest reported figures come from Norway and parts of Europe and the Middle East, with measurement differences contributing substantially. Office and computer workers, and those with sustained neck flexion, have higher prevalence, and the occupational burden is substantial.

**Where it starts.** Occupational: sustained neck flexion and awkward posture, prolonged computer and now mobile device use, repetitive work, low job control, with dose-dependent associations. Psychosocial factors, as with low back pain: depression, anxiety, somatisation, job dissatisfaction and low social support strongly predict chronicity, better than imaging findings do. A previous episode is the strongest predictor.

Whiplash injury is a distinct and important subgroup: about 50 per cent of whiplash patients report neck pain at one year, and expectation of recovery, compensation systems and early psychological response predict outcome more strongly than collision severity. Smoking, high BMI, low physical activity and sleep disturbance all contribute. Twin studies estimate heritability of about 35 to 45 per cent for neck pain, with cervical disc degeneration on imaging more heritable at above about 70 per cent.

Imaging findings are age-normal: cervical disc degeneration is present in the majority of asymptomatic adults over 40, approaching 90 per cent and above in the elderly, and its presence does not establish causation.

Specific causes are a minority: cervical radiculopathy from disc herniation or foraminal stenosis; cervical myelopathy, which is important because it is progressive and surgically treatable; inflammatory arthritis, including rheumatoid atlantoaxial involvement and axial spondyloarthritis; infection; tumour and metastasis; fracture; and vertebral artery dissection, a rare but critical diagnosis presenting with neck pain and headache.

What is not known is the pain source in most non-specific cases. Why whiplash becomes chronic in half of patients despite minor tissue injury is contested and has been politicised by its medicolegal context. Whether device use is genuinely driving incidence, or whether this is a reporting artefact, is unestablished.

**Cure status.** Acute episodes: SELF-LIMITING, with acute neck pain typically improving substantially within weeks. But recurrence and persistence are common, with about 50 to 75 per cent still reporting some pain at one to five years in cohort studies, and chronic neck pain following a fluctuating long-term course. Chronic neck pain: RELIEF ONLY, with treatment effects small as in low back pain.

CURABLE for the specific causes: cervical radiculopathy often resolves spontaneously and surgery is effective when it does not; cervical myelopathy requires surgery to halt progression, and recovery of lost function is incomplete, which makes early diagnosis important; infection and tumour are treated specifically.

**Prevention.** Exercise: MODERATE, the best-supported preventive measure, particularly neck and shoulder strengthening in office and manual workers, with workplace exercise pro-

grammes reducing incidence and severity in trials. Workstation ergonomics alone: WEAK and CONTESTED — adjusting screens and chairs without an exercise or organisational component has weak evidence, mirroring the low back pain finding. Breaks and movement variation during sustained computer work: MODERATE. Addressing psychosocial work factors, job control and workload: MODERATE. Smoking cessation and weight management: WEAK.

Early active management and reassurance after whiplash: MODERATE for preventing chronicity — in contrast to soft collars, which are harmful and prolong recovery. Act-as-usual advice beats immobilisation. Sleep and stress management: WEAK.

**Treatment.** Exercise therapy is first line for chronic neck pain. Neck-specific strengthening and endurance exercise, with or without scapulothoracic and general exercise, produces modest improvements in pain and function, and strengthening appears more effective than stretching or range-of-motion work alone. The cost is therapist time, or free.

Education, reassurance and advice to stay active, particularly after whiplash. Manual therapy or mobilisation combined with exercise is better than either alone, and the combination is the best-supported package; cervical manipulation carries a rare but serious risk of vertebral artery dissection and stroke, so mobilisation is often preferred and high-velocity cervical thrust should be used cautiously.

NSAIDs give a small short-term benefit; off-patent, EML-listed, a few to tens of US dollars a year. Paracetamol: weak evidence, as for low back pain. Muscle relaxants, short-term only. Tricyclic antidepressants, duloxetine and gabapentinoids have limited evidence for chronic neck pain specifically and are used by extrapolation from other chronic pain; the gabapentinoids are not well supported. Opioids are not recommended: the OPAL trial included neck pain and found opioids no better than placebo at six weeks, with worse pain at one year.

Acupuncture, massage, heat, TENS and laser give small short-term effects at low risk. Psychological therapy, CBT, is effective for chronic pain with significant disability or distress, as in low back pain. Multidisciplinary rehabilitation for chronic disabling neck pain. Soft collars are not recommended and prolong recovery after whiplash. Injections: cervical epidural and facet injections have weak evidence; medial branch radiofrequency ablation has some support for confirmed facet-mediated pain, and the evidence is contested.

Surgery: anterior cervical discectomy and fusion, or posterior foraminotomy, for radiculopathy with persistent severe symptoms or progressive deficit; decompression for cervical myelopathy, to prevent progression. Surgery for non-specific axial neck pain is not supported, mirroring lumbar fusion. Imaging is not indicated without red flags — trauma, neurological deficit, systemic features, suspected myelopathy or malignancy — since age-normal degenerative findings mislead.

**Simple means.** Neck and shoulder strengthening exercise is the primary treatment and the best prevention, and can be done without equipment or with a resistance band; workplace programmes work. Movement breaks and posture variation during sustained screen work, where the key is varying position rather than finding one correct posture; free. Staying active and continuing normal activities after whiplash, and not wearing a collar: an evidence-based omission that speeds recovery. Education and reassurance about age-normal imaging findings. Heat, self-massage and relaxation training. Adjusting screen height, phone use posture and pillow: low-cost with modest evidence. Smoking cessation, weight management and sleep. Psychological self-management and pain education, deliverable in groups or digitally. Not imaging and not prescribing opioids.

The honest limit: cervical myelopathy and progressive radiculopathy require surgery, and delay causes permanent deficit. Recognising myelopathy — gait disturbance, hand clumsiness, hyperreflexia — is the one place where simple means must give way to urgent referral.

**Gaps.** Neck pain is substantially less researched than low back pain despite a comparable disability rank. The source of pain is unknown in most cases. Whiplash chronicity is contested and entangled with compensation systems, which makes the literature hard to interpret. Treatment effects are uniformly small and short-term. Whether device use is driving incidence is unestablished. Radiofrequency denervation evidence is conflicting. Optimal exercise dose and type are unclear. GBD neck pain estimates rely on fewer primary studies than low back pain, so uncertainty is wider, and the GBD 2021 figures carried above could not be verified against the primary paper.

## Osteoarthritis of the knee, hip and hand

**What it is.** The cartilage in a joint thins and the underlying bone changes, causing pain, stiffness and loss of movement. It is a disease of the whole joint, not simply wear and tear, and it is the commonest form of arthritis.

**Measured.** The GBD 2021 osteoarthritis analysis gave about 595 million people, 7.6 per cent of the global population, with osteoarthritis in 2020, a 132 per cent increase in cases since 1990 (*Lancet Rheumatology* 2023). The WHO osteoarthritis fact sheet, printed 14 July 2023, gives about 528 million people worldwide in 2019, a 113 per cent increase since 1990. Both are printed; they are different cycles. The WHO musculoskeletal health fact sheet gives the same 528 million on GBD 2019 data, which is consistent between the two WHO pages.

Osteoarthritis YLDs are about 21 to 22 million†; GBD 2023 Table 1 gives 22.4 million (95 per cent UI 10.7 to 48.2), rank fourteen among YLD causes. Osteoarthritis is the leading cause of disability in the elderly.

Knee osteoarthritis is the commonest site, at about 365 million cases, about 61 per cent of all osteoarthritis; the hand accounts for about 15 to 20 per cent and the hip for about 5 to 10 per cent of cases. The WHO osteoarthritis fact sheet gives a knee prevalence of 365 million and names the knee as most frequently affected, followed by hip and hand, while giving no hip or hand figures; the page also never explicitly says that the 365 million refers to knee osteoarthritis alone. It gives 344 million moderate or severe cases that could benefit from rehabilitation, and typical onset in the late forties to mid-fifties. Projections are expected to keep increasing, with no number given on the WHO page; the condition literature projects about 1 billion people by 2050.

The WHO osteoarthritis page contradicts itself on the age share: its Key Facts say about 73 per cent of people with osteoarthritis are older than 55, while its body Scope section says about 70 per cent. Both are printed. It gives the female share as 60 per cent in Key Facts and about 60 per cent in the body, which is consistent.

Deaths are minimal directly, though osteoarthritis contributes to mortality indirectly through physical inactivity and through NSAID-related gastrointestinal and cardiovascular events. Prevalence rises steeply after 45, and radiographic knee osteoarthritis affects over 30 per cent of those over 60†, though symptomatic disease is less common: radiographic and symptomatic disease correlate only moderately, which is a key point. Female predominance, especially for knee and hand osteoarthritis, increasing after menopause, at about 1.5 to 2 times†; the hip is closer to equal.

Highest age-standardised rates are reported in high-income North America and parts of Asia, and knee osteoarthritis burden is rising fastest in low- and middle-income countries with rising obesity and ageing. Hip osteoarthritis is notably less common in Chinese and African populations than in European ones, an unexplained difference. Total knee and hip replacement are among the highest-volume elective operations in high-income countries, and demand consistently exceeds supply.

**Where it starts.** Age is the strongest risk factor, though osteoarthritis is not an inevitable consequence of ageing.

Obesity is the dominant modifiable risk factor for knee osteoarthritis: each 5 kg/m$^2$ increase in BMI raises knee osteoarthritis risk by roughly 35 per cent, and obesity raises risk about 2.5 to 4.6 times. The effect is partly mechanical and partly metabolic and inflammatory — obesity also raises hand osteoarthritis risk, which cannot be explained by load.

Joint injury: anterior cruciate ligament and meniscal injury raise knee osteoarthritis risk several-fold, with post-traumatic osteoarthritis developing in about 50 per cent within ten to twenty years of significant knee injury†; hip dysplasia and femoroacetabular impingement for the hip. Occupational loading: kneeling, squatting, heavy lifting, prolonged standing for knee and hip, and repetitive hand use for the hand. Female sex and the post-menopausal state. Malalignment, varus or valgus, and quadriceps weakness — and quadriceps weakness precedes and predicts knee osteoarthritis rather than merely following it.

Heritability is substantial and site-dependent: about 40 to 65 per cent overall, with the highest estimates for hand at about 40 to 65 per cent and hip at about 50 to 60 per cent, and

somewhat lower for knee at about 40 per cent (Spector and MacGregor twin studies). GWAS has identified over 100 loci — *GDF5*, *ASTN2*, *COL11A1*, *ALDH1A2* — explaining a modest fraction.

Running and recreational exercise do not cause osteoarthritis. Recreational runners have equal or lower rates than non-runners, and only elite or high-volume loading with injury raises risk. An important correction to common belief and to the wear-and-tear model.

What is not known is what initiates the disease at the molecular level, and why it progresses in some joints and not others. Pain correlates poorly with radiographic severity: many with severe radiographic change have no pain and vice versa. Central sensitisation, synovitis, bone marrow lesions and psychological factors all contribute, and the pain mechanism is only partly explained. No disease-modifying drug exists after decades of attempts, and no validated biomarker predicts progression. Why hip osteoarthritis is rare in some populations is unexplained.

**Cure status.** Medical treatment: RELIEF ONLY. Total knee or hip replacement: CURABLE for the joint, effectively. Both parts matter.

No disease-modifying drug exists. Cartilage loss is not reversed by any available treatment, and this has been the field's central failure, with numerous candidate disease-modifying drugs failing in trials. But symptoms and function are substantially modifiable, and weight loss with exercise can produce clinically large improvements.

Total knee and hip replacement are highly effective. Hip replacement in particular is among the most successful operations in medicine, with about 90 to 95 per cent implant survival at ten years and about 80 to 85 per cent at twenty to 25 years, and large improvements in pain and function†. That is a functional cure for the joint, though about 15 to 20 per cent of knee replacement patients report persistent pain or dissatisfaction — an important and under-disclosed figure.

Early post-traumatic and mild disease: CONTROLLABLE with load management, strength and weight.

**Prevention.** Weight management: STRONG for knee osteoarthritis, the largest modifiable effect. Each 5 kg/m² BMI reduction meaningfully reduces incidence, and the Framingham data suggested a two-unit BMI reduction could reduce knee osteoarthritis incidence by about 20 to 30 per cent.

Injury prevention: STRONG. Neuromuscular training programmes such as FIFA 11+ and PEP reduce anterior cruciate ligament injury by about 50 to 70 per cent in athletes, which prevents post-traumatic osteoarthritis. One of the clearest primary prevention opportunities, and it needs no equipment.

Muscle strengthening, quadriceps in particular: MODERATE, since weakness predicts incident knee osteoarthritis. Occupational load reduction — kneeling, squatting, heavy lifting: MODERATE. Treating hip dysplasia and femoroacetabular impingement: MODERATE for the hip. Physical activity: MODERATE and protective, not a risk factor, contrary to popular belief; moderate recreational exercise is protective of joint health. Glucosamine and chondroitin for prevention: CONTESTED and ineffective. No drug prevents osteoarthritis: absent.

**Treatment.** All major guidelines — OARSI, ACR 2019, NICE NG226, EULAR — agree on the ordering: core non-drug treatment first, for everyone.

Core treatments, first line for all patients. Therapeutic exercise: land-based strengthening, aerobic, and neuromuscular or functional exercise. The effect size on pain is roughly 0.4 to 0.6 standardised mean difference against control — comparable to NSAIDs — with improvement in function and no serious harms. Benefit requires continuation; supervised programmes outperform unsupervised, and more sessions give better results. The cost is therapist time, or free.

Weight loss where overweight, with a clear dose-response. At 5 per cent loss or more there is measurable symptom improvement. At about 10 per cent loss the benefit is substantially greater: in the IDEA trial (Messier, *JAMA* 2013, 454 adults with knee osteoarthritis), diet plus exercise achieving about 11 per cent weight loss produced greater pain reduction than either alone, with reduced knee compressive force and reduced inflammatory markers. At 20 per cent loss or more there is further improvement, approaching the effect of joint replacement

on symptoms in some analyses. Combining diet with exercise is superior to either alone — the central practical finding. Education and self-management support. Aquatic exercise where land-based exercise is too painful, with similar benefit.

Pharmacological, adjunctive rather than primary. Topical NSAIDs are recommended before oral NSAIDs for knee and hand osteoarthritis: similar efficacy to oral for the knee, with far fewer systemic adverse effects. Off-patent; tens to hundreds of US dollars a year. Underused.

Oral NSAIDs are effective with an effect size of about 0.3 to 0.4 standardised mean difference on pain, which is modest, and carry gastrointestinal, renal and cardiovascular risks; use the lowest dose for the shortest period, with a PPI in those at gastrointestinal risk. Ibuprofen, naproxen and diclofenac: EML yes; off-patent; a few to tens of US dollars a patient-year.

Paracetamol gives minimal benefit: network meta-analyses show effects that are statistically detectable but below clinical significance, around 3 to 4 points out of 100, and NICE NG226 moved away from recommending it routinely. Cheap and low-risk, and it should not be relied upon.

Intra-articular corticosteroid injection gives short-term relief, about two to four weeks, with effects largely gone by three months. One trial (McAlindon, *JAMA* 2017) found repeated three-monthly injections over two years produced greater cartilage loss than saline with no pain benefit, which argues against repeated long-term use. Off-patent, cheap. Duloxetine gives modest benefit and is useful where central sensitisation features; off-patent.

Opioids are not recommended. The SPACE trial found them no better than non-opioid analgesics for function in chronic back, hip or knee pain, with worse pain intensity at twelve months.

Intra-articular hyaluronic acid: CONTESTED. Meta-analyses give small effects of uncertain clinical significance; NICE recommends against it and some other guidelines permit it. Expensive, hundreds to thousands of US dollars a course.

Glucosamine and chondroitin: CONTESTED and ineffective. The GAIT trial (*NEJM* 2006, 1,583 patients) found neither glucosamine nor chondroitin, alone or combined, superior to placebo for the overall cohort. Widely sold.

Platelet-rich plasma and stem cell injections are not supported. The RESTORE trial (*JAMA* 2021, 288 patients) found platelet-rich plasma no better than saline for knee pain or cartilage structure at twelve months. Heavily commercialised regardless. Colchicine, methotrexate, hydroxychloroquine and anti-TNF agents are not effective for osteoarthritis; hand osteoarthritis trials of hydroxychloroquine and anti-TNF were negative.

Surgical. Total knee or hip replacement for severe symptomatic disease refractory to non-surgical care is highly effective, with the outcome figures above; cost varies from about US$1,500 in the Indian public sector to about US$30,000 to 50,000 in the United States†.

Arthroscopic partial meniscectomy, and arthroscopic lavage or debridement for osteoarthritis, are not effective. Multiple randomised and sham-controlled trials — Moseley, *NEJM* 2002; Kirkley, *NEJM* 2008; FIDELITY, Sihvonen, *NEJM* 2013, sham-controlled in degenerative meniscal tear — found no benefit over placebo surgery or over exercise therapy. The METEOR trial found physical therapy non-inferior to meniscectomy. Despite this, the procedure continues in large numbers: one of the clearest examples of low-value care persisting against strong evidence.

Osteotomy for unicompartmental disease with malalignment in younger patients. For hand osteoarthritis: thumb base splinting, hand exercise, topical NSAIDs; trapeziectomy for refractory thumb base disease; joint fusion or replacement for selected finger joints.

**Simple means.** Osteoarthritis is, with low back pain, the clearest case where simple means are first-line therapy rather than adjuncts.

Exercise has an effect size on pain comparable to NSAIDs, standardised mean difference about 0.4 to 0.6, without the gastrointestinal, renal and cardiovascular risks†. Strengthening, walking, cycling, tai chi — which has good trial evidence for knee osteoarthritis — and aquatic exercise. No equipment needed.

Weight loss, dose-dependently: 5 per cent gives benefit, 10 per cent substantially more on the IDEA trial, 20 per cent more still. Diet plus exercise beats either alone.

Walking aids, a stick or cane, reduce joint load and pain measurably: a stick. Footwear: comfortable, cushioned, flat flexible shoes; lateral wedge insoles are not effective, with negative trials. Tai chi has randomised evidence of benefit for knee osteoarthritis comparable to physical therapy and needs only space and instruction. Heat and cold application for symptomatic relief, free. Thumb splints for hand osteoarthritis: simple, cheap and effective for pain. Quadriceps strengthening at home with body weight or a resistance band. Injury prevention programmes of neuromuscular training reduce anterior cruciate ligament injury 50 to 70 per cent, preventing post-traumatic osteoarthritis: free, and done as a warm-up.

Not having arthroscopic meniscectomy; not using glucosamine, platelet-rich plasma or hyaluronic acid; not taking opioids: four evidence-based omissions saving substantial money.

*Exercise against the drugs, set side by side.* Exercise gives a standardised mean difference of about 0.4 to 0.6 for pain in knee and hip osteoarthritis, plus function gains, no serious adverse effects, and benefits to cardiovascular and metabolic health. Oral NSAIDs give a standardised mean difference of about 0.3 to 0.4 for pain, with gastrointestinal bleeding, renal and cardiovascular risks — a real harm profile, particularly in the elderly who are the main patient group. Paracetamol gives about 3 to 4 points out of 100, below clinical significance†. Opioids are no better than non-opioids and worse on pain at twelve months. Intra-articular steroid lasts two to four weeks, and repeated use may accelerate cartilage loss. What the evidence supports is that exercise matches or exceeds the analgesic drugs for pain, exceeds them clearly for function, and carries benefit rather than harm elsewhere in the body. Weight loss adds a dose-dependent effect no drug matches. The drugs are adjuncts for breakthrough symptoms, and the guidelines say so.

**Gaps.** No disease-modifying drug exists despite decades of effort, and no validated biomarker predicts progression. Pain correlates poorly with structural severity, so treatment targeting is imprecise and the pain mechanism is only partly understood. About 15 to 20 per cent of knee replacements leave persistent pain†, which is not well explained or well disclosed. Arthroscopic meniscectomy continues at scale despite sham-controlled negative trials — a practice-evidence gap rather than a knowledge gap. Why hip osteoarthritis is rare in some populations is unexplained. Optimal exercise type, dose and delivery are unsettled, and adherence declines markedly after supervised programmes end. Access to joint replacement is extremely unequal globally. GBD estimates rely on radiographic and self-report data that are not interchangeable, and primary data from Africa and much of Asia are sparse. The two WHO fact sheets that carry osteoarthritis figures disagree with the GBD 2021 condition paper on prevalence and with each other on the age share.

---

## Rheumatoid arthritis

**What it is.** The immune system attacks the lining of joints, usually symmetrically in the hands, wrists and feet. Untreated it destroys joints and shortens life. Treated early, most people now do well.

**Measured.** Global prevalence is about 0.25 to 0.5 per cent, with GBD 2019 and 2021 estimating about 17.6 to 18 million people. The WHO musculoskeletal health fact sheet gives 18 million prevalent cases and 2.4 million YLDs on GBD 2019 data. GBD 2019 gave about 38,000 to 40,000 deaths a year and roughly 3 million DALYs†.

Female to male ratio is about 2.5 to 3:1†. Peak onset is 40 to 60, though it occurs at any age. Prevalence is highest in North America and northern Europe at about 0.5 to 1 per cent, lower in Southeast Asia and much of Africa at about 0.1 to 0.3 per cent, and very high in some Indigenous North American populations, with Pima and Chippewa figures up to 5 to 7 per cent†.

Life expectancy was historically reduced by about three to ten years, mainly from cardiovascular disease, and this gap has narrowed substantially with modern treat-to-target therapy, though not closed. Remission is now an achievable target in a substantial proportion, which is a transformation since the 1990s.

**Where it starts.** Smoking is the strongest established environmental risk factor, at roughly 1.5 to 2.5 times the risk overall, and the interaction with genetics is dramatic: in HLA-DRB1 shared epitope carriers who smoke, the risk of ACPA-positive disease rises many-fold,

with odds ratios of about 20 to 40 for double-dose shared epitope plus smoking. This gene-environment interaction is one of the best-characterised in all of medicine.

HLA-DRB1 shared epitope alleles are the dominant genetic risk, with *PTPN22*, *STAT4*, *TRAF1/C5* and *PADI4*, the last prominent in Asian populations, and over 100 loci identified. Heritability is about 50 to 60 per cent from twin studies, with monozygotic concordance about 12 to 15 per cent and dizygotic about 3 to 5 per cent, and heritability is higher for ACPA-positive seropositive disease, about 50 to 65 per cent, than for seronegative.

Anti-citrullinated protein antibodies and rheumatoid factor appear years before symptoms, up to ten to fifteen years, defining a pre-clinical phase. That is the basis of current prevention trials.

Periodontal disease and *Porphyromonas gingivalis* are a leading hypothesis: the organism expresses a peptidylarginine deiminase that citrullinates proteins, potentially initiating the autoimmunity. The association is robust and the causation plausible and unproven; *Aggregatibacter actinomycetemcomitans* is also implicated. Lung exposures — silica, textile dust, air pollution — support the hypothesis that the disease may initiate at mucosal surfaces, lung, gum or gut, rather than in the joint.

Female sex, nulliparity and the post-partum period, which is a well-recognised onset window; breastfeeding is protective. Obesity, at about 1.2 to 1.3 times†, and worsening treatment response; low vitamin D, CONTESTED; high sodium intake interacting with smoking. Protective: moderate alcohol, a consistent association with unclear mechanism, oily fish and omega-3, higher socioeconomic status, and breastfeeding.

What is not known is the trigger that converts pre-clinical autoimmunity into arthritis. The second hit is unidentified, which is exactly what the prevention trials are trying to address. Why seronegative disease occurs at all and whether it is the same disease. Why the joints are targeted when the initiating event appears to be at mucosal sites. Why treatment response varies so much between individuals, and why there is still no biomarker to choose between biologics — treatment selection remains trial and error.

**Cure status.** CONTROLLABLE, and now very well controlled, though not cured. Remission is achievable in roughly 40 to 60 per cent with modern treat-to-target strategies, and low disease activity in considerably more — a transformation from the pre-methotrexate and pre-biologic era. Sustained drug-free remission occurs in a minority, about 10 to 20 per cent†, more often in those treated very early and in seronegative disease, and relapse on withdrawal is common, so the disease is suppressed rather than eliminated.

The window of opportunity is real: treatment within the first three to six months of symptom onset produces substantially better long-term outcomes and more remission, and delay causes irreversible joint damage. That makes early referral the single most important system factor. Established joint destruction is irreversible, though joint replacement restores function. Prevention of onset is now being tested and is partially supported, which is a genuinely new development.

**Prevention.** Smoking cessation: STRONG, and the only well-established modifiable preventive measure; risk declines after cessation, though slowly, over ten to twenty years. Oral and periodontal health: MODERATE — biologically plausible and epidemiologically supported, with periodontal treatment improving disease activity modestly in small trials, though prevention of onset is not demonstrated. Weight management: MODERATE. Breastfeeding: WEAK. Omega-3 and oily fish: WEAK.

Pharmacological prevention in the at-risk pre-clinical phase is emerging and partially supported. PRAIRI, a single rituximab dose, delayed onset. TREAT EARLIER, methotrexate in at-risk arthralgia, did not prevent arthritis but improved symptoms and MRI inflammation. APIPPRA, abatacept (*Lancet* 2024), significantly reduced progression to rheumatoid arthritis during treatment, with arthritis development of 6 against 29 per cent at twelve months, though the effect attenuated after stopping. So delay is demonstrated and durable prevention is not yet: MODERATE for delay, CONTESTED for prevention.

Vitamin D: CONTESTED — the VITAL trial secondary analysis suggested reduced autoimmune disease incidence with vitamin D plus omega-3, which is suggestive and not definitive. Cardiovascular risk management: STRONG for preventing the leading cause of death in

rheumatoid arthritis — statins, blood pressure control, smoking cessation. That is prevention of the fatal complication rather than of the disease.

**Treatment.** The strategy, not any single drug, is what transformed outcomes: early diagnosis, treat-to-target with regular disease activity measurement, and escalation until remission or low disease activity.

Methotrexate is the anchor drug and the first-line conventional synthetic DMARD. Monotherapy achieves an ACR50 response in roughly 25 to 40 per cent†, and it potentiates every biologic. It is given weekly, orally or subcutaneously, with folic acid supplementation to reduce toxicity, and requires blood monitoring of liver and blood count. WHO EML: yes, listed under disease-modifying antirheumatic drugs with the indication rheumatoid arthritis, and separately for juvenile joint diseases. Off-patent. Cost tens to hundreds of US dollars a patient-year for the oral generic, often less; subcutaneous is more. This is the single highest-value drug in rheumatology: a few dollars a month delivering most of the achievable benefit for many patients.

Other conventional synthetic DMARDs: sulfasalazine at tens to hundreds of US dollars a year, hydroxychloroquine at tens to hundreds of US dollars leflunomide at hundreds of US dollars. All off-patent, with sulfasalazine and hydroxychloroquine EML-listed. Triple therapy — methotrexate with sulfasalazine and hydroxychloroquine — was non-inferior to methotrexate plus etanercept in the RACAT trial (*NEJM* 2013) and in TEAR. That is a critical finding for cost-constrained settings, since triple therapy costs a tiny fraction of a biologic.

Corticosteroids give rapid symptom control as a bridge while DMARDs take effect, and low-dose prednisolone has a disease-modifying effect; long-term use is limited by bone, glucose, infection and cataract toxicity. Prednisolone off-patent, EML-listed, a few to tens of US dollars a year.

Biologic DMARDs, for inadequate response to conventional DMARDs:

| Agent | Class | Measured effect, with methotrexate | WHO EML | Off-patent / biosimilar | Approx. annual cost |
|---|---|---|---|---|---|
| Infliximab | Anti-TNF | ATTRACT / ASPIRE: ACR50 40–50% vs 20% MTX alone; major reduction in radiographic progression | listed **only as a therapeutic equivalent** to adalimumab, with rheumatoid arthritis among its indications, not as a selected medicine | originator off-patent; biosimilars widely available | originator tens of thousands of US dollars; biosimilars thousands of US dollars some tenders below thousands of US dollars |
| Adalimumab | Anti-TNF | PREMIER / ARMADA: ACR50 50–60% in combination vs 30% MTX alone | **yes, listed medicine**, rheumatoid arthritis among its indications | originator off-patent; biosimilars since 2018 in the EU, 2023 in the US | originator US$50,000–90,000 US list; biosimilars US$2,000–10,000 |
| Etanercept | Anti-TNF | TEMPO: ACR50 60–70% combined | yes | biosimilars available | originator tens of thousands of US dollars +; biosimilars thousands to tens of thousands of US dollars |
| Tocilizumab | Anti-IL6R | ACR50 40–55%; effective as monotherapy, unusual among biologics | yes | biosimilars entering | tens of thousands of US dollars falling |
| Rituximab | Anti-CD20 | REFLEX: ACR50 27% vs 5% placebo in anti-TNF failures | **yes, listed medicine**, under multiple sclerosis and targeted therapies | biosimilars widely available | originator tens of thousands of US dollars a course; biosimilars thousands of US dollars |

| Agent | Class | Measured effect, with methotrexate | WHO EML | Off-patent / biosimilar | Approx. annual cost |
|---|---|---|---|---|---|
| Abatacept | T-cell co-stimulation | ACR50 40–50% | no | no | tens of thousands of US dollars |
| Tofacitinib, baricitinib, upadaci-tinib | JAK inhibitors | ACR50 40–50%; upadacitinib superior to adalimumab in SELECT-COMPARE | no | tofacitinib generics entering | originator US$50,000–70,000 US list; generic tofacitinib potentially below thousands of US dollars |

On JAK inhibitor safety: the ORAL Surveillance trial found tofacitinib did not meet non-inferiority against TNF inhibitors for major adverse cardiovascular events and malignancy in an enriched-risk population, which led to regulatory warnings and to restriction, in many jurisdictions, to patients who have failed a TNF inhibitor.

The biosimilar price collapse is the central economic fact. Anti-TNF agents fell from tens of thousands of US dollars a year to thousands to tens of thousands of US dollars and in some tenders below thousands of US dollars. Adalimumab is a listed EML medicine with rheumatoid arthritis among its indications; infliximab appears on the list only as a therapeutic equivalent to adalimumab, not as a selected medicine. Rituximab is a listed medicine, under multiple sclerosis and targeted therapies in the complementary list. Between them these make biologic therapy for rheumatoid arthritis feasible in middle-income health systems for the first time.

Treat-to-target monitoring with DAS28, CDAI or SDAI measured regularly, with escalation until target, produces better outcomes than any individual drug choice (TICORA, BeSt, CAMERA). It requires a measuring tape, a trained assessor and a CRP, not expensive technology.

Physiotherapy, occupational therapy and hand exercise maintain function, protect joints and provide aids and splints. Cardiovascular risk management, osteoporosis prevention, and vaccination — pneumococcal, influenza, hepatitis B, and zoster where appropriate before immunosuppression — with screening for latent tuberculosis and hepatitis before biologics. Surgery: joint replacement, tendon repair, cervical spine stabilisation; rates have fallen markedly with better drug control.

**Simple means.** Smoking cessation is the only established modifiable cause, and it also improves drug response and reduces cardiovascular death. Free.

Exercise, aerobic and resistance training, improves pain, function, fatigue and cardiovascular risk without worsening disease activity or joint damage — a long-held fear now refuted. That matters, because these patients have high cardiovascular mortality and become deconditioned.

Hand exercise programmes: the SARAH trial (*Lancet* 2015, 490 patients) found a tailored hand exercise programme improved hand function at twelve months at low cost, added to usual care. Taught exercises, no equipment.

Dental and periodontal hygiene has a plausible disease-modifying effect and gives a measurable improvement in disease activity in small trials: brushing and interdental cleaning. Weight management improves response to therapy. Joint protection and assistive devices, splints and adapted utensils are occupational therapy measures that preserve independence at minimal cost. Mediterranean diet and omega-3 give modest symptomatic benefit in trials: food, not a drug.

Methotrexate with folic acid at tens to hundreds of US dollars a year is manufactured but cheap, off-patent and EML-listed, and is the backbone of effective treatment worldwide. Triple conventional DMARD therapy at a few hundred dollars a year is non-inferior to methotrexate plus etanercept (RACAT) — the key affordability finding. Early referral: recognising persistent synovitis and referring within weeks rather than months is a knowledge and pathway intervention, not a technology, and it determines long-term outcome more than drug choice.

The honest limit: rheumatoid arthritis cannot be managed without DMARDs. Diet, exercise and hygiene are valuable adjuncts, not alternatives, and delay in starting a DMARD causes permanent damage.

**Gaps.** The initiating trigger is unknown, and the mucosal-origin hypothesis — gum, lung, gut — remains unproven. There is no biomarker to select between biologics, so treatment is sequential trial and error: a major and costly gap. Prevention trials show delay but not durable prevention, and whom to treat pre-clinically raises unresolved ethical questions. Whether seronegative disease is the same entity is unclear. Optimal tapering and withdrawal strategies after remission are not established. JAK inhibitor cardiovascular and malignancy risk is contested beyond the enriched-risk ORAL Surveillance population. Biosimilar availability and pricing vary by more than tenfold between countries, so the cost of treatment is not a single number. Access to any DMARD remains poor in much of Africa and South Asia, where the disease is under-diagnosed and GBD estimates rest on sparse data.

---

## Ankylosing spondylitis and axial spondyloarthritis

**What it is.** Inflammation of the spine and of the joints where it meets the pelvis, causing back pain and stiffness that is worse with rest and better with movement. Over years the spine can fuse. It typically begins in young adulthood.

**Measured.** Prevalence of axial spondyloarthritis is about 0.3 to 1.4 per cent, with ankylosing spondylitis specifically about 0.1 to 0.5 per cent, closely tracking HLA-B27 prevalence in the population. GBD does not model axial spondyloarthritis as a separate top-level cause; it sits within other musculoskeletal disorders, which GBD 2023 Table 1 places eighth among YLD causes at 43.2 million (95 per cent UI 29.9 to 58.3). The burden of this condition is therefore substantially under-represented in global statistics relative to its disability impact in young working-age adults.

Onset is typically 20 to 30, and onset after 45 is rare, which is a useful diagnostic point. The male to female ratio is about 2 to 3:1 for radiographic ankylosing spondylitis but close to 1:1 for non-radiographic axial spondyloarthritis, and women are diagnosed later and more often missed, partly because of the historical male stereotype. Diagnostic delay averages five to ten years from symptom onset — comparable to endometriosis, and for similar reasons: young people with back pain are assumed to have mechanical pain.

Geography tracks HLA-B27: high in Northern European, Inuit, with up to 25 to 40 per cent B27 carriage†, and some Indigenous Siberian populations; low in sub-Saharan Africa and Japan; and the disease is correspondingly rare in populations with low B27 frequency.

**Where it starts.** HLA-B27 is present in about 85 to 95 per cent of people with ankylosing spondylitis against about 6 to 8 per cent of northern European populations, but only about 1 to 5 per cent of HLA-B27 carriers develop the disease, so the association is strong and far from sufficient.

Heritability is among the highest of any common disease, about 90 per cent, with HLA-B27 accounting for roughly 20 to 30 per cent of total genetic risk (Brown, twin and sibling studies). Other loci: *ERAP1*, which interacts with B27, *IL23R*, *IL12B*, *TNFSF15*. Sibling recurrence risk is about 5 to 10 times†. Family history is the strongest practical predictor.

Gut inflammation: subclinical gut inflammation is present in a substantial proportion, about 5 to 10 per cent develop overt inflammatory bowel disease†, and the gut-joint axis with microbial dysbiosis is a leading mechanistic hypothesis, supported by the shared response to IL-17 and IL-23 pathway drugs and by the association with *Klebsiella* and other organisms. It is not established as causal.

Associated conditions: acute anterior uveitis at about 25 to 40 per cent lifetime†, psoriasis, and inflammatory bowel disease — the spondyloarthritis family. Mechanical stress at entheses may localise inflammation, and smoking worsens progression and spinal damage.

What is not known is how HLA-B27 causes disease. The arthritogenic peptide, the misfolding and unfolded protein response, and the free heavy chain theories all have support and none is established, after fifty years. Why only a small minority of carriers are affected. Why men develop more radiographic fusion while women have similar symptom burden. Whether non-radiographic axial spondyloarthritis is early ankylosing spondylitis or a distinct entity

that often does not progress, which is clinically important and genuinely unresolved. And whether any treatment prevents structural progression, which is contested.

**Cure status.** The disease: CONTROLLABLE, not curable. It is lifelong. Spinal deformity: CURABLE surgically by osteotomy, at high risk and as a last resort.

Symptom control is now good: NSAIDs help most, and biologics produce major improvement in a majority of NSAID-refractory patients, with ASAS40 response of about 40 to 60 per cent. Structural progression — syndesmophyte formation and fusion — is only partly modifiable: long-term observational data suggest TNF inhibitors slow radiographic progression after about four years of use, but the randomised evidence for prevention of structural damage is weaker than for symptoms, and this remains contested. Established fusion is irreversible: loss of spinal mobility, once fused, cannot be recovered, which is why early treatment and lifelong exercise matter.

**Prevention.** No primary prevention exists: absent. HLA-B27 screening is not recommended, since most carriers never develop disease.

Smoking cessation: MODERATE — smoking is associated with worse spinal damage, worse function and worse treatment response, and it is the clearest modifiable factor for preventing progression. Regular exercise throughout life: STRONG for preventing loss of mobility and deformity, as secondary prevention. Early diagnosis and treatment: MODERATE for preventing accumulated disability, and reducing the five to ten year diagnostic delay is the highest-value system intervention available.

Osteoporosis prevention: STRONG. Bone loss and vertebral fracture risk are increased in ankylosing spondylitis despite the paradoxical appearance of new bone formation, and this is often overlooked. Uveitis awareness: prompt treatment of a red painful eye prevents visual loss, and patient education costs nothing.

**Treatment.** Exercise and physiotherapy are the foundation, for everyone, lifelong. Supervised group exercise is superior to home exercise, which is superior to none; exercise maintains spinal mobility, posture and function and improves pain. This is genuinely first-line and is never superseded by drugs.

NSAIDs are first-line drug therapy and unusually effective here, more so than in mechanical back pain. Most patients respond well, and response to NSAIDs is itself a supportive diagnostic feature. Continuous rather than on-demand use may slow radiographic progression, which is contested. Ibuprofen, naproxen, diclofenac and indomethacin: EML yes; off-patent; a few to tens of US dollars a patient-year. Extremely cheap, and effective for most.

Biologics for persistent high disease activity despite NSAIDs. TNF inhibitors — adalimumab, etanercept, infliximab, certolizumab, golimumab — give an ASAS40 response of about 40 to 60 per cent against about 15 to 20 per cent placebo. Adalimumab is on the WHO EML as a listed medicine with axial spondyloarthritis as a listed indication. Infliximab is EML-listed only as a therapeutic equivalent to adalimumab, not as a selected medicine, and axial spondyloarthritis is among the indications of that therapeutic-equivalent listing; a bare “on the EML” overstates it. Biosimilars cost thousands to tens of thousands of US dollars a year against originator prices of tens of thousands of US dollars.

IL-17 inhibitors, secukinumab and ixekizumab, give similar efficacy and are an alternative after TNF failure; on patent, tens of thousands of US dollars. JAK inhibitors, tofacitinib and upadacitinib, are effective with the same safety caveats as in rheumatoid arthritis. Note that IL-23 inhibitors, ustekinumab and risankizumab, failed in axial spondyloarthritis despite working in psoriasis and psoriatic arthritis — an instructive and unexplained dissociation.

Conventional synthetic DMARDs, methotrexate and sulfasalazine, do not work for axial disease, which is an important negative. Sulfasalazine has some effect on peripheral arthritis only, and prescribing methotrexate for axial spondyloarthritis is a common error. Local corticosteroid injection for sacroiliac joints or enthesitis; systemic steroids are not generally useful for axial disease, another contrast with rheumatoid arthritis.

Treat the extra-articular manifestations: topical steroids and mydriatics for uveitis, with urgent ophthalmology; inflammatory bowel disease treatment, choosing agents that treat both, noting that etanercept does not work for bowel disease so a monoclonal anti-TNF is preferred in that overlap. Osteoporosis assessment and treatment, often missed. Surgery: hip replace-

ment, since hip involvement is common and disabling; spinal osteotomy for severe deformity; stabilisation for fracture. Smoking cessation.

**Simple means.** This condition has an unusually strong simple-means core, because exercise is genuinely disease-modifying for function.

Daily exercise is the single most important long-term intervention: spinal extension and mobility exercises, posture work, deep breathing and chest expansion, since chest wall involvement restricts breathing, and swimming, which is excellent because it loads the spine minimally while mobilising it. Group exercise and hydrotherapy outperform home exercise, and home exercise far outperforms nothing. No equipment required.

Postural awareness, and sleeping flat on a firm surface with a thin pillow, reduces flexion deformity over years. Smoking cessation is the clearest modifiable determinant of spinal damage. NSAIDs at a few to tens of US dollars a year are manufactured but extremely cheap, and more effective in this condition than in most back pain.

Patient education: recognising uveitis — a red painful eye with photophobia — and seeking same-day care prevents blindness; and recognising that rest worsens and movement improves the pain, which is counter-intuitive and often mismanaged. Weight-bearing exercise, calcium and vitamin D for the increased fracture risk. Early recognition and referral: the inflammatory back pain features — onset under 45, morning stiffness over 30 minutes, improvement with exercise, night pain, good NSAID response, alternating buttock pain — are a free diagnostic tool that could cut the five to ten year delay.

The honest limit: exercise does not control inflammation in active disease, and patients with high disease activity need NSAIDs and often biologics. Where biologics are unaffordable, NSAIDs plus intensive exercise is the realistic standard, and it is far from useless.

**Gaps.** How HLA-B27 causes disease is unknown after five decades. Whether any drug prevents structural progression is contested: the randomised evidence is weak and the observational evidence confounded. Whether non-radiographic axial spondyloarthritis is uniformly early ankylosing spondylitis is unresolved, which complicates treatment decisions and trial interpretation. The five to ten year diagnostic delay persists, and women are disproportionately affected by it. The failure of IL-23 inhibitors despite IL-17 success is unexplained and undermines the assumed pathway. MRI interpretation of sacroiliitis has significant inter-reader variability and false positives, in athletes and postpartum women, causing both over- and under-diagnosis. Axial spondyloarthritis is not separately modelled in GBD, so its global burden is effectively uncounted. There are almost no epidemiological data from Africa.

---

## Psoriatic arthritis

**What it is.** An inflammatory arthritis that occurs in people with psoriasis. It affects joints, tendons, the spine and the fingers and toes, often asymmetrically, and can destroy joints.

**Measured.** It affects about 20 to 30 per cent of people with psoriasis, with a population prevalence of about 0.1 to 0.25 per cent, and up to 0.5 per cent in some studies. Psoriasis itself affects about 60 to 125 million people globally, about 2 to 3 per cent of adults, so the psoriatic arthritis pool is large. It is not modelled as a separate GBD cause and sits within other musculoskeletal disorders or within psoriasis, so its burden is under-represented.

Male to female ratio is approximately 1:1, unlike rheumatoid arthritis. Peak onset is 30 to 50. Skin disease usually precedes arthritis by about seven to ten years in about 70 to 80 per cent of cases†, which creates a window for early detection that is largely unused. Under-diagnosis is substantial: about 15 to 30 per cent of psoriasis clinic patients have undiagnosed psoriatic arthritis on screening. Geography follows psoriasis: higher in northern Europe and North America, lower in East Asia and much of Africa.

**Where it starts.** Psoriasis is the necessary precursor in nearly all cases. Risk is higher with severe psoriasis, and with scalp, nail and intergluteal or perianal involvement. Nail psoriasis is a particularly strong predictor: nail and enthesis share anatomical continuity with the distal interphalangeal joint, which may explain the distribution.

Genetics: HLA-B27 for axial disease; HLA-B*08, B*38, B*39 and C*06, with C*06 more associated with psoriasis than with arthritis;* IL23R*,* TNIP1*,* TRAF3IP2**. Heritability is high: the recur-

rence risk ratio in first-degree relatives is about 30 to 55 times, among the highest for any rheumatic disease, and twin data support a strong genetic component.

Obesity is a well-established, dose-dependent risk factor for developing psoriatic arthritis in people with psoriasis, and weight loss improves response to treatment. Physical trauma, the deep Koebner phenomenon, with joint or tendon trauma preceding onset, is an intriguing and repeatedly observed association. Infection — streptococcal, and HIV, where HIV-associated psoriatic arthritis can be severe. Smoking, which is paradoxically associated with psoriasis but inversely associated with psoriatic arthritis among psoriasis patients, an unexplained finding. Stress.

What is not known is why only 20 to 30 per cent of psoriasis patients develop arthritis, and no biomarker predicts who. The smoking paradox is unexplained. Why the disease pattern is so heterogeneous within one diagnosis — oligoarticular, polyarticular, axial, enthesitic, dactylitic, distal interphalangeal, arthritis mutilans — is unexplained, and these may be distinct entities. Whether treating psoriasis prevents arthritis is contested and confounded: observational data suggest biologics for the skin may reduce incidence.

**Cure status.** CONTROLLABLE, not curable. A lifelong disease with relapses. Remission or low disease activity is achievable in a substantial proportion with modern therapy, and the treat-to-target approach, as in TICOPA, improves outcomes. Structural joint damage is irreversible, and about 20 to 40 per cent develop erosive disease†; arthritis mutilans, the severe destructive form, affects a small percentage. Both skin and joints respond to several agents, which is a treatment advantage. Drug-free remission is uncommon.

**Prevention.** Weight management: MODERATE — obesity raises incidence dose-dependently in psoriasis patients, and weight loss improves both disease activity and treatment response. The clearest modifiable factor.

Screening psoriasis patients for arthritis: MODERATE for preventing accumulated damage. Simple questionnaires — PEST, PASE, EARP — are free and effective at case-finding, and dermatology-rheumatology collaboration is the practical mechanism. Given that skin disease precedes arthritis by years in most, this is an unusually tractable early-detection opportunity.

Treating psoriasis effectively to prevent arthritis: CONTESTED — observational evidence suggests biologic treatment of skin disease may reduce arthritis incidence, with no randomised evidence. Avoiding joint trauma: WEAK, based on the Koebner observation. There is no established primary prevention of psoriasis itself.

**Treatment.** Treatment is chosen by which domains are involved — peripheral arthritis, axial disease, enthesitis, dactylitis, skin, nails — which is why the GRAPPA and EULAR recommendations are domain-based.

NSAIDs for mild peripheral arthritis and enthesitis: off-patent, EML-listed, a few to tens of US dollars a year. Local corticosteroid injection for mono- or oligoarthritis, enthesitis and dactylitis; systemic steroids are used cautiously, because withdrawal can precipitate a severe pustular psoriasis flare.

Conventional synthetic DMARDs for peripheral arthritis. Methotrexate: the SEAM-PsA trial found methotrexate monotherapy produced meaningful responses, ACR20 about 51 per cent†, though etanercept was superior, and the earlier MIPA trial was equivocal. It treats both skin and joints and remains widely used first-line in most of the world on cost grounds. EML yes, listed for rheumatoid arthritis and for skin differentiation and proliferation disorders; off-patent; tens to hundreds of US dollars a year. Sulfasalazine and leflunomide give modest benefit for peripheral arthritis; off-patent and cheap. None of the conventional DMARDs work for axial disease or enthesitis. Hydroxychloroquine is generally avoided, since it may exacerbate psoriasis.

Biologics and targeted therapies, effective across more domains:

| Agent | Class | Measured effect | WHO EML | Biosimilar / generic | Approx. annual cost |
|---|---|---|---|---|---|
| Adalimumab, etanercept, infliximab | Anti-TNF | ACR20 55–65% vs 15–25% placebo; effective for skin, joints, axial disease, enthesitis and dactylitis; inhibit radiographic progression | **adalimumab yes, listed medicine** with psoriasis among its indications; **infliximab only as a therapeutic equivalent** to adalimumab | biosimilars widely available | biosimilars thousands to tens of thousands of US dollars; originators tens of thousands of US dollars |
| Secukinumab, ixekizumab | Anti-IL17A | ACR20 50–60%; excellent skin response | no | no | tens of thousands of US dollars |
| Ustekinumab | Anti-IL12/23 | ACR20 42–50%; good skin response | no | biosimilars entering 2024–25 | US$25,000–60,000, falling† |
| Guselkumab, risankizumab | Anti-IL23 | ACR20 52–64%; strong skin response, unlike in axial disease | no | no | tens of thousands of US dollars |
| Tofacitinib, upadacitinib | JAK inhibitors | ACR20 50–57% | no | tofacitinib generics entering | originator tens of thousands of US dollars; generic potentially below thousands of US dollars |
| Apremilast | PDE4 inhibitor | ACR20 32–40%, modest; oral, no monitoring required | no | generics entering | originator tens of thousands of US dollars; generics far lower |

Treat-to-target: the TICOPA trial (*Lancet* 2015) showed tight control with protocolised escalation improved joint and skin outcomes against standard care. Physiotherapy and exercise for function, axial mobility and enthesitis. Skin and nail care, with dermatology collaboration. Cardiometabolic risk management, since psoriatic disease carries increased cardiovascular risk, metabolic syndrome, fatty liver and depression, which are often the bigger threat to life. Weight loss, which improves disease activity and treatment response measurably.

**Simple means.** Weight loss reduces incidence, improves disease activity and improves biologic response — among the few interventions affecting all three. Exercise maintains function and axial mobility and reduces cardiovascular risk, with no evidence of joint harm.

Methotrexate at tens to hundreds of US dollars a year is manufactured but cheap, off-patent and EML-listed, and treats skin and joints together; for most of the world this with NSAIDs is the realistic regimen. NSAIDs at a few to tens of US dollars a year. Sunlight and natural ultraviolet exposure for psoriasis where appropriate is free phototherapy, with the obvious caution about burning and skin cancer risk. Emollients and simple topical treatments — coal tar, salicylic acid — are cheap and effective for mild skin disease. Smoking cessation and alcohol moderation, for cardiovascular risk and because alcohol worsens psoriasis and complicates methotrexate.

Screening questionnaires such as PEST in psoriasis patients: a piece of paper that finds undiagnosed arthritis years earlier. Free, and arguably the highest-value simple intervention here. Psychological support, since depression prevalence is high in psoriatic disease and independently worsens outcomes.

The honest limit: active erosive or axial disease needs DMARDs or biologics, and nothing simple halts joint destruction.

**Gaps.** No biomarker predicts which psoriasis patients will develop arthritis, despite a years-long window of opportunity. Whether treating the skin prevents arthritis is unresolved and would be highly consequential. The heterogeneity of disease patterns within one label suggests several distinct conditions, and no classification is biologically validated. The smoking paradox is unexplained. Head-to-head biologic trials are few, so positioning across the six domains rests largely on indirect comparison. Apremilast's modest efficacy against its con-

venience is a poorly resolved trade-off. Conventional DMARD evidence is surprisingly weak for a drug class used for decades, since the MIPA trial was equivocal. Psoriatic arthritis is not separately counted in GBD, so global burden is unknown. Data from Africa, Asia and Latin America are sparse.

---

## Osteoporosis and fragility fracture

**What it is.** Bone loses density and structure, so it breaks after minor force. The fractures — hip, spine, wrist — are the disease; the low bone density is only the risk factor. Hip fracture in the old frequently leads to death or permanent loss of independence.

**Measured.** About 500 million people worldwide have osteoporosis, with prevalence by DXA criteria of a T-score of −2.5 or below at roughly 19 to 23 per cent of women and 6 to 8 per cent of men over 50. There are about 9 million fragility fractures a year globally, one every three seconds or so. Lifetime fracture risk after age 50 is about 40 to 50 per cent in women and 13 to 22 per cent in men.

Hip fractures number about 1.6 to 2 million a year globally and are projected to rise to 4.5 to 6 million by 2050 with population ageing, with the greatest increase in Asia†. Hip fracture mortality is high and under-appreciated: about 8 to 10 per cent at 30 days and about 20 to 30 per cent at one year, comparable to many cancers, and about 40 per cent never regain prior mobility while about 20 per cent require long-term care†. Excess mortality persists for years.

Osteoporosis itself is not a separate GBD cause, so its burden appears under falls and fractures. GBD 2019 gave falls, the proximate cause of most fragility fractures, roughly 680,000 deaths and about 39 million DALYs†. GBD 2023 Table 1 gives falls 53.1 million YLDs (95 per cent UI 38.4 to 72.2), rank four, which is 5.4 per cent of all-cause YLDs, and 74.3 million DALYs (58.9 to 95.0), rank eight. The WHO falls fact sheet, printed 26 April 2021 and the oldest in the WHO set, gives 684,000 fatal falls a year, over 80 per cent of them in low- and middle-income countries, 37.3 million non-fatal falls needing medical attention, and over 38 million DALYs, with no data year given for most figures. The WHO musculoskeletal health fact sheet gives 440 million prevalent fracture cases and 26 million YLDs on GBD 2019 data.

Vertebral fractures are the commonest, and about two-thirds are clinically silent and undiagnosed. They are visible on any chest or abdominal radiograph and are routinely unreported — a large missed-opportunity finding.

The treatment gap is the central problem of this field: about 70 to 80 per cent of people at high fracture risk, including after a fragility fracture, receive no osteoporosis treatment, and treatment rates have fallen in several high-income countries over the last fifteen years, largely from fear of rare adverse effects.

Highest age-standardised hip fracture rates are in Northern Europe, particularly Scandinavia; the lowest are in Africa and parts of Latin America. That gradient is not fully explained by bone density.

**Where it starts.** Age and female sex are the dominant non-modifiable factors, and bone loss accelerates sharply at menopause, at about 2 per cent a year of trabecular bone in the early postmenopausal years.

Oestrogen deficiency: menopause, premature ovarian insufficiency, hypothalamic amenorrhoea in athletes and in eating disorders, with potentially irreversible loss of peak bone mass in adolescence, and aromatase inhibitor therapy.

Low peak bone mass, determined in childhood and adolescence by genetics, nutrition, physical activity and pubertal timing. Peak bone mass is reached by about 20 and about 90 per cent is accrued by age 18†, so adolescence is the critical window and inactivity or undernutrition then has lifelong consequences.

Glucocorticoids are the commonest drug cause: 5 mg of prednisolone daily or more for three months or more substantially raises fracture risk, and the risk rises within months, before much bone density is lost, because steroids also impair bone quality. Under-recognised and under-treated.

A previous fragility fracture is the single strongest clinical predictor: it roughly doubles the risk of a further fracture, and the risk is highest in the first one to two years — imminent fracture risk — which argues for immediate treatment after a fracture.

Smoking; excess alcohol at three units a day or more; low body weight with BMI under 20; physical inactivity; and falls risk, which is substantially separable from bone density and equally important. Parental hip fracture and family history.

Secondary causes are present in about 30 per cent of women and over 50 per cent of men with osteoporosis† and are frequently missed: hyperparathyroidism, hyperthyroidism, coeliac disease, inflammatory bowel disease, chronic kidney disease, chronic liver disease, myeloma, rheumatoid arthritis, hypogonadism, diabetes of both types — and type 2 raises fracture risk despite normal or high bone density, an important trap — anorexia nervosa, bariatric surgery, vitamin D deficiency and immobility. Drug causes: glucocorticoids, aromatase inhibitors, androgen deprivation therapy, anticonvulsants, PPIs, which is weak and contested, SSRIs, thiazolidinediones, heparin and depot medroxyprogesterone.

Heritability is high: bone mineral density heritability is about 60 to 85 per cent in twin studies, while fracture risk itself is less heritable at about 25 to 35 per cent, because falls and environment intervene. GWAS has identified over 500 bone-mineral-density loci — *WNT16*, *LRP5*, *ESR1*, *SOST*, *RANKL/RANK/OPG* — and the *SOST* and *LRP5* biology led directly to romosozumab.

What is not known is why the geographic gradient in hip fracture rates is so large and not explained by bone density. Why type 2 diabetes raises fracture risk despite higher bone density — bone quality rather than quantity, but the mechanism is unclear. The optimal duration of bisphosphonate therapy, and the biology of atypical femoral fracture and osteonecrosis of the jaw, both rare and both disproportionately influential on prescribing. Why treatment rates are falling despite strong evidence. And how to measure bone quality rather than density.

**Cure status.** CONTROLLABLE, and substantially preventable. The fractures, not the density, are the target.

Bone density can be increased, by 5 to 10 per cent with bisphosphonates over three years† and more with anabolic agents, and fracture risk reduced by 40 to 70 per cent† depending on agent and fracture site.

It is not curable: the underlying bone loss tendency persists, and bone density falls again after stopping treatment — rapidly after denosumab, with rebound vertebral fracture risk if it is stopped without follow-on therapy, which is an important safety issue, and slowly after bisphosphonates, which persist in bone and so permit drug holidays.

An established fracture is treatable, and hip fracture surgery restores mobility for many, but about 40 per cent never regain prior function, so the damage is partly irreversible.

Reversible in specific cases: treating hyperparathyroidism, coeliac disease, hyperthyroidism or hypogonadism, or restoring energy availability and weight in hypothalamic amenorrhoea or anorexia nervosa, can substantially recover bone — though bone mass lost during adolescence may never be fully regained.

**Prevention.** Weight-bearing and resistance exercise: STRONG for bone density and, more importantly, for falls prevention. Progressive resistance and high-impact training increase or maintain bone mineral density, and balance and strength training reduces falls by about 20 to 25 per cent, with tai chi and multicomponent programmes having the best evidence (Cochrane). Falls reduction may matter more than density for fracture prevention in the very old.

Adequate calcium and vitamin D: MODERATE, with the honest version given under simple means. Correcting deficiency matters; supplementing the already-replete does little.

Smoking cessation and alcohol moderation: MODERATE. Adequate protein and energy intake, and avoiding underweight: MODERATE, especially in the elderly, where protein-energy malnutrition and sarcopenia drive both falls and fracture.

Falls prevention programmes: STRONG — exercise, medication review, especially of psychotropics, antihypertensives and anticholinergics, vision correction, home hazard modification and footwear. Multifactorial programmes reduce falls meaningfully.

Glucocorticoid-sparing strategies, and bone protection whenever three months or more of 5 mg or more of prednisolone is prescribed: STRONG, and widely neglected. Hip protectors: MODERATE in care home populations, reducing hip fracture when worn, with adherence the limiting factor.

Maximising peak bone mass in childhood and adolescence through activity and nutrition: MODERATE on physiological grounds — the most upstream intervention available.

Fracture Liaison Services, or fracture liaison nurses, for secondary fracture prevention: STRONG and cost-effective. Systematically identifying and treating everyone presenting with a fragility fracture is the highest-yield system intervention, and it closes the treatment gap.

Case-finding with FRAX, with or without DXA: STRONG in targeted populations; universal screening is debated, though the UK SCOOP trial showed community screening reduced hip fractures. Menopausal hormone therapy: STRONG for fracture prevention, since WHI showed reduced hip and total fractures, though it is not used primarily for this indication in most guidelines except in early menopause or premature ovarian insufficiency, where it is essential.

**Treatment.** Bisphosphonates are first line, and extremely cheap.

Alendronate, taken weekly by mouth, reduces vertebral fracture by about 45 to 50 per cent, hip fracture by about 40 to 53 per cent and non-vertebral fracture by about 20 to 25 per cent in those with prior fracture or osteoporosis (the FIT trial). Risedronate is similar. Zoledronic acid, as an annual intravenous infusion, reduces vertebral fracture by about 70 per cent and hip fracture by about 41 per cent, and in the HORIZON Recurrent Fracture Trial after hip fracture it reduced new clinical fractures by 35 per cent and all-cause mortality by 28 per cent — a mortality benefit, which is notable. Annual dosing solves the adherence problem, and adherence to oral bisphosphonates is poor, at about 50 per cent at one year†.

Both are off-patent. Alendronate costs tens of US dollars a patient-year generically; zoledronic acid tens to hundreds of US dollars per annual infusion generically, plus administration. Alendronate at a few US dollars a month to prevent a hip fracture is among the most cost-effective interventions in medicine.

*And no bisphosphonate is on the WHO Essential Medicines List for osteoporosis.* This was checked live against the electronic EML, twice, and it is not a retrieval artefact.

Alendronate is not on the 24th List (2025) in any form. A direct query of the electronic EML returns “Found 0 recommendations for 0 medicines and 0 therapeutic equivalents”, and every filter count on the page is zero, so the zero is not a filter artefact.

Zoledronic acid is on the list, but only under Supportive medicines, section 8.2.5, in the complementary list, for malignant neoplasm metastasis in bone or bone marrow, and for osteogenesis imperfecta. The word osteoporosis does not appear on its record.

So the most cost-effective fracture-prevention drug class in medicine is absent from the Essential Medicines List for its main indication. A drug costing a few US dollars a month, which reduces hip fracture by 40 to 53 per cent in a condition whose hip fractures kill 20 to 30 per cent of those who sustain them within a year, is not a selected essential medicine for that use anywhere on the list. The consequence is practical rather than rhetorical: health systems that build their procurement and their formularies from the EML have no listing to build from for the main indication, and the treatment gap already runs at 70 to 80 per cent. The figures are set out and left to stand.

Adverse effects of the bisphosphonates: oesophagitis with the oral preparations, where dosing instructions matter; an acute-phase reaction with the intravenous; and the rare but much-feared atypical femoral fracture, at about one per 10,000 to 100,000 patient-years, and osteonecrosis of the jaw, at about one per 10,000 to 100,000 at osteoporosis doses and far higher at oncology doses†. The absolute benefit vastly exceeds these risks in those at high fracture risk, and falling treatment rates are documented.

Denosumab, six-monthly subcutaneous anti-RANKL, reduces vertebral fracture by 68 per cent, hip by 40 per cent and non-vertebral by 20 per cent (FREEDOM), and is suitable in renal impairment. The critical caveat is that it must not be stopped without transitioning to a bisphosphonate, because rebound bone loss and multiple vertebral fractures occur. Biosim-

ilars became available in 2024 and 2025, reducing cost from about US$1,500 to 3,000 a year toward a few hundred†.

Anabolic agents, for severe and very high risk disease. Teriparatide, PTH 1-34, daily injection for eighteen to 24 months, reduces vertebral fracture by 65 per cent and non-vertebral by 53 per cent, and was superior to risedronate for vertebral fracture in the VERO trial. It is now off-patent with biosimilars, and cost has fallen from tens of thousands of US dollars a year to thousands of US dollars or less. Abaloparatide. Romosozumab, anti-sclerostin, for twelve months, was superior to alendronate in ARCH, with 48 per cent fewer vertebral fractures than alendronate†, but a cardiovascular safety signal led to a boxed warning and to avoidance within a year of myocardial infarction or stroke; on patent, tens of thousands of US dollars a year. Sequence matters: anabolic first, then antiresorptive, gives better bone density outcomes than the reverse, and this is often got wrong.

Hormonal: menopausal hormone therapy, effective, cheap and off-patent; raloxifene, which reduces vertebral fracture only, with breast cancer risk reduction and venous thromboembolism risk; testosterone in hypogonadal men.

Calcium and vitamin D as an adjunct to ensure repletion, not as stand-alone therapy. Calcium carbonate and colecalciferol EML-listed, off-patent, a few to tens of US dollars a year. Treat the secondary causes, present in about 30 to 50 per cent.

Hip fracture care is where mortality is determined. Surgery within 24 to 48 hours reduces mortality and complications. Orthogeriatric co-management reduces mortality, delirium and length of stay, and is one of the best-evidenced service interventions in geriatric medicine. Early mobilisation, delirium prevention, nutritional support, analgesia including nerve blocks, and bone protection started before discharge. Fascia iliaca and femoral nerve blocks reduce opioid use and delirium, and are cheap.

Vertebral fracture: analgesia, early mobilisation, occasional bracing. Vertebroplasty and kyphoplasty are CONTESTED — sham-controlled trials (INVEST, Buchbinder, VERTOS IV) were largely negative, though some argue for benefit in acute severe pain. Falls prevention and medication review are integral, not optional.

**Simple means.** Weight-bearing and resistance exercise maintains bone and, crucially, reduces falls by about 20 to 25 per cent: progressive resistance training, balance work, and tai chi, which has good trial evidence for falls. Free, and effective into very old age.

Falls prevention at home: removing loose rugs and clutter, improving lighting, grab rails, correcting vision, sensible footwear, and reviewing sedating drugs. Cheap or free, and it addresses the proximate cause of most fractures. Medication review alone — stopping psychotropics and unnecessary antihypertensives — measurably reduces falls.

Adequate dietary calcium from dairy, tinned fish with bones, calcium-set tofu, green leaves, sesame and fortified foods; and adequate protein, which is at least as important and routinely under-consumed by the elderly.

Vitamin D, the honest version. Correcting deficiency, which is common in the housebound, the veiled, the dark-skinned at high latitude and the institutionalised, improves bone and muscle function. But calcium and vitamin D supplementation in community-dwelling, replete adults does not meaningfully reduce fractures: multiple large trials and meta-analyses are negative. And high-dose intermittent vitamin D, in annual or monthly mega-doses, increases falls and fractures. So identify and treat deficiency, do not supplement indiscriminately, and avoid mega-doses. Sunlight exposure is free where latitude and culture permit.

Smoking cessation and limiting alcohol. Maintaining healthy weight and avoiding underweight. Childhood and adolescent physical activity — jumping, running, sport — is the cheapest possible intervention, with a lifelong effect on peak bone mass. Hip protectors in care homes.

Looking at existing radiographs for vertebral fractures: two-thirds are silent and already visible on films taken for other reasons, and reporting them costs nothing and identifies people at high imminent risk.

Alendronate at tens of US dollars a year is manufactured, but so cheap and effective that it belongs in any discussion of accessible prevention — and it is not on the Essential Medicines List. Asking about falls and prior fractures is a question, and the best risk predictor available.

**Gaps.** The 70 to 80 per cent treatment gap is the dominant problem, and it is a behavioural and system failure rather than a knowledge gap, and the rare harms are quantitatively dwarfed by fracture risk.

No bisphosphonate is on the WHO EML for osteoporosis: alendronate returns zero results and zoledronic acid is listed only for bone metastases and osteogenesis imperfecta, both verified live against the electronic EML. That is a significant omission for the most cost-effective drug class here, and a barrier to procurement in systems that follow the list.

Optimal bisphosphonate duration and drug-holiday strategy are not established. The biology of atypical femoral fracture and jaw osteonecrosis is unclear. Bone quality cannot be measured clinically, which is why diabetic fracture risk is missed by DXA. The geographic gradient in hip fracture rates is unexplained. Vertebroplasty evidence is contradictory between sham-controlled and open trials. Screening strategies differ between countries without clear resolution. Data on fracture incidence from Africa, South Asia and Latin America are sparse, though the projected growth in hip fracture is concentrated there. Men are substantially under-diagnosed and under-treated despite worse outcomes after hip fracture.

---

## Gout

*Gout is classified in ICD-11 under Chapter 15, diseases of the musculoskeletal system or connective tissue, as well as having metabolic aspects. This entry covers its musculoskeletal presentation.*

**What it is.** Uric acid crystallises in a joint and causes a sudden, severe attack of inflammation, classically in the big toe. Over years crystals build into lumps and damage joints. It is caused by too much urate in the blood, and it is curable.

**Measured.** Global prevalence is about 1 to 4 per cent of adults with wide variation, and GBD 2019 and 2021 estimated about 55 to 56 million people with gout. The WHO musculoskeletal health fact sheet gives 54 million prevalent cases and 1.7 million YLDs on GBD 2019 data. GBD 2019 gave gout roughly 1.7 to 2 million DALYs; directly attributable deaths are few, though gout is associated with excess cardiovascular and renal mortality.

Prevalence has roughly doubled over recent decades in many countries, tracking obesity, metabolic syndrome, diuretic use and ageing. The male to female ratio is about 3 to 4:1 overall; in women gout is largely post-menopausal, since oestrogen is uricosuric, so the ratio narrows sharply after 60.

The highest prevalence recorded is in the Indigenous populations of Oceania: Māori and Pacific Islander populations in New Zealand have prevalences of about 6 to 8 per cent and higher in men, with some estimates above 10 per cent, reflecting genetically determined reduced renal urate excretion plus dietary and socioeconomic factors; rates are also high in Taiwanese Indigenous groups. Incidence rises with age, with a peak at 40 to 60 in men. Gout is the most common inflammatory arthritis in men over 40†.

**Where it starts.** Hyperuricaemia is necessary and not sufficient: most people with raised urate never develop gout. Risk rises steeply above a serum urate of about 0.36 mmol/L (6 mg/dL), the approximate saturation point, and that threshold is the basis of the treatment target.

Renal underexcretion accounts for about 90 per cent of hyperuricaemia and overproduction for about 10 per cent†. That is the key physiological point and it is largely genetic.

Genetics are dominant and often underappreciated. *SLC2A9* and *ABCG2* are the major loci, together explaining a substantial share of population urate variance, with *SLC22A12* (URAT1), *SLC17A1* and others contributing. Heritability of serum urate is about 40 to 70 per cent, and of gout itself about 30 to 60 per cent in twin and family studies. *ABCG2* variants are particularly prevalent in Polynesian populations, which largely explains the Oceanic prevalence rather than diet, contrary to persistent and stigmatising assumptions.

Diuretics — thiazides and loop diuretics — are a major and reversible cause, raising urate substantially; also ciclosporin, tacrolimus, low-dose aspirin, pyrazinamide and ethambutol. Chronic kidney disease, through reduced excretion, bidirectionally. Obesity and metabolic syndrome, dose-dependently, since insulin resistance reduces renal urate excretion. Alcohol,

with beer worst because it is purine-rich as well as alcoholic, then spirits, with wine least; dose-dependently.

Diet: red meat, organ meat, shellfish, and fructose and sugar-sweetened beverages, which is a strong and well-replicated association. But diet explains far less of urate variance than genetics does: a large genomic analysis found food items explained under 1 per cent of urate variance against about 24 per cent for a genetic score (Major, *BMJ* 2018). That matters for how patients are counselled. Gout has long been moralised as a disease of dietary indulgence, and the evidence does not support that framing.

Protective: dairy, especially low-fat; coffee; vitamin C; cherries, on modest evidence; losartan and calcium channel blockers, which are uricosuric antihypertensives; and SGLT2 inhibitors, which lower urate and reduce gout flares.

What is not known is why most hyperuricaemic people never develop gout, and what triggers crystallisation and the inflammatory flare at a particular moment. Whether asymptomatic hyperuricaemia should be treated, where the current answer is generally no. And whether urate-lowering therapy reduces cardiovascular and renal events: the large CKD-FIX and PERL trials were negative for kidney outcomes, the cardiovascular question remains open, and the benefit of treating urate outside gout is unproven.

**Cure status.** CONTROLLABLE.

Gout is one of the few chronic rheumatic diseases in which treatment can remove all flares and tophi in essentially every patient while it continues. Sustained lowering of serum urate below about 0.30 to 0.36 mmol/L dissolves the existing crystal deposits, after which flares cease entirely and tophi resolve. Patients become symptom-free indefinitely while treatment continues.

Treatment must usually be lifelong, since urate rises again if it is stopped, so the disease is held and not removed. A correctly treated gout patient has no flares. Acute flares are also SELF-LIMITING: untreated attacks resolve over one to two weeks.

The gap between what is achievable and what is delivered is extreme. Adherence to urate-lowering therapy is among the worst of any chronic disease, at about 30 to 50 per cent, and many patients are never offered it, or are kept on sub-therapeutic doses without urate monitoring. Gout is a cheap, controllable disease that is badly treated almost everywhere: a care-delivery failure, not a scientific one.

**Prevention.** Urate-lowering therapy to target in established gout: STRONG. It prevents all further flares and tophus formation, as secondary prevention that is near-complete.

Reviewing and substituting diuretics where clinically possible: STRONG. Swapping a thiazide for an alternative antihypertensive, or choosing losartan or a calcium channel blocker, both mildly uricosuric, or an SGLT2 inhibitor in diabetes, removes a major cause.

Weight management: MODERATE, with dose-dependent reduction in urate and flares. Reducing alcohol, especially beer: MODERATE. Reducing sugar-sweetened beverages and fructose: MODERATE. Dairy and coffee intake: WEAK, on protective associations.

Dietary purine restriction: WEAK, and this needs honest statement. Strict purine restriction lowers urate by only around 0.06 to 0.12 mmol/L (1 to 2 mg/dL) at best, usually insufficient to reach target, and it is poorly tolerated and poorly adhered to. Diet is a useful adjunct, not a substitute for allopurinol, and presenting it as the primary treatment leaves patients with ongoing joint damage.

Treating asymptomatic hyperuricaemia: not recommended, CONTESTED — no demonstrated benefit, and the renal outcome trials were negative. Flare prophylaxis when starting urate-lowering therapy: STRONG. Low-dose colchicine or an NSAID for the first three to six months prevents the paradoxical early flares that otherwise cause patients to abandon treatment. A key and frequently omitted step.

**Treatment.** For an acute flare, treat early and hard; any of three options works.

NSAIDs — naproxen, indomethacin, diclofenac — at full dose are effective; off-patent, EML-listed, a few US dollars a course.

Colchicine: low dose is as effective as high dose and far better tolerated. The AGREE trial established 1.2 mg then 0.6 mg, a total of 1.8 mg, as equivalent to the old high-dose regi-

men with dramatically less diarrhoea. Dose-reduce in renal impairment and with interacting drugs — clarithromycin, ciclosporin, statins. Off-patent, though a notorious US pricing exception when it was granted market exclusivity, which raised the price of an ancient drug roughly fiftyfold; a few to tens of US dollars a course generically, far more in some markets. Colchicine is EML-listed.

Corticosteroids: oral prednisolone, for example 30 to 35 mg for five days, is equivalent to NSAIDs in randomised trials, and is the option of choice in renal impairment, where NSAIDs are contraindicated. Intra-articular steroid for a single accessible joint. Off-patent, EML-listed, a few US dollars a course.

IL-1 inhibitors, canakinumab and anakinra, for refractory flares with contraindications to all the above; very expensive, with canakinumab at tens of thousands of US dollars or more a dose.

Do not start or stop urate-lowering therapy because of a flare: it can be started during a flare, since trials show this is safe and improves uptake, and it should never be interrupted.

Urate-lowering therapy is the curative element, and allopurinol is first line and the key drug. It is a xanthine oxidase inhibitor, and the dose is titrated upward to achieve a target serum urate below 0.36 mmol/L (6 mg/dL), or below 0.30 mmol/L (5 mg/dL) with tophi. Treat-to-target dose escalation, not a fixed 300 mg dose, is what works, and failure to titrate is the commonest treatment error; doses up to 900 mg may be needed.

WHO EML: yes. Allopurinol is a listed medicine under medicines used to treat gout, section 29.1, and separately as a supportive medicine for tumour lysis syndrome, section 8.2.5 complementary. Off-patent. Cost tens of US dollars a patient-year, and in many markets tens of US dollars. Note a discrepancy between dossiers: another chapter of this book gives US$5 to 20 a patient-year for allopurinol, dated 2024. The two ranges overlap and are not the same, and both are printed.

That is the central economic fact of this entry: a disease that destroys joints and causes severe recurrent pain is permanently controlled by a drug costing a few dollars a year, on the Essential Medicines List, available everywhere.

On safety: allopurinol hypersensitivity syndrome is rare and serious, presenting as severe cutaneous adverse reaction or DRESS. Risk is strongly associated with HLA-B*58:01, which is prevalent in Han Chinese, Thai and Korean populations, and screening for HLA-B*58:01 before starting allopurinol is recommended in these groups and is cost-effective there. Starting at a low dose, 100 mg, or 50 mg in renal impairment, and titrating slowly reduces risk.

Febuxostat is an alternative xanthine oxidase inhibitor, effective and useful in allopurinol intolerance. The CARES trial (*NEJM* 2018) found higher cardiovascular and all-cause mortality against allopurinol, which led to regulatory warnings; the subsequent FAST trial (*Lancet* 2020) did not confirm this and found non-inferiority. The two trials disagree and the issue is genuinely unresolved; both are printed. Now off-patent in many markets; tens to hundreds of US dollars a year.

Uricosurics — probenecid, benzbromarone, which is potent but carries hepatotoxicity concerns and is unavailable in some countries, and sulfinpyrazone; lesinurad was withdrawn commercially — are useful as add-ons. Probenecid off-patent and cheap. Pegloticase, recombinant uricase, for severe refractory tophaceous gout, rapidly dissolves deposits; very expensive at hundreds of thousands of US dollars or more a year and immunogenic, with methotrexate co-therapy improving response. Reserved for a tiny minority.

Monitoring: serum urate measurement to confirm target attainment is a cheap blood test and the single most important process measure. Treating gout without measuring urate is the equivalent of treating hypertension without a blood pressure cuff.

Nurse-led gout care: the Doherty trial (*Lancet* 2018, 517 patients) showed nurse-led treat-to-target care with patient education achieved the urate target in 95 per cent at two years against 30 per cent with usual general practice care, with fewer flares and resolution of tophi. A striking result: the problem is care organisation, not pharmacology, and the fix is cheap and task-shareable.

Manage the comorbidity: hypertension, chronic kidney disease, diabetes, cardiovascular risk and obesity, choosing urate-friendly antihypertensives.

**Simple means.** Allopurinol at tens of US dollars a year is manufactured but EML-listed, off-patent, and among the cheapest curative therapies in all of medicine. It belongs in any minimal essential formulary.

Measuring serum urate and titrating to target is a cheap blood test plus dose adjustment, and it is the intervention that converts partial control into complete control.

Patient education: explaining that gout is caused mainly by inherited reduced renal urate excretion, not by moral dietary failure, and that it is curable with a cheap daily tablet taken lifelong. The Doherty trial shows education plus nurse-led titration achieves 95 per cent target attainment†. That is a conversation, and it is the most effective intervention in this entry after the drug itself.

Reviewing diuretics, substituting a thiazide, often removes the cause entirely: free, and frequently curative in itself. Weight loss, and reducing alcohol, especially beer, and sugar-sweetened drinks: adjunct measures with real but modest effect. Dairy and coffee, on protective associations, as ordinary foods. Rest, elevation and ice to the affected joint during an acute flare, with ice reducing pain measurably in a small randomised trial; free. Cheap prednisolone or an NSAID for the flare, at a few US dollars. Flare prophylaxis with low-dose colchicine when starting allopurinol, which prevents the early flares that cause patients to stop treatment.

The honest framing: unlike most entries here, the simple means are not the main treatment. The main treatment is a very cheap tablet. The simple means that matters most is organising care properly and explaining it, which the trial evidence shows raises target attainment from 30 per cent to 95 per cent.

**Gaps.** The gap between a curable disease and the observed treatment quality is the dominant issue, and it is behavioural and organisational. Adherence is among the worst in medicine and poorly understood. Febuxostat cardiovascular safety is unresolved, with CARES and FAST disagreeing. Whether to treat asymptomatic hyperuricaemia is unsettled, and the renal outcome trials, CKD-FIX and PERL, were negative. Whether urate lowering reduces cardiovascular events is unknown. Why only a minority of hyperuricaemic people get gout, and what triggers a flare, are unexplained. The stigmatising dietary narrative persists despite genetic evidence that diet explains under 1 per cent of urate variance — a communication failure with real consequences for care-seeking. HLA-B*58:01 screening is cost-effective in high-prevalence populations and inconsistently implemented. Gout burden data from Africa and much of Asia are sparse. The two allopurinol price ranges carried in this book differ and are both printed.

---

## Fibromyalgia

**What it is.** Widespread body pain with fatigue, unrefreshing sleep and difficulty thinking, lasting months or years. No joint or muscle damage is found. It is now understood as altered pain processing in the nervous system.

**Measured.** Prevalence is about 2 to 4 per cent of the general population, with estimates ranging from 0.2 to 6.6 per cent depending on criteria, since the Wolfe 1990 tender-point criteria and the 2010, 2011 and 2016 symptom-based criteria give substantially different figures. It is not a separate GBD cause and sits within other musculoskeletal disorders, so its global burden is effectively uncounted despite substantial disability.

Deaths: none directly, though suicide risk is elevated. The female to male ratio is about 2 to 3:1 under the newer criteria, much lower than the roughly 9:1 ratio given by the old tender-point criteria, which systematically under-identified men because men report fewer tender points. That is a measurement-artefact correction worth noting, because the figure of nine out of ten being women is still widely quoted and is wrong.

Peak age is 30 to 55, though it occurs in children and the elderly. Comorbidity is high: it is present in about 10 to 30 per cent of patients with rheumatoid arthritis, lupus, axial spondyloarthritis and osteoarthritis, where it is frequently mistaken for inflammatory disease activity, leading to inappropriate escalation of immunosuppression. That is clinically important. It is reported everywhere, and apparent variation reflects criteria and clinical recognition more than true difference.

**Where it starts.** Central sensitisation, or nociplastic pain, is the current mechanistic model, supported by measurable findings: augmented central pain processing on functional MRI, reduced descending inhibition, raised cerebrospinal substance P, altered neurotransmitter balance, and small fibre neuropathy demonstrated in about 30 to 50 per cent of patients on skin biopsy, a finding of uncertain significance.

Female sex and family history: first-degree relatives have about eight times the risk, and heritability is estimated at about 50 per cent, with implicated genes in serotonin, dopamine and catecholamine pathways — *COMT*, *5-HTT* — though none robustly replicated.

Triggers: physical trauma including whiplash and surgery; infection, with Epstein-Barr virus, Lyme disease and notably post-COVID illness; emotionally stressful events. Adverse childhood experiences, abuse and trauma are consistently associated with substantial effect sizes, and post-traumatic stress disorder is frequently comorbid.

Sleep disturbance is bidirectional and probably causal in part: experimental sleep deprivation in healthy people produces fibromyalgia-like symptoms and lowers pain thresholds.

Comorbid conditions: irritable bowel syndrome, chronic fatigue syndrome and ME, temporomandibular disorder, chronic headache, interstitial cystitis, endometriosis — the central sensitivity syndromes, which overlap heavily and are probably facets of one process. Obesity, physical inactivity, and depression and anxiety, bidirectionally.

What is not known is the cause. Whether it is one condition or several. Why some people develop central sensitisation after a trigger and others do not. The significance of the small fibre findings, whether causal, consequential or incidental. Why women predominate. Crucially, the diagnosis rests entirely on symptom report with no biomarker, and the criteria have changed three times, which means prevalence, trial populations and outcome data are not comparable across eras. The condition's legitimacy was contested for decades, which shaped the literature and the patient experience; it is now accepted as a real disorder of pain processing.

**Cure status.** RELIEF ONLY, and this is stated plainly, because false promises are a documented harm in this condition.

No treatment cures fibromyalgia. All established treatments produce small to moderate average effects on pain, function and quality of life. Drug effect sizes are small: numbers needed to treat of about 7 to 14 for a 30 to 50 per cent pain reduction with the best-supported agents, duloxetine, pregabalin and amitriptyline, and discontinuation for adverse effects is common. Exercise and the non-pharmacological approaches have comparable or better effect sizes with fewer harms.

Substantial improvement is achievable and common: many patients achieve good function and quality of life with a combination of exercise, psychological approaches, sleep management and modest drug support. Full remission occurs and is not the norm. Prognosis is better in children and adolescents, where recovery rates are higher. And the diagnosis itself helps: receiving a clear explanation reduces healthcare utilisation and distress, and ends the cycle of fruitless investigation.

**Prevention.** No established primary prevention: absent. Treating sleep disorders: WEAK, mechanistically supported. Early active management after trauma or whiplash, and avoiding prolonged immobilisation and over-investigation: WEAK. Addressing adverse childhood experiences and trauma: plausible and not demonstrated as prevention. Physical activity: WEAK as prevention, STRONG as treatment. Avoiding iatrogenic harm — opioid initiation, repeated negative investigation, diagnostic limbo: MODERATE as prevention of chronicity and disability, and a real and achievable preventive measure.

**Treatment.** All major guidelines — EULAR 2016, Canadian, German S3 — agree: non-pharmacological treatment first, with drugs as adjuncts. EULAR's only "strong for" recommendation is exercise.

Exercise is the single strongest recommendation and the only one EULAR grades strong. Aerobic exercise improves pain, function, fatigue and quality of life on moderate-quality Cochrane evidence; start low and go slow, because too-rapid progression causes flares and drop-out, which is the usual reason it appears to fail. Resistance and strength training improves pain, function and strength. Aquatic exercise is well tolerated with good evidence, warm water particularly. Tai chi, yoga and qigong have trial evidence of benefit compara-

ble to aerobic exercise, and one randomised trial found tai chi equal or superior to aerobic exercise (Wang, *BMJ* 2018). The cost is free to low.

Patient education and explanation of central sensitisation: pain neuroscience education improves outcomes and reduces catastrophising, and the diagnosis itself is therapeutic. Cognitive behavioural therapy gives small to moderate, durable effects on pain, mood, function and sleep; acceptance and commitment therapy is also supported. Sleep intervention, CBT for insomnia, improves sleep and pain, and is often neglected despite unrefreshing sleep being a core feature. Multicomponent and multidisciplinary rehabilitation, combining exercise, psychological therapy and education, is the best-supported overall package.

Drugs, adjunctive with modest effects. Amitriptyline at low dose, 10 to 50 mg at night, is a long-standing first-line in practice and helps pain and sleep; off-patent; EML-listed as an antidepressant; a few to tens of US dollars a patient-year. The cheapest option, with reasonable evidence. Duloxetine, an SNRI, is the best-evidenced, with a number needed to treat of about 7 to 8 for 30 per cent pain reduction†; off-patent; tens to hundreds of US dollars a year. Milnacipran is similar and not available in all markets. Pregabalin has a number needed to treat of about 8 to 10†, with sedation, weight gain and dizziness, and misuse potential that has led to control in several countries; off-patent; tens to hundreds of US dollars a year. Gabapentin is used similarly with weaker evidence. Cyclobenzaprine gives modest benefit, mainly on sleep. Low-dose naltrexone has promising small trials and is not yet established; very cheap if confirmed.

NSAIDs and paracetamol are largely ineffective for fibromyalgia pain as monotherapy, since there is no peripheral inflammation to treat, and are commonly prescribed regardless. Opioids are not recommended and are potentially harmful: no evidence of benefit, risk of opioid-induced hyperalgesia which worsens the underlying problem, dependence and worse functional outcomes, with strong guideline recommendations against. Tramadol has weak supportive evidence and is the only partial exception. Corticosteroids and immunosuppressants have no role. Cannabinoids: CONTESTED, insufficient evidence despite widespread use and marketing.

Treat the comorbidities — depression, anxiety, sleep apnoea, irritable bowel syndrome, vitamin D deficiency if present. And in patients with inflammatory arthritis, recognise concurrent fibromyalgia rather than escalating biologics for what is not inflammatory pain: an important and expensive error.

Acupuncture, massage, balneotherapy and mindfulness give small benefits at low risk, and EULAR gives weak positive recommendations to some. Avoid repeated investigation after diagnosis, prolonged rest, and the search for a missed structural cause, all of which cause harm.

**Simple means.** This condition is managed almost entirely by simple means, and they outperform the drugs.

Graded aerobic exercise is the strongest recommendation in every guideline: walking, cycling, swimming. Start at a level well below what the patient thinks they should manage and increase very gradually; this single principle determines success or failure. Free. Strength training, with body weight or resistance bands, improves pain and function. Tai chi, yoga and qigong have trial evidence equal or superior to aerobic exercise (Wang, *BMJ* 2018), and need instruction and space. Warm water exercise, or simply warm baths, is well tolerated and symptomatically helpful. Sleep hygiene and CBT for insomnia address a core driver and are deliverable as self-help.

Pain neuroscience education — explaining that the pain is real, that it reflects a sensitised nervous system rather than tissue damage, and that activity is safe and therapeutic — is free, and one of the most effective single interventions. Pacing and activity management, to avoid the boom-and-bust cycle, is a taught skill. Mindfulness and relaxation training. Peer support groups, since the condition carries substantial disbelief and stigma, and validated support measurably improves coping. Amitriptyline at a few to tens of US dollars a year: if a drug is used, the cheapest has reasonable evidence.

Not taking opioids, not undergoing repeated investigation, and not escalating biologics for fibromyalgia in inflammatory arthritis: three evidence-based omissions that prevent harm and save substantial money.

The honest framing: no simple means cures this, and overpromising is harmful. But the interventions with the best evidence are also the cheapest, and the expensive drugs add little.

**Gaps.** No biomarker, no objective diagnostic test, and criteria that have changed three times, so prevalence estimates span 0.2 to 6.6 per cent and the literature is not comparable across eras. The mechanism is partly characterised as central sensitisation, and the cause is unknown. The significance of small fibre neuropathy findings in 30 to 50 per cent of patients is unresolved and potentially important. All treatment effects are small, and most trials are short, small, and have high drop-out and high placebo response. Long-term outcome data are limited. Whether fibromyalgia, ME/CFS, irritable bowel syndrome and the other central sensitivity syndromes are one condition or several is unresolved and consequential for research. Post-COVID fibromyalgia-like illness is a large new and poorly characterised group. The condition is not counted in GBD, so global burden is unknown. Research funding is low relative to prevalence and disability. Male fibromyalgia is under-studied.

---

## Rotator cuff disorders

**What it is.** The tendons that hold and move the shoulder become painful, degenerate or tear. Reaching overhead and lying on the shoulder hurt. Most tears are degenerative rather than traumatic, and many cause no symptoms at all.

**Measured.** Shoulder pain affects about 7 to 26 per cent of adults at any time, and rotator cuff disorders are the commonest cause, accounting for about 70 per cent of shoulder pain presentations†.

Full-thickness rotator cuff tear prevalence rises steeply with age and is frequently asymptomatic. In population imaging studies, roughly 10 per cent under 50, 20 to 25 per cent over 60, 30 to 50 per cent over 70, and over 50 to 60 per cent over 80 have a tear — and about a third to two-thirds of these are painless†. Yamamoto's and Minagawa's population studies are the standard references. That is the key epidemiological fact and it mirrors the spine: structural abnormality is largely age-normal, so finding a tear does not establish it as the cause of pain.

It is not separately modelled in GBD and falls within other musculoskeletal disorders. Deaths: none. Degenerative tears accumulate from the fifth decade, and traumatic tears occur at any age. The sexes are roughly equal, with a slight male predominance for traumatic tears. Occupational prevalence is high in overhead workers — painters, construction, assembly — and in overhead athletes.

Rotator cuff repair and subacromial decompression are high-volume operations, and rates have risen several-fold in many countries over two decades — a rise not matched by evidence of benefit for decompression.

**Where it starts.** Age is the dominant factor, through tendon degeneration with reduced vascularity, altered collagen and impaired healing capacity. Overhead and repetitive loading, occupational and athletic. Smoking, which impairs tendon vascularity and healing and is associated with larger tears and worse repair outcomes. Diabetes, strongly associated with tendinopathy generally and with poorer healing, and also with adhesive capsulitis. Hypercholesterolaemia and metabolic syndrome, with consistent associations suggesting a metabolic component to what was assumed purely mechanical. Acromial morphology and subacromial anatomy — critical shoulder angle, acromial index — are associated, though the causal impingement model has been substantially revised. Family history is significant: siblings of patients with full-thickness tears have roughly two to five times the risk, and a genetic contribution is established though heritability is not precisely quantified. Trauma, in a minority, giving acute tears in younger patients.

The impingement model has largely been abandoned as a causal explanation. The idea that the acromion mechanically abrades the tendon, which justified decades of subacromial decompression surgery, is not supported: tendinopathy appears to be primarily a degenerative and load-related process, and surgical reshaping of the acromion does not outperform placebo. A significant conceptual reversal.

What is not known is why some tears hurt and others do not — the single most important gap, since it determines whom to treat. Why tear size and pain correlate poorly. What drives tendon degeneration at a molecular level, and why healing capacity is so limited. And why repairs that fail structurally, with re-tear rates of 20 to 60 per cent depending on size, often still produce good clinical outcomes — an awkward finding for the repair rationale.

**Cure status.** Degenerative tears, the great majority: CONTROLLABLE. Pain and function improve with exercise-based rehabilitation while the tear remains, degenerative tears do not heal spontaneously, and structural healing is not what produces the symptomatic improvement.

Acute traumatic tears in younger active patients: CURABLE, where repair is indicated and effective.

Cuff-tear arthropathy, and irreparable tears with pseudoparalysis: CURABLE by reverse total shoulder arthroplasty — a genuine functional cure for a previously untreatable problem.

Many people improve substantially with exercise-based rehabilitation, and symptomatic improvement does not require structural healing. Degenerative tears do not heal spontaneously, and tears tend to enlarge slowly over years in a minority, though enlargement does not reliably produce symptoms. Surgical repair achieves structural healing in many, but re-tear rates are 20 to 60 per cent, higher with larger tears, older patients, smokers and diabetics, and clinical outcomes of repair are not clearly superior to structured exercise for most degenerative tears.

Adhesive capsulitis, frozen shoulder, is a frequent differential diagnosis rather than a rotator cuff disorder, and it is genuinely SELF-LIMITING over one to three years, though often with residual restriction.

**Prevention.** Exercise and scapular and cuff strengthening: MODERATE, reducing shoulder pain incidence in overhead workers and athletes in workplace trials. Reducing overhead and repetitive loading, job rotation, workstation modification: MODERATE. Smoking cessation: MODERATE, affecting tendon health and healing. Diabetes and metabolic control: MODERATE. Gradual load progression in athletes, avoiding sudden increases in throwing or overhead volume: MODERATE. No drug prevents it: absent.

**Treatment.** Exercise-based rehabilitation is first line for almost everyone, including for most degenerative full-thickness tears: progressive loading, rotator cuff and scapular strengthening, and range-of-motion work. It produces clinically important improvement in the majority, and trials show it is equivalent to surgery for degenerative tears and for impingement syndrome. The cost is physiotherapist time, or free with instruction.

Education, load modification and analgesia: NSAIDs and paracetamol for short-term symptom control; NSAIDs off-patent, EML-listed, a few to tens of US dollars a year.

Subacromial corticosteroid injection gives short-term pain relief, weeks to a few months, with no long-term benefit over exercise, and repeated injections may impair tendon quality and subsequent repair healing. Useful to enable rehabilitation. Off-patent, cheap.

Subacromial decompression surgery is not effective. This is one of the clearest negative findings in orthopaedics. The CSAW trial (Beard, *Lancet* 2018, 313 patients) found arthroscopic subacromial decompression no better than arthroscopy alone, which was placebo surgery, and the small difference against no treatment was not clinically important. The FIMPACT trial (Paavola, *BMJ* 2018, 210 patients) found decompression no better than diagnostic arthroscopy, which was sham, at two years, and neither beat exercise therapy. Guidelines and several national bodies now recommend against it, and it continues to be performed in large numbers — a practice-evidence gap comparable to arthroscopic meniscectomy.

Rotator cuff repair is appropriate for acute traumatic tears, especially in younger patients, where repair should be early; for symptomatic tears failing three to six months of good rehabilitation; and for progressive weakness or large tears at risk of becoming irreparable. For degenerative tears, trials comparing repair with conservative management show small or no differences in patient-reported outcomes at one to five years, for example Kukkonen, though structural integrity is better with repair. The decision is individualised, and patient selection matters more than technique.

Reverse total shoulder arthroplasty for cuff-tear arthropathy, irreparable tears with pseudoparalysis, and failed repairs, is highly effective for pain and overhead function. Tendon transfers, superior capsular reconstruction and balloon spacers for irreparable tears have limited and evolving evidence, and several are marketed ahead of the evidence. Platelet-rich plasma and stem cell injections are not supported by adequate evidence for rotator cuff disease, and are heavily commercialised.

Imaging: ultrasound and MRI detect tears accurately, but given that tears are largely age-normal and often asymptomatic, imaging should follow a failure of conservative management or suspicion of a traumatic reparable tear rather than precede treatment. Early imaging drives unnecessary surgery.

For adhesive capsulitis, if that is the actual diagnosis: intra-articular steroid with exercise early, and hydrodilatation; it is self-limiting, and aggressive intervention is usually unnecessary.

**Simple means.** Progressive loading exercise is the primary treatment and is equivalent to surgery in randomised trials. It can be done with a resistance band, a water bottle or body weight, with instruction, and needs no equipment beyond that. Home exercise programmes with periodic supervision are nearly as effective as fully supervised physiotherapy in trials, which matters where therapists are scarce.

Activity and load modification: temporarily reducing overhead work, then rebuilding capacity rather than permanently avoiding it. Education — that a tear found on a scan is often age-normal and not necessarily the cause of pain, and that the shoulder can improve without structural healing. Heat, cold, simple analgesia. Sleep positioning advice, avoiding lying on the affected side and using pillow support: night pain is often the most disabling symptom and is helped by this alone. Workplace exercise and job rotation for overhead workers, as prevention at low cost. Smoking cessation.

Not having subacromial decompression, and not having platelet-rich plasma: two evidence-based omissions saving considerable money, on CSAW and FIMPACT.

The honest limit: acute traumatic tears in young patients benefit from timely repair, and pseudoparalysis from an irreparable tear needs arthroplasty. Exercise does not reattach a torn tendon.

**Gaps.** Why some tears hurt and others do not is unknown, and it is the central clinical question. Pain and structural findings correlate poorly, as in the spine. Subacromial decompression continues at scale despite two good sham-controlled trials — a practice problem, not an evidence problem. Optimal patient selection for repair of degenerative tears is unresolved, and the fact that structurally failed repairs often do well clinically undermines the mechanical rationale. Re-tear rates vary widely and are poorly predicted. Newer procedures — superior capsular reconstruction, balloon spacers, biologic augmentation — are being adopted ahead of adequate evidence. Optimal exercise dose and progression are unclear. Rotator cuff disease is not counted in GBD, so global burden is unknown, and almost all trials come from high-income settings.

---

## Carpal tunnel syndrome

**What it is.** The median nerve is compressed where it passes through the wrist. The hand tingles and goes numb, typically waking the person at night, and the thumb muscles can waste. It is the commonest nerve entrapment.

**Measured.** Prevalence is about 1 to 5 per cent of the general adult population, and about 3.8 per cent in population studies using symptoms plus electrophysiology. Lifetime risk is about 10 per cent, with an annual incidence of about one to three per 1,000. It is not separately modelled in GBD. Deaths: none. Female to male ratio is about 3:1. Peak age is 45 to 60, and it is also common in pregnancy, where it is usually transient.

It is the commonest indication for hand surgery, and carpal tunnel release is one of the highest-volume operations performed worldwide. Occupational prevalence is high in repetitive forceful hand work, vibrating tool use, and assembly and meatpacking work. The association with ordinary keyboard and computer use is weak and largely unsupported — a persistent misconception.

**Where it starts.** Raised pressure within an anatomically confined space. The carpal tunnel is bounded by carpal bones and the transverse carpal ligament, so any increase in contents or decrease in space compresses the median nerve. That mechanism is clear and uncontested, in contrast to most entries here.

Female sex, through a smaller tunnel cross-sectional area. Obesity, dose-dependently, as a strong and consistent risk factor. Diabetes, where the nerve is also more vulnerable to compression; hypothyroidism; rheumatoid arthritis, through tenosynovitis; pregnancy, through fluid retention and usually resolving after delivery; acromegaly; and amyloidosis — notably, bilateral carpal tunnel syndrome can be the earliest manifestation of transthyretin amyloidosis, preceding cardiomyopathy by five to ten years, which makes it a potentially important diagnostic clue.

Occupational: repetitive forceful gripping, wrist flexion and extension, and vibration, which is the strongest occupational association. Keyboard use: weak or no association. Prior wrist fracture or deformity; ganglion; anatomical variants. Haemodialysis, through amyloid deposition; menopause.

A genetic contribution is established, with heritability estimated at about 46 per cent in some analyses, and GWAS identifying loci relating to extracellular matrix and growth factors — *ADAMTS17*, *SERPINA1*, *GDF5*. Family history is associated with earlier onset and bilateral disease.

What is not known is why symptoms and electrophysiological severity correlate imperfectly, and why some patients with severe nerve conduction abnormality have few symptoms. The precise pathophysiology of the nocturnal pattern, where fluid shift and sustained wrist flexion during sleep are the usual explanations. Why some progress to axonal loss and thenar wasting while others remain stable for years. The true magnitude of occupational contribution against constitutional factors is contested and has medicolegal implications.

**Cure status.** CURABLE, unusually clearly so for a musculoskeletal condition. Carpal tunnel decompression, surgical release, is definitively curative in about 75 to 90 per cent, with durable relief and low recurrence of about 1 to 5 per cent. It is one of the most reliably effective operations in surgery.

But recovery is incomplete where axonal loss and thenar wasting are established: sensation and strength may not fully return, which is why delay matters. Pain and paraesthesia relief is good even in severe cases; muscle recovery is not.

SELF-LIMITING in specific settings: pregnancy-related carpal tunnel syndrome usually resolves after delivery, and mild cases may fluctuate or remit spontaneously. CURABLE by treating the cause where there is one: hypothyroidism, acromegaly, inflammatory tenosynovitis, weight loss in obesity. CONTROLLABLE non-surgically in mild to moderate disease, where splinting and injection give real but often temporary benefit.

**Prevention.** Weight management: MODERATE, since obesity is a strong dose-dependent risk factor. Reducing occupational vibration and repetitive forceful gripping, tool redesign, job rotation: MODERATE. Treating hypothyroidism and diabetes: MODERATE. Ergonomic keyboard interventions: WEAK and CONTESTED — given the weak association with keyboard use, these have little evidence of preventing carpal tunnel syndrome specifically, though they may help other upper limb complaints. Wrist splints for prevention in at-risk workers: WEAK. Early treatment to prevent axonal loss: MODERATE — this is prevention of irreversible damage rather than of the condition, and it is the practically important one, since thenar wasting does not reverse.

**Treatment.** Nocturnal wrist splinting in the neutral position is effective for mild to moderate disease, improving symptoms in the short to medium term, with most benefit in those with predominantly nocturnal symptoms. Cost a few to tens of US dollars for a splint, and locally manufacturable. First-line, and excellent value.

Corticosteroid injection into the carpal tunnel is effective, with benefit demonstrated at up to six to twelve months in randomised trials; it is superior to splinting alone in the short term and can defer or avoid surgery in a proportion. Off-patent, a few to tens of US dollars per injection for the drug. Also useful diagnostically. Ultrasound guidance improves accuracy and is not essential. Oral corticosteroids, as a short course, give modest short-term benefit.

Carpal tunnel release surgery is definitive, with 75 to 90 per cent success and durable results. Open and endoscopic release have equivalent long-term outcomes; endoscopic release gives slightly faster return to work at higher cost and a small increase in nerve injury risk. Open release under local anaesthetic is cheap, safe and quick and requires no theatre infrastructure — it can be done in a procedure room, which matters greatly for access. Surgery is superior to splinting and injection in the medium to long term in randomised trials, so it should not be unduly delayed in moderate to severe disease, and is indicated promptly where there is thenar wasting, axonal loss on electrophysiology, or failure of conservative treatment.

Treat the secondary causes: levothyroxine, glycaemic control, weight loss, inflammatory arthritis treatment. Levothyroxine is an EML-listed medicine, section 18.7, for hypothyroidism. Consider transthyretin amyloidosis in bilateral disease in older patients, especially with cardiac features.

Nerve and tendon gliding exercises, manual therapy and yoga have modest evidence at low risk and may help mild cases. Not supported or ineffective: diuretics; pyridoxine, vitamin B6, long used with no evidence; NSAIDs, with no benefit for the compression itself; ultrasound therapy, conflicting; laser; magnets.

Nerve conduction studies confirm the diagnosis and grade severity, and are useful before surgery and where the diagnosis is uncertain, but a clear clinical picture does not require them to proceed, which matters where they are unavailable. Clinical diagnosis plus a positive response to injection is a reasonable pathway in low-resource settings. Ultrasound is an increasingly used, cheaper alternative that also detects space-occupying causes.

**Simple means.** A nocturnal wrist splint at a few to tens of US dollars is the first-line treatment, effective for mild to moderate disease, and readily made from locally available materials — thermoplastic, or even a well-padded rigid support holding the wrist neutral. One of the best examples in this book of an effective treatment with essentially no supply chain.

Keeping the wrist neutral at night: even positional advice without a splint helps some. Weight loss addresses a strong dose-dependent risk factor. Activity and tool modification, reducing vibration exposure, job rotation and breaks, as workplace measures at low cost. Nerve and tendon gliding exercises, taught, with no equipment. Cheap corticosteroid injection at a few to tens of US dollars defers or avoids surgery in a proportion, and is deliverable by trained non-specialists.

Open release under local anaesthetic is the definitive cure, performable in a procedure room with local anaesthetic, a blade and sutures, by a trained generalist or task-shared surgeon. Among the highest-value minor operations available, and feasible in outreach and camp settings.

Recognising it early, before thenar wasting develops, since muscle loss does not recover. And not using vitamin B6 or diuretics: evidence-based omissions.

The honest note: unlike most entries, the cure here is cheap, quick and definitive. The main barrier is access to a minor operation, not cost of technology.

**Gaps.** Symptoms and electrophysiology correlate imperfectly, so severity grading and surgical thresholds are imprecise. The optimal timing of surgery against conservative management is not well defined, particularly for moderate disease. The true occupational attributable fraction is contested and entangled with compensation systems. Whether ergonomic interventions prevent the condition is unresolved, and the keyboard association is weaker than public belief. Long-term outcomes of injection against early surgery need more data. Recurrence and revision surgery outcomes are under-studied. The condition is not counted in GBD, so its global burden — likely substantial given a 10 per cent lifetime risk — is unknown, and unmet surgical need in low-income settings is unquantified despite the operation being cheap and simple. Awareness of carpal tunnel syndrome as a herald of transthyretin amyloidosis is new and the yield of screening for it is not established.

## Tendinopathies of the Achilles, patellar, lateral elbow and gluteal tendons

**What it is.** A tendon becomes painful and thickened where it is loaded, typically after a change in activity. The tissue is degenerate rather than inflamed. Anti-inflammatory treatment disappoints and loading treatment works.

**Measured.** Lateral elbow tendinopathy, tennis elbow, has a prevalence of about 1 to 3 per cent of adults, with a peak age of 35 to 54; about 75 per cent of cases are in the dominant arm; and it is mostly occupational rather than sporting — only about 5 to 10 per cent of cases are in tennis players, despite the name†.

Achilles tendinopathy has a lifetime incidence of about 6 to 11 per cent in runners and about 2 per cent in the general population, and is also common in sedentary middle-aged people, in the insertional type. Patellar tendinopathy, jumper's knee, has a prevalence of up to about 45 per cent in elite volleyball and about 30 per cent in basketball players†.

Gluteal tendinopathy, the commonest cause of lateral hip pain and formerly mislabelled trochanteric bursitis, has a prevalence of about 10 to 25 per cent in women over 40 — far more common than previously recognised, and the relabelling reflects the finding that bursal inflammation is usually absent while tendon pathology is present.

Rotator cuff tendinopathy is covered separately. Tendinopathies collectively account for about 30 per cent of all musculoskeletal consultations. They are not separately modelled in GBD. Deaths: none. By sex: gluteal tendinopathy is strongly female-predominant, Achilles male-predominant, and lateral elbow roughly equal.

**Where it starts.** Load error is the central mechanism: a rapid increase in training volume, intensity or frequency, or a return to activity after a break, exceeding the tendon's adaptive capacity. Tendons adapt to load slowly, since collagen turnover takes months, so the mismatch between rapid activity change and slow tissue adaptation is the proximate cause.

The pathology is degenerative, not inflammatory: disorganised collagen, neovascularisation, increased ground substance, and the absence of inflammatory cells on histology. Hence "tendinopathy" replaced "tendinitis" — a terminology change with treatment consequences, since it argues against steroids and NSAIDs as disease-modifying.

Age, through reduced tendon healing capacity and vascularity. Metabolic factors are increasingly recognised and important: obesity, type 2 diabetes with roughly three times the risk of tendinopathy, metabolic syndrome, and hypercholesterolaemia are all associated, independent of load. That reframes tendinopathy as partly a metabolic disease rather than purely an overuse injury.

Fluoroquinolone antibiotics are a well-established drug cause of Achilles tendinopathy and rupture; the risk is highest in older patients and with concurrent corticosteroids, and it has prompted regulatory restrictions. Corticosteroids, both systemic and by repeated local injection, also weaken tendon.

Biomechanical factors: for the Achilles, reduced ankle dorsiflexion, foot posture and calf weakness; for the gluteal tendons, hip adduction posture and pelvic width; for the lateral elbow, gripping with wrist extension, vibration and forceful repetitive work. Menopause and oestrogen deficiency have been proposed for the female predominance of gluteal tendinopathy: plausible, not established.

A genetic contribution is established for Achilles tendinopathy and rupture, with *COL5A1*, *TNC* and *MMP3* variants implicated and family history conferring roughly two to five times the risk; precise heritability figures are not well established.

What is not known is why pain occurs. Pathology on imaging correlates poorly with symptoms, and asymptomatic tendons frequently show marked abnormality on ultrasound and MRI, as with the spine and the rotator cuff. Why loading exercise works is only partly understood: it was assumed to remodel collagen, but pain relief often precedes any structural change, which implicates neural and central mechanisms. Why some tendinopathies become chronic and recalcitrant. And whether the metabolic associations are causal.

**Cure status.** Achilles, patellar and gluteal tendinopathy: CURABLE by loading programmes, in about 60 to 90 per cent†. Lateral elbow tendinopathy: SELF-LIMITING, with about 80 to

90 per cent recovering within one to two years regardless of treatment. Recalcitrant cases, perhaps 10 to 25 per cent†: RELIEF ONLY.

Curable in most, but slowly — and the time course is the key piece of honest information. Progressive loading exercise resolves or substantially improves most tendinopathies, but takes three to six months, and sometimes twelve. Patients told to expect weeks abandon treatment; patients told to expect months adhere.

The self-limiting course of lateral elbow tendinopathy is why almost any intervention appears to work in uncontrolled series, and why the randomised evidence matters so much. Achilles and patellar tendinopathy are curable with loading programmes in about 60 to 90 per cent†, with recurrence if load management lapses. Gluteal tendinopathy is curable, and the LEAP trial showed education plus exercise gave the best outcomes. The recalcitrant 10 to 25 per cent† remain symptomatic despite good treatment, and the options then are limited and poorly evidenced. Tendon rupture, Achilles especially, is a separate problem requiring immobilisation or surgery.

**Prevention.** Gradual load progression: STRONG on mechanistic and observational grounds — avoiding sudden increases in training volume or intensity is the single most important measure. The "10 per cent per week" rule is a convention rather than a trial-validated figure.

Eccentric and heavy slow resistance training as prophylaxis in athletes: MODERATE, with trials in volleyball and soccer showing reduced tendinopathy incidence. Nordic hamstring exercise programmes reduce hamstring injury by about 50 to 70 per cent in randomised trials — the best-evidenced prevention in this family, and done without equipment.

Metabolic health — weight management, glycaemic control, lipid management: MODERATE, given the strength of the metabolic associations. Avoiding fluoroquinolones where alternatives exist, especially in older patients and those on corticosteroids: MODERATE. Avoiding repeated corticosteroid injection into weight-bearing tendons: MODERATE. Workplace load reduction, tool and grip modification, job rotation: MODERATE for lateral elbow. Calf strengthening and appropriate footwear: WEAK for the Achilles.

**Treatment.** Progressive loading exercise is first line for every tendinopathy, with good randomised evidence.

For the midportion Achilles: eccentric calf loading, the Alfredson protocol, is the foundational evidence, with about 60 to 90 per cent good outcomes†; heavy slow resistance training is equally effective and often better tolerated. Insertional Achilles tendinopathy needs limited dorsiflexion range, so floor-level rather than step exercises. For the patellar tendon: decline-squat eccentric loading, or heavy slow resistance. For the lateral elbow: progressive wrist extensor loading and grip strengthening. For the gluteal tendons: the LEAP trial (Mellor, *BMJ* 2018, 204 patients) found education plus exercise was superior to corticosteroid injection and to wait-and-see at eight weeks and at 52 weeks — an important result favouring the cheap, durable option over the injection. The cost is free to low: body weight, a step, a resistance band, or a loaded backpack.

Education and load management: explaining the slow time course, modifying aggravating activity without complete rest, since complete rest is harmful and deconditions the tendon, and progressive return. Analgesia with paracetamol or short-course NSAIDs for symptom control; NSAIDs do not treat the underlying pathology, since it is not inflammatory, and prolonged use is not indicated. Off-patent, cheap.

Corticosteroid injection gives short-term relief and worse long-term outcomes. This is the critical evidence point. In lateral elbow tendinopathy, the landmark Coombes trial (*JAMA* 2013, 165 patients) found corticosteroid injection gave better four-week outcomes but significantly worse complete recovery at one year, 83 against 96 per cent without injection, and higher recurrence. Similar findings have come from gluteal tendinopathy in LEAP and from Achilles tendinopathy. So steroid injection trades short-term relief for worse long-term recovery and should generally be avoided, particularly in weight-bearing tendons, where it also raises rupture risk.

Extracorporeal shockwave therapy has moderate evidence for some tendinopathies — insertional Achilles, plantar fasciopathy, calcific rotator cuff — and is contested for others; it is equipment-dependent and costly.

Platelet-rich plasma injection is not supported. Multiple adequately powered randomised trials are negative, including for Achilles tendinopathy (Kearney, *JAMA* 2021 — no benefit over sham) and for lateral elbow. It is nonetheless heavily marketed and widely sold: a significant consumer-protection issue.

Glyceryl trinitrate patches have some positive, inconsistent trials and low cost. High-volume injection, sclerosing injection, prolotherapy and dry needling have limited or conflicting evidence. Orthoses and braces: a counterforce brace for lateral elbow gives short-term symptom relief, and heel raises help the Achilles; useful as adjuncts, not treatments.

Surgery for the recalcitrant minority after six to twelve months of good conservative care: tendon debridement, release or repair. Outcomes are moderate and the evidence is weak, with few randomised comparisons against continued conservative care, and placebo-controlled trials are largely absent — which, given the history of subacromial decompression and meniscectomy, should induce caution. Treat the metabolic contributors: glycaemic control, weight, lipids. Review fluoroquinolone and corticosteroid exposure.

**Simple means.** Tendinopathy is a near-pure simple-means condition: the best-evidenced treatment is a loaded exercise requiring no equipment.

Progressive loading exercise, eccentric or heavy slow resistance. For the Achilles: calf raises off a step, progressing to added load in a backpack. For the patellar tendon: decline squats. For the lateral elbow: wrist extension with a weight or band. For the gluteal tendons: hip abductor loading. These are the first-line treatments with the best evidence, and they cost nothing.

Education on the time course: telling patients recovery takes three to six months prevents premature abandonment and the search for injections. Free, and it determines outcome. Load modification without complete rest: reducing the aggravating volume while continuing to load the tendon. Gradual return to activity with sensible progression rules, for prevention and treatment. Nordic hamstring exercises and similar prophylactic programmes give about 50 to 70 per cent injury reduction with no equipment†. A counterforce brace or strap for the lateral elbow, and a heel raise for the Achilles: cheap adjuncts. Weight loss and glycaemic control, addressing the metabolic contribution.

Not having a corticosteroid injection is an evidence-based omission that improves one-year recovery, 96 against 83 per cent (Coombes 2013)†; and not having platelet-rich plasma (Kearney 2021, negative)†. Two omissions that save money and improve outcomes. Avoiding fluoroquinolones where an alternative exists.

The honest limit: a small recalcitrant minority do not respond, and ruptures need immobilisation or surgery. But for the majority, the correct treatment is free.

**Gaps.** Why loading works is not fully understood, and pain relief often precedes structural change. Imaging findings correlate poorly with symptoms, so imaging adds little. The optimal loading protocol — eccentric against heavy slow resistance, dose, frequency, pain permitted during exercise — is not resolved, and protocols are largely convention. The recalcitrant 10 to 25 per cent† have no well-evidenced options, and surgery for tendinopathy has almost no placebo-controlled evidence despite the cautionary precedents of decompression and meniscectomy. Whether the metabolic associations are causal is unestablished, and if they are, the treatment implications would be significant. Shockwave evidence is inconsistent across sites. Platelet-rich plasma continues to be sold despite negative trials. Gluteal tendinopathy was misclassified as bursitis for decades and its epidemiology is still being established. These conditions are not counted in GBD despite accounting for about 30 per cent of musculoskeletal consultations, so global burden is unknown.

---

## Scoliosis

**What it is.** A sideways curve and rotation of the spine. Most cases appear in adolescence with no known cause. Small curves do not matter; large ones progress, deform the trunk and can affect breathing.

**Measured.** Adolescent idiopathic scoliosis affects about 1 to 3 per cent of children aged ten to sixteen, using the standard threshold of a Cobb angle of 10 degrees or more†. Curves of 30

degrees or more are present in about 0.1 to 0.3 per cent, and curves of 40 degrees or more in about 0.1 per cent, so the great majority of scoliosis is mild and clinically unimportant.

Female to male ratio is about 1.5:1 at the 10-degree threshold but about 7 to 10:1 for curves requiring treatment — girls are far more likely to progress, which is why screening and monitoring focus on them.

Adult degenerative, de novo, scoliosis is much more common than is generally appreciated, with a prevalence of about 30 to 68 per cent in adults over 60 in imaging studies, usually with mild curves, and it is a cause of back pain, stenosis and deformity in the elderly. Congenital scoliosis occurs in about one per 1,000 births, and neuromuscular scoliosis is common in cerebral palsy, up to 20 to 60 per cent in severe forms†, and in Duchenne muscular dystrophy and spinal muscular atrophy.

It is not separately modelled in GBD. Deaths are rare, from respiratory failure in very severe untreated curves, typically above 90 to 100 degrees, and in neuromuscular disease. The distribution is broadly similar across countries, but access to bracing and surgery is extremely unequal, so untreated severe deformity remains common in low-income countries and is essentially absent in high-income ones.

**Where it starts.** Idiopathic: by definition the cause is unknown, and that is the honest headline for about 80 to 85 per cent of cases†.

Genetics: strong familial clustering, with first-degree relatives at about seven to eleven times the risk; concordance is higher in monozygotic than dizygotic twins, with heritability estimated at about 38 to 87 per cent depending on study, the wide range reflecting methodological differences. GWAS has identified loci including *LBX1*, the most robustly replicated, with *GPR126/ADGRG6*, *BNC2* and *PAX1*: polygenic, each variant of small effect. No clinically useful genetic test exists — the ScoliScore test was commercialised and then withdrawn after failing validation, which is a cautionary case.

Female sex, and peripubertal growth velocity. Progression risk is driven by remaining growth: curves progress fastest during the adolescent growth spurt and largely stop at skeletal maturity. Risser sign, Sanders stage and menarcheal status are the practical predictors, and this growth dependence governs all treatment decisions. Curve magnitude at presentation is the strongest single predictor of progression: larger curves in younger, less mature patients progress most.

Associated or contributory in non-idiopathic cases: vertebral malformations, in congenital disease; neuromuscular disease — cerebral palsy, muscular dystrophy, spinal muscular atrophy, spina bifida; connective tissue disorders, Marfan and Ehlers-Danlos; neurofibromatosis type 1; and syringomyelia and tethered cord, which is why atypical features — a left thoracic curve, neurological signs, pain, rapid progression — mandate MRI.

Proposed and unproven in idiopathic disease: abnormal melatonin signalling, leptin and body composition, proprioceptive and vestibular dysfunction, differential growth of anterior and posterior spinal elements, and platelet calmodulin abnormalities.

Not a cause: backpacks, posture, sitting position, sports and sleeping position. These are common parental concerns and are not supported.

What is not known is the cause. Why it is female-predominant for progression. Why some curves progress rapidly and others not at all, beyond growth and magnitude. Whether adult curves cause back pain or are coincidental in many. And there is no means of preventing onset.

**Cure status.** This depends entirely on magnitude and growth remaining, so each stratum is named.

Curves under about 25 degrees in a maturing adolescent: SELF-LIMITING. They usually stabilise at skeletal maturity and require only observation, and the great majority never need treatment.

Curves of about 20 to 40 degrees with growth remaining: CONTROLLABLE by bracing. Bracing does not straighten the spine; it prevents progression to the surgical threshold. That is the correct and often misunderstood goal.

Curves at or above the surgical threshold: CURABLE by surgery. Spinal fusion with instrumentation achieves substantial, permanent curve correction and halts progression, at the cost of a major operation and loss of segmental motion.

Established deformity at skeletal maturity does not resolve, and curves above 50 degrees tend to progress slowly through adult life, at about 0.5 to 1 degree a year†. Exercise does not correct curves: it may have a small effect on progression, which is contested, and it helps pain and function, but claims of curve correction by exercise or manual therapy are not supported.

**Prevention.** Primary prevention is not possible, since the cause is unknown: absent.

Screening to prevent severe deformity: MODERATE, and contested. School screening with the Adams forward-bend test plus a scoliometer detects curves early. The US Preventive Services Task Force historically recommended against routine screening, citing over-referral, radiation and uncertain benefit, then in 2018 concluded the evidence was insufficient — an honest "we don't know". Several European countries screen and others do not. The argument for screening strengthened after the BrAIST bracing trial demonstrated that bracing works, since early detection is only worthwhile if effective treatment follows.

Bracing as secondary prevention: STRONG. Preventing surgery through timely detection and bracing: MODERATE. Vitamin D and calcium adequacy, and general fitness: WEAK — reasonable and not established as affecting curve behaviour. In neuromuscular disease, maintaining mobility and nutrition, and in spinal muscular atrophy the new disease-modifying therapies nusinersen, onasemnogene and risdiplam, substantially reduce scoliosis severity: STRONG for that group, though extremely expensive.

**Treatment.** Decisions rest on curve magnitude plus remaining growth, not on symptoms.

Observation for curves under 20 to 25 degrees in a growing child: serial clinical examination and radiographs every four to twelve months until maturity. Most need nothing further. Using low-dose or biplanar slot-scanning radiography reduces cumulative radiation.

Bracing for curves of about 20 to 40 degrees with significant growth remaining. The evidence is strong and specific. The BrAIST trial (Weinstein, *NEJM* 2013, 242 patients in randomised and preference cohorts) found bracing significantly reduced progression to the surgical threshold of 50 degrees or more, with success in 72 per cent with bracing against 48 per cent with observation, and the trial was stopped early for efficacy. There was a clear dose-response with wear time: success rose to about 90 to 93 per cent in those wearing the brace 12.9 hours a day or more, and was little better than observation with minimal wear. So adherence is the determinant, and measuring it with temperature sensors and supporting it is the practical task. The typical prescription is a thoracolumbosacral orthosis, Boston or Chêneau type, for sixteen to 23 hours a day until skeletal maturity. Cost about US$500 to 3,000 per brace in high-income settings†, and far less where locally fabricated — braces can be made from thermoplastic by a trained orthotist with simple equipment, which is important for access.

Scoliosis-specific exercise, Schroth or SEAS, shows modest evidence of reducing progression and improving trunk appearance and pain, and SOSORT guidelines support them as an adjunct, often alongside bracing. The evidence quality is moderate at best and the trials are small: CONTESTED for curve modification, reasonable for function and pain. Low cost.

Surgery for curves of 45 to 50 degrees or more, or progressive curves, or significant deformity. Posterior spinal fusion with pedicle screw instrumentation is the standard, achieving about 50 to 70 per cent curve correction†, halting progression and improving trunk appearance; complication rates are meaningful, with infection, neurological injury at about 0.3 to 1 per cent†, implant problems, pseudarthrosis and adjacent segment issues. Anterior approaches, growing rods, magnetically controlled growing rods and vertebral body tethering for early-onset and skeletally immature patients: tethering preserves motion and is growing in use, with limited long-term data and revision rates not yet established. Cost about US$20,000 to 150,000 in high-income systems†, far less elsewhere, though instrumentation cost is a real barrier in low-income settings.

Adult degenerative scoliosis: treat symptoms, not the curve — exercise, analgesia, physiotherapy; decompression with or without limited fusion for stenosis and radicular symptoms; major deformity correction only in selected patients, since complication rates in older adults

are high. Neuromuscular scoliosis: seating and postural management, wheelchair modification, respiratory care, nutritional support, and fusion when sitting balance or respiratory function is threatened, with underlying disease treatment where available.

Not supported: chiropractic manipulation, scoliosis correction devices, electrical stimulation which was tested and abandoned, and exercise alone presented as an alternative to bracing for curves in the braceable range. These are commonly marketed to parents. MRI is indicated for atypical presentation — a left thoracic curve, neurological signs, early onset, pain, rapid progression — to exclude syrinx, tethered cord or tumour.

**Simple means.** Observation: for the great majority of mild curves the correct management is monitoring and reassurance. It costs a clinic visit and prevents substantial unnecessary intervention and anxiety.

The forward-bend test and a scoliometer are the entire screening apparatus. A scoliometer is a simple inclinometer costing very little, the test takes seconds and needs no radiation, and it can be used by school nurses, teachers or community health workers. The highest-value simple tool here.

Locally fabricated thermoplastic braces: the effective treatment, with BrAIST giving 72 against 48 per cent and rising to about 90 per cent with good wear, can be made by a trained orthotist with a heat source and a thermoplastic sheet. Where orthotic services exist, bracing prevents the need for major surgery — a large benefit from modest infrastructure.

Supporting brace adherence through education, peer support, involving the adolescent in decisions, and addressing the real psychosocial burden of wearing a brace through adolescence. Adherence is the single determinant of brace success, and supporting it costs nothing but attention.

Exercise and general fitness for pain, posture, respiratory function and self-image, with honesty about not correcting the curve. Scoliosis-specific exercises: low cost, modest evidence, reasonable adjunct. Reassurance about non-causes — backpacks, posture and sport do not cause scoliosis, and children should not be restricted from activity. Correct explanation of the goal of bracing, which is preventing progression rather than straightening, and which prevents the disappointment that drives families toward unproven alternatives.

The honest limit: a curve above about 50 degrees needs surgery, and no simple means substitutes. Access to safe spinal surgery is the binding global inequity here.

**Gaps.** The cause of idiopathic scoliosis is unknown. No test predicts which curves will progress beyond growth status and current magnitude, so some children are braced unnecessarily and others are detected too late. Genetic prediction has failed in practice, with ScoliScore withdrawn. School screening's net benefit remains formally insufficient evidence per the USPSTF, and policies differ between countries without resolution. Scoliosis-specific exercise evidence is weak and the trials are small, yet it is widely promoted. Vertebral body tethering is being adopted ahead of long-term outcome data. Long-term outcomes of modern instrumented fusion beyond 40 years are not yet known, and adjacent segment degeneration and late revision rates are uncertain. Whether adult degenerative curves cause the back pain attributed to them is unclear. Scoliosis is not counted in GBD, and the global burden of untreated severe deformity — concentrated where orthotics and spinal surgery are unavailable — is unquantified.

---

## Osteomyelitis

**What it is.** Infection of bone. It arrives through the bloodstream, from a nearby wound or ulcer, or after surgery or a fracture. Bone infection is hard to clear because dead bone and biofilm shield the organisms from antibiotics and from the immune system.

**Measured.** Incidence is about 22 to 25 per 100,000 person-years overall in high-income settings, and rising, driven by diabetic foot infection, orthopaedic implants and injecting drug use.

Acute haematogenous osteomyelitis in children runs at about 8 to 20 per 100,000 a year in high-income countries, and several-fold higher in low-income settings and in Indigenous

populations; in parts of sub-Saharan Africa and the Pacific it is a common cause of childhood disability through chronic osteomyelitis and growth plate damage.

Diabetic foot osteomyelitis is now the largest category in adults: it is present in about 20 per cent of mild to moderate and about 50 to 60 per cent of severe diabetic foot infections, and underlies a large share of the roughly one million lower-limb amputations performed annually in people with diabetes. Prosthetic joint infection affects about 1 to 2 per cent of primary hip and knee replacements, higher in revision surgery, and given the volume of arthroplasty this is a growing absolute burden.

It is not separately modelled in GBD. Mortality is low directly, but limb loss, chronic disability and recurrent hospitalisation are the real outcomes, and in low-resource settings chronic osteomyelitis is a significant cause of lifelong disability in children. Age distribution is bimodal: children with haematogenous disease in the long bone metaphyses, and older adults with contiguous spread, diabetic foot infection, vertebral and implant-related disease. Vertebral osteomyelitis incidence rises steeply with age and is increasing. There is a male predominance of about 1.5 to 2:1.

**Where it starts.** *Staphylococcus aureus* is the dominant organism across all categories, at about 50 to 70 per cent, including MRSA in many settings†. Others: coagulase-negative staphylococci with implants; streptococci; *Kingella kingae* in young children, now recognised as a major paediatric cause with improved PCR detection; Gram-negatives and anaerobes in diabetic foot and contiguous infection; *Salmonella* in sickle cell disease, a classic and important association; *Pseudomonas* with injecting drug use and puncture wounds through footwear; *Mycobacterium tuberculosis* in spinal Pott disease, a major global cause that Western accounts often under-weight; *Brucella* in endemic regions; and fungi in the immunocompromised.

Routes: haematogenous in children, in vertebral disease in adults and with injecting drug use; contiguous spread from a diabetic foot ulcer, pressure ulcer, dental or sinus infection; and direct inoculation through open fracture, surgery, implant, puncture wound or gunshot.

Risk factors: diabetes with peripheral neuropathy and peripheral arterial disease is the dominant adult risk set, since neuropathy allows unnoticed ulceration while ischaemia impairs healing and antibiotic delivery. Then peripheral vascular disease; injecting drug use; immunosuppression; sickle cell disease; malnutrition; smoking; alcohol excess; chronic kidney disease; prior surgery or trauma; the presence of implanted material, since biofilm on a foreign surface drastically lowers the infecting dose and resists antibiotics; and pressure ulcers and immobility.

In children, the metaphyseal vascular anatomy, with sluggish sinusoidal flow in growing bone, explains the typical site, and preceding minor trauma is often reported. Heritability is not meaningfully applicable, since this is an acquired infection, though susceptibility is modified by genetic conditions — sickle cell disease, chronic granulomatous disease, immunodeficiencies — and by diabetes risk.

What is not known is the optimal duration and route of antibiotic therapy for most categories. Decades of practice rested on convention — the six weeks of intravenous therapy tradition — rather than trial evidence, which has now been partly overturned. How to tell reliably whether infection has been eradicated: there is no test of cure, and relapse can occur years later. How much dead bone must be removed. In diabetic foot osteomyelitis, whether surgery or antibiotics alone is better is genuinely unresolved. And the role and value of local antibiotic carriers and of newer biofilm-targeting approaches.

**Cure status.** Five strata, each with its own label.

Acute osteomyelitis treated promptly, especially acute haematogenous osteomyelitis in children: CURABLE in about 90 to 95 per cent† with prompt antibiotics plus drainage of any abscess, because there is no established dead bone or biofilm yet. Early treatment is what makes it curable, and delay converts it into chronic disease.

Chronic osteomyelitis with adequate debridement: CURABLE in about 70 to 90 per cent†, but only with adequate surgical debridement combined with antibiotics. Antibiotics alone rarely cure established chronic infection with sequestrum, dead bone. Recurrence years later is possible, so cure is provisional and long follow-up is needed.

Implant-associated infection, with implant removal or exchange: CURABLE. Debridement with implant retention succeeds only in early post-operative or acute haematogenous infection with a stable implant and a susceptible organism; otherwise one- or two-stage exchange is needed. Biofilm is the proposed reason.

Diabetic foot osteomyelitis: CURABLE, including with antibiotics alone in selected cases — a significant and relatively recent shift from automatic amputation.

Where cure is unachievable, in patients unfit for surgery, at an unresectable site, or with a retained essential implant: RELIEF ONLY, by long-term suppressive antibiotics.

The determinant throughout is surgical removal of dead bone and biofilm, not the choice of antibiotic. Amputation is sometimes the curative option and should not be regarded only as failure: for an unsalvageable, chronically infected, painful or non-functional limb it can restore mobility and quality of life faster than years of failed limb salvage.

**Prevention.** Diabetic foot care: STRONG. This is where most adult osteomyelitis could be prevented. Structured foot screening, education, appropriate footwear, callus and nail care, prompt ulcer treatment and offloading, and multidisciplinary foot clinics reduce ulceration and amputation by about 50 to 85 per cent in cohort and programme evaluations. One of the highest-yield preventive programmes in chronic disease care, and consistently underresourced.

Glycaemic control and smoking cessation: MODERATE. Surgical antibiotic prophylaxis before orthopaedic implant surgery: STRONG — a single dose of a cephalosporin substantially reduces infection, and cefazolin is cheap and EML-listed.

Open fracture management: STRONG — prompt antibiotics within an hour, thorough debridement, and early soft tissue coverage. Debridement quality and timing of coverage matter more than antibiotic choice.

Aseptic technique, theatre discipline, laminar flow, skin antisepsis with chlorhexidine-alcohol, and *S. aureus* screening and decolonisation with nasal mupirocin and chlorhexidine washes: MODERATE for implant surgery. Pressure ulcer prevention by repositioning, support surfaces and nutrition: STRONG for preventing contiguous osteomyelitis of the sacrum and heel. Harm reduction for injecting drug use — sterile equipment, needle exchange, safer injecting education: MODERATE. Penicillin prophylaxis and vaccination in sickle cell disease: STRONG, for pneumococcal and salmonella risk. BCG vaccination and tuberculosis control: MODERATE for skeletal tuberculosis. Prompt treatment of acute osteomyelitis: STRONG for preventing chronic osteomyelitis — the key preventive step in children, and the one most often missed in low-resource settings.

**Treatment.** The proportion of diabetic foot osteomyelitis cured with antibiotics alone is not given here. Obtain microbiology before antibiotics wherever possible: bone biopsy or intraoperative samples, not superficial swabs, since superficial wound swabs in diabetic foot infection do not reliably reflect bone pathogens and mislead treatment. Blood cultures in acute haematogenous disease. This single principle improves outcomes and reduces unnecessary broad-spectrum therapy.

Surgical debridement is the cornerstone for chronic osteomyelitis: removal of all dead bone and infected tissue, management of dead space with local antibiotic carriers, bone graft, muscle flap, the Masquelet technique or Ilizarov bone transport, and stabilisation. Antibiotics cannot cure what has no blood supply.

Two antibiotic trials changed practice fundamentally.

On oral against intravenous therapy, the OVIVA trial (Li, *NEJM* 2019, 1,054 patients with bone and joint infection) found oral antibiotic therapy non-inferior to intravenous therapy for the first six weeks, with treatment failure of 13.2 per cent on oral against 14.6 per cent on intravenous, and with fewer complications and shorter hospital stay in the oral group. That overturned the long-standing six-weeks-of-intravenous doctrine, and it is enormously consequential for cost, for hospital capacity and for low-resource settings where prolonged intravenous access is impractical.

On duration in children, short courses suffice. Randomised and large cohort evidence (Peltola) supports a total of about two to four weeks with early switch to oral therapy for un-

complicated acute haematogenous osteomyelitis in children, rather than the traditional six weeks.

Duration in adults: about six weeks is conventional for chronic osteomyelitis after debridement, and twelve weeks for prosthetic joint infection with implant retention or exchange. The DATIPO trial did not demonstrate non-inferiority of six against twelve weeks for prosthetic joint infection — twelve weeks was better — so duration remains condition-specific.

Agents: flucloxacillin or cefazolin for methicillin-susceptible *S. aureus*; vancomycin, daptomycin or linezolid for MRSA; rifampicin combinations for implant-related infection, for biofilm penetration, and never as monotherapy; clindamycin, with good bone penetration, oral, cheap and EML-listed; co-trimoxazole with rifampicin, a cheap oral option with good evidence; and fluoroquinolones for Gram-negatives, with excellent bone penetration and oral bioavailability.

Drug costs: flucloxacillin, clindamycin, co-trimoxazole, rifampicin, ciprofloxacin and doxycycline are all off-patent and mostly EML-listed, at tens to hundreds of US dollars a course. Vancomycin and daptomycin are more expensive, with daptomycin at thousands of US dollars a course, and linezolid is now off-patent and much cheaper than at launch. The OVIVA result means a curative course of bone infection treatment can cost tens of dollars in oral generics rather than thousands in inpatient intravenous therapy.

Diabetic foot osteomyelitis, specific points. Antibiotics alone can cure a substantial proportion of forefoot osteomyelitis without ischaemia: trials and cohorts report about 60 to 80 per cent remission, comparable to conservative surgery in some comparisons, and this has shifted practice away from automatic bone resection. Offloading is essential, with a total contact cast or removable walker, because without pressure relief healing fails regardless of antibiotic. Revascularisation where there is ischaemia, which often determines the outcome more than the antibiotic. And a multidisciplinary foot team, which reduces amputation substantially.

Prosthetic joint infection: debridement with antibiotics and implant retention (DAIR) for early and acute infection; one- or two-stage exchange arthroplasty otherwise; suppression if unfit. Rifampicin-based combinations for staphylococci.

Vertebral osteomyelitis is usually treated medically, for six weeks with an oral switch per OVIVA, with surgery for instability, epidural abscess with neurological compromise, or failure. Image-guided biopsy before antibiotics is important.

Skeletal tuberculosis: standard antituberculous regimens for nine to twelve months, with surgery for instability or deformity. All first-line antituberculous drugs are EML-listed and cheap.

Adjuncts: nutritional support, glycaemic control and smoking cessation, all of which affect healing; hyperbaric oxygen, CONTESTED on limited evidence; and local antibiotic beads and absorbable carriers, widely used on moderate evidence. Amputation, considered positively where limb salvage would mean prolonged disability, repeated surgery or an unusable limb.

**Simple means.** Diabetic foot care: daily foot inspection, with a mirror or a family member if the patient cannot see or reach; washing and drying between the toes; correct footwear; prompt attention to any break in the skin; and never walking barefoot. Combined with structured screening, this prevents the ulcers that become osteomyelitis and reduces amputation by about 50 to 85 per cent in programme evaluations†. It requires education and a pair of adequate shoes — among the highest-value simple interventions in this book, because the alternative outcome is limb loss.

Offloading: a total contact cast is plaster and skill, and even felt padding, crutches and sandals with pressure relief help. Pressure relief is as important as the antibiotic.

The 10 g monofilament and a tuning fork detect the neuropathy that identifies at-risk feet: pennies, and no electricity.

Oral antibiotics: the OVIVA finding means bone infection can be treated orally, without central lines, infusion pumps or prolonged admission. That is transformative for low-resource and outpatient care.

Prompt treatment of acute infection in children: recognising a limping or non-weight-bearing febrile child early and treating promptly prevents chronic osteomyelitis and lifelong defor-

mity. Wound care, cleaning and dressing, and pressure ulcer prevention by repositioning, are nursing measures requiring time rather than technology. Nutrition and glycaemic control, and smoking cessation. Sterile injecting equipment and needle exchange.

Surgical debridement itself is simple in the sense that it needs skill and basic instruments rather than expensive technology — and it is the single most important curative act. A trained surgeon with instruments and anaesthesia cures more bone infection than any drug.

The honest limit: chronic osteomyelitis with dead bone cannot be cured without surgery, and implant infection usually needs implant removal. No simple means substitutes.

**Gaps.** There is no test of cure, so relapse cannot be excluded and follow-up duration is arbitrary. Optimal antibiotic duration for most adult categories remains convention-based despite OVIVA settling the route question. Whether surgery or antibiotics alone is better for diabetic foot osteomyelitis is genuinely unresolved, with trials small and heterogeneous. Diagnosis is difficult: MRI is sensitive but cannot reliably distinguish infection from Charcot neuroarthropathy or post-surgical change, and bone biopsy is under-used. Local antibiotic carriers and biofilm-targeted approaches lack good comparative evidence. Hyperbaric oxygen evidence is weak. The condition is not counted in GBD, so global burden is unknown, particularly childhood chronic osteomyelitis in low-income countries, which causes substantial lifelong disability and is barely measured. Antibiotic resistance, especially MRSA and Gram-negative resistance, is narrowing oral options in many regions.

---

## Septic arthritis

**What it is.** Infection inside a joint. It destroys cartilage within days, so it is a medical emergency. A hot, swollen, extremely painful joint with fever must be aspirated and treated at once.

**Measured.** Incidence is about 4 to 12 per 100,000 a year in the general population, rising to about 30 to 70 per 100,000 in those with rheumatoid arthritis and about 40 to 70 per 100,000 in people with prosthetic joints†. In children it is about 4 to 10 per 100,000 a year†, higher in low-income settings and in Indigenous populations.

Mortality is about 7 to 15 per cent in adults, and up to about 25 to 30 per cent in polyarticular disease, in the elderly, and in those with sepsis. That is high, and it is often not appreciated that septic arthritis kills. Permanent joint damage occurs in about 25 to 50 per cent of adult cases even with treatment: function is lost, not merely threatened.

It is not separately modelled in GBD. Age distribution is bimodal: young children, especially under three, and adults over 60. The knee is affected in about 50 per cent†, then hip, shoulder, ankle and wrist, with the hip commonest in young children. Polyarticular involvement occurs in about 10 to 20 per cent†, usually in immunocompromised or bacteraemic patients. There is a male predominance, with a strong association with injecting drug use, which also causes unusual joints — sternoclavicular and sacroiliac. Gonococcal arthritis is a distinct and important entity in sexually active young adults, often polyarticular with tenosynovitis and skin lesions, and it has a much better prognosis than staphylococcal disease.

**Where it starts.** Haematogenous seeding is the commonest route: the synovium is highly vascular and lacks a basement membrane, so bacteraemia from any source can seed a joint. Also direct inoculation by injection, surgery, trauma or bite, and contiguous spread from adjacent osteomyelitis, especially in children, where metaphyseal infection can breach into the joint.

*Staphylococcus aureus* is the leading organism at about 40 to 60 per cent, including MRSA; streptococci at about 20 per cent†; *Neisseria gonorrhoeae* in young sexually active adults; Gram-negatives in the elderly, the immunocompromised and injecting drug users; *Kingella kingae* in young children; *Salmonella* in sickle cell disease; *Mycobacterium tuberculosis* and *Brucella* in endemic areas, causing chronic monoarthritis; *Borrelia burgdorferi* in Lyme disease-endemic regions; and fungi in the immunocompromised.

Risk factors: pre-existing joint disease, with rheumatoid arthritis the single strongest through damaged synovium and immunosuppression; a prosthetic joint; age above 80; diabetes; injecting drug use; immunosuppression, including from biologics, particularly anti-TNF agents, and from corticosteroids; chronic kidney disease; cirrhosis; recent intra-

articular injection, a small but real iatrogenic cause where aseptic technique matters; skin infection or ulceration; alcohol excess; haemophilia; malignancy; and crystal arthritis — and crucially, gout and septic arthritis can coexist, so finding crystals does not exclude infection.

What is not known is why only a small proportion of bacteraemic patients develop septic arthritis. How to distinguish septic arthritis reliably from crystal arthritis and inflammatory flares at presentation is the central practical problem, since synovial white cell count, CRP and even Gram stain all have imperfect sensitivity and specificity, and synovial fluid cultures are negative in about 10 to 30 per cent of true cases†. The optimal drainage method — needle aspiration against arthroscopic against open washout — is not established by good randomised evidence despite being the key therapeutic decision. And whether adjunctive corticosteroids help: the evidence in children is suggestive and adult evidence is absent.

**Cure status.** CURABLE, but only if treated urgently, and function is often permanently lost regardless.

Prompt drainage plus antibiotics cures the infection in the great majority, and gonococcal arthritis in particular resolves well with antibiotics and has an excellent functional prognosis. But cartilage destruction begins within days and is irreversible: bacterial enzymes and the host inflammatory response degrade cartilage rapidly, so about 25 to 50 per cent are left with permanent damage, pain or reduced range of movement, and some progress to secondary osteoarthritis requiring joint replacement. Time to treatment is the main determinant of functional outcome, which is why it is an emergency. Mortality of 7 to 15 per cent means it is not only a joint problem.

Prosthetic joint infection: CURABLE, but usually requiring implant removal or exchange, as in the osteomyelitis entry; debridement with implant retention works only in early infection.

In children, outcomes are generally better with prompt treatment, but hip septic arthritis in infants can destroy the growth plate and femoral head, causing lifelong deformity — a devastating outcome that is still common where presentation is late.

**Prevention.** Aseptic technique for intra-articular injection and joint surgery: STRONG. Surgical prophylaxis for arthroplasty, and *S. aureus* decolonisation: STRONG. Prompt treatment of skin and soft tissue infection and of bacteraemia: MODERATE, especially *S. aureus* bacteraemia, where joints should be actively sought. Harm reduction in injecting drug use: MODERATE. Treating gonorrhoea and chlamydia promptly, with partner treatment and condoms: STRONG for gonococcal arthritis. Diabetes control, and glycaemic and foot care: MODERATE.

Vigilance in patients on biologics and in rheumatoid arthritis: MODERATE. These patients may present atypically with blunted fever and inflammatory markers, and a hot joint in an immunosuppressed patient should be aspirated rather than assumed to be a disease flare. That is the commonest serious diagnostic error in this condition.

Penicillin prophylaxis and vaccination in sickle cell disease: STRONG. Education that an acutely hot, swollen joint requires same-day assessment: MODERATE — free, and it determines the time to treatment that determines the outcome.

**Treatment.** Joint aspiration before antibiotics, immediately, is the single most important action. Send synovial fluid for urgent Gram stain, culture, cell count and differential, and crystal examination; take blood cultures too. Suggestive findings are a synovial white cell count above 50,000 per $mm^3$ with over 90 per cent neutrophils, though lower counts occur, particularly in prosthetic joints, in immunosuppression and in early disease, and a lower count does not exclude it. Remember that crystals and infection coexist: finding urate crystals does not rule out septic arthritis. A needle, a syringe and a microscope constitute the diagnostic apparatus.

Drainage is mandatory and repeated until the effusion stops reaccumulating. Repeated closed-needle aspiration, daily or more often, is effective and cheap and needs no theatre; it is appropriate for accessible joints such as the knee. Arthroscopic washout is for larger or loculated joints, or failed aspiration, and allows lavage and debridement with low morbidity. Open arthrotomy is for the hip, especially in children, where it is urgent to prevent femoral head necrosis, and for inaccessible joints or failure of other methods. No good randomised evidence establishes which is superior; practice varies, and the essential principle is that pus must be removed, promptly and repeatedly, by whatever means is available.

Empirical intravenous antibiotics immediately after aspiration, guided by local resistance and Gram stain: flucloxacillin or cefazolin for suspected methicillin-susceptible *S. aureus*; adding or substituting vancomycin, teicoplanin, daptomycin or linezolid where MRSA is prevalent; adding a Gram-negative agent such as ceftriaxone in the elderly, the immunocompromised and injecting drug users; and ceftriaxone for suspected gonococcal arthritis, with treatment for chlamydia and partner management. Then narrow according to culture.

Duration is about two to four weeks in total for uncomplicated cases, and up to four to six weeks with osteomyelitis or staphylococcal bacteraemia; gonococcal arthritis responds in about seven to fourteen days. Early oral switch is now supported by the OVIVA evidence, which included septic arthritis within bone and joint infection: oral therapy was non-inferior to intravenous over the first six weeks, with failure at 13.2 against 14.6 per cent. That permits much shorter admissions.

Costs: flucloxacillin, cefazolin, ceftriaxone and clindamycin are off-patent and mostly EML-listed, with ceftriaxone verified on the EML, at a few to hundreds of US dollars a course. Vancomycin is off-patent and moderately cheap; daptomycin and linezolid are more expensive, and linezolid is now off-patent.

Analgesia, with joint rest in a functional position initially, then early mobilisation and physiotherapy once infection is controlled, to preserve range of movement; prolonged immobilisation causes stiffness.

Adjunctive corticosteroids in children: several randomised trials suggest dexamethasone reduces duration of symptoms and possibly long-term dysfunction in paediatric septic arthritis, which is promising and not standard, and adult evidence is lacking: CONTESTED. Dexamethasone is an EML-listed medicine across palliative care, antiallergics and hormones and antihormones, with an indicative UNICEF price of US$24.00 per pack of 100 4 mg tablets, about US$0.24 a tablet, October 2026.

Prosthetic joint infection: debridement with implant retention if early and acute with a stable implant, otherwise one- or two-stage exchange, with rifampicin-containing combinations for staphylococci and never rifampicin alone. Treat the source: endocarditis, with echocardiography in *S. aureus* bacteraemia, skin infection, dental sepsis or a urinary source. Late reconstruction — joint replacement, arthrodesis or osteotomy — for the post-infectious destroyed joint, once infection is definitively cleared. Tuberculous and brucellar arthritis need prolonged specific antimicrobial therapy, and should be considered in chronic monoarthritis in endemic areas, where they are frequently missed for months.

**Simple means.** Aspirating the joint needs a needle and a syringe. It is simultaneously the diagnostic test and the first therapeutic act, and it can be done at any level of the health system with basic training and sterile technique. That is the highest-value simple means in this entry, because the whole outcome depends on doing it early.

Repeated needle aspiration as definitive drainage, for accessible joints, needs no operating theatre, no arthroscope and no anaesthetic service. A microscope gives synovial white cell count, Gram stain and crystal examination, with polarised or improvised polarised light, and yields most of the diagnostic information available anywhere.

Recognition and urgency: teaching patients, families and frontline health workers that a hot, acutely swollen, very painful joint with fever means same-day care. Free, and it is the determinant of whether the joint survives, since cartilage loss begins within days.

Aspirating the hot joint in an immunosuppressed or rheumatoid patient rather than assuming a flare is a decision, not a technology, and it corrects the commonest serious error here.

Cheap off-patent antibiotics with early oral switch, per OVIVA, give a curative course for tens of dollars without prolonged intravenous access. Early mobilisation and physiotherapy preserves the function that the infection threatens, through a taught exercise programme. Clean injecting equipment, aseptic injection technique, and treating gonorrhoea and notifying partners.

The honest limit: this is one of the clearest cases in this book where simple means are necessary but not sufficient. The condition needs antibiotics and effective drainage, and a septic hip, especially in a child, needs urgent surgical decompression. Delay costs the joint and sometimes the life.

**Gaps.** No test reliably distinguishes septic arthritis from crystal or inflammatory arthritis at presentation: synovial cell counts overlap, cultures are negative in 10 to 30 per cent, and the two can coexist. That is the central diagnostic gap and it causes both delayed treatment and unnecessary washouts. No good randomised evidence compares needle aspiration, arthroscopic and open drainage, despite this being the key management decision. Optimal antibiotic duration is convention-based, though OVIVA settled the route question. Adjunctive corticosteroid benefit is suggested in children and unstudied in adults. Why functional outcomes remain poor in 25 to 50 per cent despite successful microbiological cure is not well understood, and no treatment protects cartilage. Prosthetic joint infection management rests largely on cohort data. The condition is not counted in GBD, so global burden and the outcomes of late presentation — especially infant hip septic arthritis in low-income settings, which causes lifelong disability — are unquantified. Rising MRSA and Gram-negative resistance narrows empirical options.

# ICD-11 Chapter 16 — Diseases of the genitourinary system

---

## Chronic kidney disease

**What it is.** The kidneys lose filtering capacity over months or years. It is usually silent until advanced. At the end stage, survival requires dialysis or a transplant.

**Measured.** Global prevalence is about 9.1 to 13.4 per cent of adults, so roughly 700 to 850 million people have some stage of chronic kidney disease — more than diabetes, and more than any single cancer. The WHO fact sheet, which is titled Kidney disease rather than Chronic kidney disease and printed 20 April 2026, gives an estimated 674 million people worldwide, with no reference year stated anywhere on the page. Both are printed, and the WHO figure carries no year.

GBD 2019 gave about 1.4 million deaths directly, ranking it around twelfth among causes of death globally, with a projection to fifth by 2040 on current trends†, and about 35 to 42 million DALYs†. GBD 2023 Table 1 gives chronic kidney disease 10.3 million YLDs (95 per cent UI 7.53 to 13.3), rank 24. The WHO kidney disease page gives no death figure at all, saying only that kidney disease contributes to millions of preventable deaths each year, and it gives no rank, and no dialysis or transplant access figures. It does give the diagnostic thresholds: eGFR below 60 ml/min/1.73m² on two tests at least 90 days apart, and a urinary albumin-creatinine ratio above 3 mg/mmol (30 mg/g). The World Health Assembly adopted a resolution on kidney health in May 2025.

Impaired kidney function is additionally attributed a further large burden as a risk factor, through cardiovascular disease; total attributable deaths including that pathway are on the order of 3.1 to 3.2 million†. The dual counting is important: chronic kidney disease kills far more through cardiovascular disease than through kidney failure itself.

Only a minority of those needing kidney replacement therapy receive it. Estimates suggest about 2.6 million people on dialysis against a need of 5 to 10 million, with the shortfall overwhelmingly in low- and middle-income countries. Death from untreated kidney failure is largely invisible in statistics.

Prevalence rises steeply after 60, and a substantial share of chronic kidney disease in the very old is age-related eGFR decline of uncertain prognostic significance. Burden is high in South Asia, Latin America, sub-Saharan Africa, and among Indigenous populations in Australia, New Zealand and North America. Chronic kidney disease of unknown aetiology clusters in agricultural communities in Central America, as Mesoamerican nephropathy, and in Sri Lanka and India, affecting young male agricultural workers; heat stress, dehydration, agrochemicals and heavy metals are all implicated and none confirmed.

**Where it starts.** Diabetes is the leading cause worldwide, at about 30 to 50 per cent of end-stage disease in many countries†. Hypertension is second, and bidirectional with kidney disease. Glomerulonephritis; and polycystic kidney disease, autosomal dominant, from *PKD1* and *PKD2*, at about one in 400 to 1,000†, the commonest inherited kidney disease.

Obstructive uropathy from benign prostatic hyperplasia or stones; recurrent pyelonephritis and reflux nephropathy; HIV; hepatitis B and C; sickle cell disease; multiple myeloma; lupus; vasculitis.

Nephrotoxins: NSAIDs in chronic use, aminoglycosides, calcineurin inhibitors, lithium, cisplatin; aristolochic acid, in Balkan endemic nephropathy and Chinese herb nephropathy, a proven cause and also carcinogenic; and lead, cadmium and mercury.

Low birth weight and reduced nephron endowment is a well-supported developmental origin: fewer nephrons at birth means less reserve, linking maternal nutrition to adult kidney disease. Episodes of acute kidney injury each raise subsequent risk substantially, and the injury-to-chronic transition is now recognised as a major pathway.

eGFR heritability is estimated at about 30 to 55 per cent in family and twin studies, and *APOL1* G1 and G2 risk variants are the strongest known: in people of West African ancestry, two risk alleles confer roughly seven to ten times the risk of hypertension-attributed end-stage kidney disease and about seventeen to 29 times for HIV-associated nephropathy. That largely explains the long-observed excess of kidney failure in African-ancestry populations, previously attributed to hypertension or to social factors alone, and it prompted the removal of the race coefficient from eGFR equations in 2021.

What is not known is the cause of chronic kidney disease of unknown aetiology, a disease affecting hundreds of thousands of young agricultural workers with no established cause, and among the more striking unexplained epidemics in current medicine. Why progression rates vary so much between individuals with identical eGFR and proteinuria is not predictable. Whether age-related eGFR decline in the elderly is disease or physiology is genuinely contested and affects hundreds of millions of diagnoses. And the mechanism linking kidney disease to such extreme cardiovascular risk is only partly explained.

**Cure status.** Four strata, each with its own label.

Established chronic kidney disease: CONTROLLABLE, not curable. Established nephron loss is irreversible and the aim is to slow progression, which modern therapy does substantially.

Specific reversible causes — obstruction, lupus nephritis, vasculitis, a drug cause, an infection: CURABLE, by relieving obstruction, treating lupus nephritis and vasculitis early, withdrawing the drug, or treating the infection.

End stage after transplantation: CONTROLLABLE. Function is restored, though it requires lifelong immunosuppression, with a graft half-life of about twelve to fifteen years for a deceased donor and longer for a living donor.

End stage on dialysis without transplant access: RELIEF ONLY, and replacement rather than cure.

The important modern fact is that progression can now be slowed enough to change the natural history: combination therapy can roughly halve the rate of eGFR decline, deferring or preventing dialysis for many.

**Prevention.** Blood pressure control: STRONG, reducing progression and cardiovascular events, with the greatest benefit where there is proteinuria. ACE inhibitors or ARBs in proteinuric disease: STRONG, reducing progression to end-stage disease by about 30 per cent in proteinuric disease. SGLT2 inhibitors: STRONG, the major advance of the last decade. Glycaemic control in diabetes: STRONG. Avoiding NSAIDs and other nephrotoxins, and avoiding aristolochic-acid-containing herbal products: STRONG. Preventing and promptly treating acute kidney injury: MODERATE. Smoking cessation: MODERATE. Weight management: MODERATE. Treating hepatitis B and C and HIV: STRONG for those causes.

Occupational heat and hydration protection in agricultural workers — water, rest, shade: MODERATE, plausible and supported by intervention studies in Central America, and not definitively proven to prevent chronic kidney disease of unknown aetiology. Population salt reduction and sugar-sweetened beverage reduction: MODERATE. Maternal nutrition and avoiding low birth weight: MODERATE, on the developmental pathway.

**Treatment.** An ACE inhibitor or ARB is foundation therapy for proteinuric disease, reducing proteinuria and slowing progression by about 30 per cent relative risk reduction for doubling of creatinine or end-stage kidney disease in proteinuric disease (RENAAL, IDNT, AASK). Enalapril, lisinopril or losartan: EML yes; off-patent; a few to tens of US dollars a patient-year. Among the highest-value drugs in medicine.

SGLT2 inhibitors are the single largest therapeutic advance in nephrology in decades, and they work with and without diabetes. DAPA-CKD (Heerspink, *NEJM* 2020, 4,304 patients):

dapagliflozin reduced the primary composite of a 50 per cent or greater eGFR decline, end-stage kidney disease, and renal or cardiovascular death, with a hazard ratio of 0.61 (95 per cent CI 0.51 to 0.72), about a 39 per cent relative reduction, and an all-cause mortality hazard ratio of 0.69. EMPA-KIDNEY (*NEJM* 2023, 6,609 patients): empagliflozin reduced kidney disease progression or cardiovascular death, hazard ratio 0.72 (0.64 to 0.82). CREDENCE, with canagliflozin in diabetic kidney disease, gave a hazard ratio of 0.70 for the renal composite†. Dapagliflozin and empagliflozin were added to the EML in the 2023 and 2025 cycles†. Dapagliflozin generics are now available in India and several markets; the originator US list price is about US$6,000 a year, and generics run as low as about US$30 to 120 a patient-year in India†. The price range is the key access fact.

Finerenone, a non-steroidal mineralocorticoid antagonist: FIDELIO-DKD gave a kidney composite hazard ratio of 0.82 (95 per cent CI 0.73 to 0.93) in diabetic kidney disease. On patent; thousands of US dollars a year.

Spironolactone is the cheap steroidal mineralocorticoid antagonist; it reduces proteinuria, with hyperkalaemia risk. Off-patent; an EML-listed medicine under diuretics, section 16, and heart failure, section 12.4; tens of US dollars a year. A low-cost substitute for finerenone with less outcome evidence at a fraction of the cost.

Statins reduce cardiovascular events, the main cause of death, in chronic kidney disease, though not in dialysis patients, where the 4D and AURORA trials were negative. Off-patent, EML-listed, tens of US dollars a year. Blood pressure control to about 120 to 130 systolic, individualised, with all the major agents off-patent and cheap.

Management of complications: anaemia with erythropoiesis-stimulating agents, iron, and now oral HIF prolyl hydroxylase inhibitors. Note that the EML lists erythropoiesis-stimulating agents as the selected medicine for anaemia due to chronic disease, in the complementary list, section 10.1, with epoetin alfa, beta, theta and methoxy polyethylene glycol-epoetin beta listed only as therapeutic equivalents to that class entry rather than as selected medicines in their own right. Metabolic acidosis with sodium bicarbonate, which is cheap and slowed progression in trials; hyperphosphataemia with phosphate binders and dietary phosphate restriction; secondary hyperparathyroidism with vitamin D analogues and cinacalcet; hyperkalaemia with dietary measures and potassium binders.

Sodium bicarbonate is a remarkable value case: a kitchen chemical that slowed progression and improved nutritional status in trials (de Brito-Ashurst, *JASN* 2009), at pennies a year.

Kidney replacement therapy: haemodialysis, peritoneal dialysis, transplantation. Peritoneal dialysis is cheaper to establish, needs no electricity-dependent machine and no water treatment plant, and is well suited to rural and low-income settings; a PD-first policy is used successfully in Hong Kong, Thailand and Mexico. Dialysis costs tens of thousands of US dollars a patient-year depending on country, and transplant is cheaper after the first year. Conservative kidney management is a legitimate, planned pathway for frail elderly patients in whom dialysis offers little survival or quality-of-life benefit.

**Simple means.** Blood pressure control with cheap off-patent drugs costs a few dollars a year for the largest modifiable effect; measuring blood pressure needs a cuff. Sodium restriction, under 5 to 6 g of salt a day, improves blood pressure and reduces proteinuria measurably. Sodium bicarbonate for metabolic acidosis costs pennies and slows progression. Stopping NSAIDs and nephrotoxic herbal remedies, including aristolochic-acid products, which are a proven cause of kidney failure and urothelial cancer.

Water, rest and shade for agricultural workers in hot climates is the leading candidate intervention for chronic kidney disease of unknown aetiology and requires no technology. Weight loss, physical activity and smoking cessation. Moderate dietary protein, about 0.8 g/kg a day, slows progression modestly; avoid severe restriction, which causes malnutrition. Avoiding sugar-sweetened beverages.

Dipstick urinalysis and a blood pressure cuff are the entire screening apparatus needed to find treatable chronic kidney disease early. Proteinuria dipsticks cost cents and are the highest-yield simple diagnostic in this entry. Peritoneal dialysis is the simple means of kidney replacement: gravity, bags and training, with no machine and no water plant.

The honest limit: end-stage kidney failure cannot be managed by simple means. Without dialysis or a transplant it is fatal, and that is the situation for most of the world’s patients.

**Gaps.** Chronic kidney disease of unknown aetiology is unexplained and affects a large, young, poor population. Whether age-related eGFR decline constitutes disease is unresolved and affects prevalence figures enormously. Progression prediction in individuals is poor. The true global mortality of untreated kidney failure is unknown because those patients die undiagnosed and uncounted, and GBD almost certainly understates it. The WHO kidney disease fact sheet carries almost no burden data: one prevalence figure with no year, and no deaths, no rank and no access figures. *APOL1*-targeted therapy is in trials and not established. Dialysis access is grossly inequitable and mostly unmeasured. Generic SGLT2 inhibitor pricing and availability are changing rapidly, so cost figures date quickly. Evidence for most interventions in dialysis patients is weak or negative, despite their extreme risk. Trials underrepresent Africa and South Asia.

---

## Acute kidney injury

**What it is.** Kidney function falls over hours or days. Urine output may drop and waste builds up in the blood. It is usually a complication of something else — infection, blood loss, dehydration or a drug.

**Measured.** It occurs in about 10 to 15 per cent of all hospital admissions and in over 50 per cent of intensive care admissions in high-income settings. There are about 13.3 million cases a year globally, with about 1.7 million deaths attributed, though these are modelled estimates with wide uncertainty (Mehta, ISN 0by25 initiative).

About 85 per cent of cases occur in low- and middle-income countries, where the causes differ fundamentally: diarrhoeal disease and dehydration, obstetric haemorrhage and sepsis, malaria, leptospirosis, snake envenomation and traditional or herbal remedies, rather than the cardiac surgery, contrast and intensive-care sepsis of high-income settings.

It is not a separate top-level GBD cause, and the burden is distributed and under-captured. In-hospital mortality for severe injury requiring dialysis is about 40 to 50 per cent. Incidence rises steeply with age, but in low-income settings a large share occurs in children, from diarrhoeal illness, and in young women, from obstetric causes.

**Where it starts.** Classification by mechanism is practically useful, because it determines reversibility.

Pre-renal, about 40 to 70 per cent†: volume depletion from diarrhoea, vomiting, haemorrhage or burns; sepsis-induced vasodilation; heart failure; cirrhosis and hepatorenal syndrome; and NSAIDs with ACE inhibitors or ARBs reducing autoregulation, the triple whammy when a diuretic is added.

Intrinsic: acute tubular necrosis, ischaemic or toxic; acute interstitial nephritis from drugs including PPIs, antibiotics and NSAIDs; glomerulonephritis; rhabdomyolysis from crush injury, exertion, statins or seizures; haemolysis; myeloma; tumour lysis; contrast-associated injury; thrombotic microangiopathy; malaria; leptospirosis; and snakebite, a major cause in South Asia and Africa.

Post-renal, obstruction: prostatic disease, stones, pelvic malignancy, retroperitoneal fibrosis, a blocked catheter. Always to be excluded, because it is immediately reversible.

Nephrotoxic drugs: aminoglycosides, amphotericin, cisplatin, vancomycin, calcineurin inhibitors, NSAIDs, contrast media; and traditional remedies and unregulated analgesics, a major and under-recognised cause in several regions. Risk factors: pre-existing chronic kidney disease, which is the strongest, then age, diabetes, heart failure, cirrhosis, sepsis, major surgery and hypovolaemia. Heritability is not meaningfully established, since this is an acquired event, though genetic susceptibility including *APOL1* modifies risk†.

What is not known is why some patients recover fully and others progress to chronic kidney disease: the injury-to-chronic transition is a major research gap with no predictive test. Contrast-associated injury's true attributable risk has been substantially revised downward and is now contested — much of what was blamed on contrast was confounding. And no drug has ever been shown to treat established acute kidney injury despite decades of trials, which is itself unexplained.

**Cure status.** Pre-renal, obstructive and drug-induced injury with the cause corrected: CURABLE. That is the key feature. Pre-renal injury reverses within hours to days with volume restoration; obstructive injury reverses on relief of obstruction, sometimes dramatically; and drug-induced injury reverses on withdrawal.

Acute tubular necrosis in a surviving patient: SELF-LIMITING, typically recovering over one to three weeks if the patient survives, because tubular epithelium regenerates.

But recovery is often incomplete. A substantial proportion are left with reduced eGFR, and an episode raises long-term chronic kidney disease risk roughly eight to ten times and end-stage kidney disease risk substantially. So “cured” overstates it for many survivors. And no drug treats established acute kidney injury: supportive care and dialysis are all there is.

**Prevention.** Prevention is the whole game here, since treatment does not exist.

Maintaining volume status and treating dehydration early: STRONG. In low-income settings, oral rehydration therapy for diarrhoeal illness prevents a large share of the global burden, and is the single highest-impact preventive measure.

Avoiding nephrotoxins, and stopping NSAIDs, ACE inhibitors or ARBs and diuretics during acute illness, the sick day rules: STRONG. Avoiding aminoglycosides where alternatives exist, once-daily rather than divided dosing, and therapeutic drug monitoring: STRONG. Recognising and relieving obstruction promptly: STRONG. Early sepsis treatment: STRONG.

Isotonic crystalloid rather than hydroxyethyl starch: STRONG — starches cause acute kidney injury and increase mortality (6S, CHEST) and have been withdrawn for this indication. Balanced crystalloid rather than saline: MODERATE, with SMART and BaSICS mixed.

For contrast: volume expansion with isotonic saline in high-risk patients: MODERATE. N-acetylcysteine: CONTESTED and refuted — the PRESERVE trial (*NEJM* 2018, 5,177 patients) found no benefit of N-acetylcysteine or of sodium bicarbonate over saline. Another clear negative that reversed practice.

Acute kidney injury alerts and electronic warnings: CONTESTED, with modest or no outcome benefit in trials. Antivenom availability for snakebite: STRONG in endemic areas. Hydration and heat protection for outdoor workers: MODERATE.

**Treatment.** There is no specific drug. Management is supportive, and the evidence is largely about what not to do.

Identify and treat the cause: infection, haemorrhage, obstruction, drug. Restore circulating volume with isotonic crystalloid, titrated, and avoid both under-resuscitation and fluid overload, since positive fluid balance is independently associated with mortality and routine fluid boluses in established injury cause harm. Sodium chloride 0.9 per cent or Ringer’s lactate: EML yes†; off-patent; about US$0.50 to 3 a litre. Oral rehydration solution: EML yes, at an indicative UNICEF price of US$4.80 per carton of 100 sachets, about US$0.048 a sachet, read 19 October 2026 — the cheapest and most consequential intervention in this entry globally.

Stop nephrotoxic drugs and dose-adjust everything else. Relieve obstruction with a catheter, nephrostomy or stent: a urinary catheter costs little and can reverse established renal failure within hours. Treat hyperkalaemia with calcium gluconate, insulin-dextrose, nebulised salbutamol, sodium bicarbonate, potassium binders, and dialysis if refractory; all except the binders are cheap and EML-listed. Correct acidosis; manage pulmonary oedema with diuretics if responsive, otherwise dialysis or ultrafiltration.

Dialysis when indicated — refractory hyperkalaemia, acidosis, fluid overload, uraemic complications. On timing, earlier is not better: the STARRT-AKI trial (*NEJM* 2020, 3,019 patients) and AKIKI found no mortality benefit from accelerated initiation, and accelerated strategies caused more dialysis dependence and more catheter complications. Wait for an indication. Peritoneal dialysis is effective for acute kidney injury and feasible without electricity, water treatment or machines, validated in Africa and Asia and the basis of the ISN 0by25 approach to preventable deaths.

Do not use: low-dose dopamine; furosemide to convert oliguric to non-oliguric injury; routine mannitol; N-acetylcysteine for contrast. All tested, all without benefit.

Nutrition with adequate energy and protein, avoiding protein restriction. Follow-up: survivors need eGFR and proteinuria monitoring because of the eight- to tenfold chronic kidney disease risk, and this is widely neglected.

**Simple means.** This is the condition in this book where simple means save the most lives.

Oral rehydration solution — sugar, salt and clean water, at about US$0.048 a sachet on the UNICEF indicative price of October 2026 — prevents the diarrhoeal-dehydration injury that constitutes a large share of the global burden, particularly in children. The highest-yield intervention here by a wide margin.

Early oral fluids in any acute illness, and the sick day rules — stopping NSAIDs, ACE inhibitors or ARBs and diuretics during vomiting or diarrhoea. Free, and they prevent a large share of community-acquired injury.

A urinary catheter reverses obstructive renal failure immediately, at cents. Urine output measurement and a basic creatinine are the entire monitoring requirement. Avoiding nephrotoxic traditional remedies and unregulated analgesics, which are a major preventable cause in several regions. Peritoneal dialysis using locally produced fluid gives kidney replacement without electricity or machines, and the ISN demonstrated feasibility in low-resource settings. Prompt antivenom in snakebite-endemic regions. Water, shade and rest breaks for heat-exposed workers.

And not doing harmful things: no starch solutions, no dopamine, no routine furosemide, no N-acetylcysteine, no early dialysis. Several of these are cost-saving as well as safer.

**Gaps.** Most of the world's acute kidney injury is neither diagnosed nor counted, so burden figures are modelled and uncertain. The injury-to-chronic transition has no predictive test and no treatment. No drug has ever succeeded for established injury despite many trials, a striking and unexplained failure. Contrast-associated injury's attributable risk is contested and probably much smaller than long believed. Optimal fluid type and volume remain unsettled. Biomarkers — NGAL, TIMP-2/IGFBP7 — have not changed outcomes. Serum creatinine is a poor and lagging marker, and baseline values are often unknown, so the diagnosis itself is unreliable. Follow-up of survivors is poor everywhere.

---

## Glomerulonephritis

**What it is.** Inflammation of the kidneys' filtering units. Protein and blood leak into the urine. Some forms settle by themselves; others destroy the kidneys over years.

**Measured.** IgA nephropathy is the commonest primary glomerulonephritis worldwide, with an incidence of about 2.5 per 100,000 a year and marked geographic variation: highest in East Asia, in Japan, China and Korea, intermediate in Europe, and apparently low in Africa, though this may partly reflect biopsy practice.

Glomerulonephritis causes about 10 to 20 per cent of end-stage kidney disease globally, and a higher share in Asia. GBD 2019 attributed roughly 200,000 to 250,000 deaths a year to glomerulonephritis as a cause of chronic kidney disease.

Post-streptococcal glomerulonephritis remains common in low-income settings and in Indigenous populations and has largely disappeared from high-income countries, with incidence estimated at about 470,000 cases a year globally, mostly in children†. Membranous nephropathy runs at about one per 100,000 a year; focal segmental glomerulosclerosis is rising in incidence and is the commonest cause of nephrotic syndrome in adults in several countries; and minimal change disease accounts for about 80 to 90 per cent of childhood nephrotic syndrome†.

By age: minimal change disease in children; IgA nephropathy in the second to fourth decades; membranous nephropathy and ANCA vasculitis in later life. IgA nephropathy shows male predominance in Europe and North America and is closer to equal in Asia.

**Where it starts.** IgA nephropathy: galactose-deficient IgA1 with immune complex deposition, with mucosal immunity involvement, and associations with coeliac disease and liver disease. Familial clustering exists and GWAS has found loci in the MHC and complement regions; heritability is appreciable and not precisely quantified.

Post-infectious: group A *Streptococcus*, from skin or throat, a clear and preventable cause; also staphylococcal infection, hepatitis B and C, HIV, syphilis, malaria, schistosomiasis and endocarditis.

Membranous nephropathy: anti-PLA2R antibodies in about 70 to 80 per cent and anti-THSD7A in a few per cent† — a genuine mechanistic breakthrough that converted an idiopathic disease into an identifiable autoimmune one. Secondary causes: hepatitis B, malignancy, lupus, NSAIDs, gold, penicillamine.

Focal segmental glomerulosclerosis: *APOL1* risk variants, strong in African ancestry; obesity-related disease; reflux and reduced nephron mass; HIV; heroin; pamidronate; and genetic podocyte mutations — *NPHS1*, *NPHS2*, *INF2*, *ACTN4* — in familial and steroid-resistant cases.

ANCA-associated vasculitis: anti-MPO and anti-PR3 antibodies, with silica exposure, some drugs including hydralazine and propylthiouracil, and HLA associations. Anti-GBM, Goodpasture, disease: HLA-DRB1*15:01 strongly associated, with hydrocarbon exposure and smoking as co-factors. Lupus nephritis: female predominance, ancestry effects, a strong genetic component.

What is not known is what triggers the autoimmunity in most cases — why anti-PLA2R antibodies appear, why galactose-deficient IgA1 is produced, what initiates ANCA. Progression is not well predicted at the individual level. Whether the apparent low incidence in Africa is real or an artefact of absent biopsy services is unresolved and important. And the relative contribution of the complement pathways is being actively revised.

**Cure status.** This varies by type more than almost any other entry here, so each stratum is named.

Post-streptococcal glomerulonephritis: SELF-LIMITING. It recovers almost completely in children, over 95 per cent†, with supportive care only.

Minimal change disease: CONTROLLABLE. Over 90 per cent of children† respond to corticosteroids, relapses are common, so the state is held rather than removed, and long-term kidney function is usually preserved.

Membranous nephropathy: SELF-LIMITING in about 30 per cent†, through spontaneous remission, with the remainder CONTROLLABLE by immunosuppression — rituximab induces remission in about 60 per cent.

IgA nephropathy: CONTROLLABLE. Progression is slowed, not cured, and about 20 to 40 per cent† reach end-stage disease over twenty years.

ANCA vasculitis and lupus nephritis: CONTROLLABLE, often with sustained remission. ANCA vasculitis went from about 80 per cent one-year mortality untreated to over 80 per cent five-year survival† with immunosuppression — one of the great therapeutic transformations in medicine. Relapse is common.

Anti-GBM disease: CURABLE if treated urgently, with plasma exchange plus immunosuppression, and irreversible if the patient is dialysis-dependent at presentation.

Focal segmental glomerulosclerosis: CONTROLLABLE in immunosuppression-responsive disease, RELIEF ONLY in genetic forms, which do not respond to immunosuppression; recurrence after transplant is common in circulating-factor disease.

Established sclerosis in any form is irreversible, and early treatment is decisive throughout.

**Prevention.** Treating streptococcal skin and throat infection, scabies control, and improved housing, hygiene and skin health: STRONG for post-streptococcal disease, which was essentially eliminated in high-income countries by these means. Hepatitis B vaccination, hepatitis B and C treatment, and HIV treatment: STRONG for those secondary forms, with HIV-associated nephropathy responding markedly to antiretroviral therapy.

Avoiding NSAIDs, gold and penicillamine, and silica exposure control: MODERATE. Blood pressure and proteinuria control to prevent progression: STRONG, as secondary prevention. Early biopsy and diagnosis: MODERATE for preventing irreversible loss, since the main preventable harm in high-income settings is diagnostic delay.

No primary prevention exists for IgA nephropathy, membranous nephropathy, focal segmental glomerulosclerosis or ANCA vasculitis: absent. Tonsillectomy for IgA nephropathy: CONTESTED — practised in Japan, not supported elsewhere.

**Treatment.** Supportive treatment, for all proteinuric forms. An ACE inhibitor or ARB reduces proteinuria and slows progression; off-patent, EML-listed, a few to tens of US dollars a year. Foundation therapy. SGLT2 inhibitors are now established in proteinuric chronic kidney disease including IgA nephropathy, with DAPA-CKD including IgA patients and giving an overall hazard ratio of 0.61 for the kidney composite; generics about US$30 to 120 a year in India†. Blood pressure control, salt restriction, statins.

Disease-specific treatment. Corticosteroids are first line for minimal change disease, with over 90 per cent response in children†, and part of regimens for lupus nephritis, ANCA vasculitis and some IgA nephropathy. Prednisolone: EML yes; off-patent; a few to tens of US dollars a year. A cheap drug that saves kidneys and lives.

Cyclophosphamide for induction in severe lupus nephritis, ANCA vasculitis and anti-GBM disease: EML yes, as a cytotoxic; off-patent; tens to hundreds of US dollars a course. Highly effective, with gonadal toxicity and malignancy risk.

Rituximab for membranous nephropathy — the MENTOR trial found it superior to cyclosporine for sustained remission, about 60 against 20 per cent at 24 months — and non-inferior to cyclophosphamide for ANCA vasculitis induction (RAVE, *NEJM* 2010) and better for relapsing disease; increasingly used in lupus nephritis and minimal change disease. Rituximab is an EML-listed medicine, under medicines for multiple sclerosis, section 5.1.2 complementary, and targeted therapies, section 8.2.2 complementary; the recorded indications are multiple sclerosis and four lymphoid malignancies, and glomerulonephritis is not among them. Biosimilars are widely available; the originator was tens of thousands of US dollars a course, and biosimilars run thousands of US dollars and lower in India. The biosimilar price fall has made this broadly accessible.

Mycophenolate mofetil for lupus nephritis induction and maintenance, at least as effective as cyclophosphamide with less gonadal toxicity, and also used in IgA vasculitis; off-patent; hundreds of US dollars a year; EML yes. Calcineurin inhibitors, tacrolimus and cyclosporine, for focal segmental glomerulosclerosis, membranous nephropathy and lupus, with voclosporin now approved for lupus nephritis; tacrolimus off-patent, hundreds to thousands of US dollars a year.

Targeted newer agents: nefecon, a targeted-release budesonide, and sparsentan, a dual endothelin and angiotensin antagonist, for IgA nephropathy, both reducing proteinuria and slowing eGFR decline, both on patent and very expensive, with sparsentan at hundreds of thousands of US dollars a year list. Avacopan for ANCA vasculitis, as a steroid-sparing agent; belimumab and voclosporin for lupus nephritis. All patented and costly. Complement inhibitors, iptacopan and ravulizumab, are in trials or approval for C3 glomerulopathy and IgA nephropathy.

Plasma exchange for anti-GBM disease, where it is essential, and in selected severe ANCA vasculitis — though the PEXIVAS trial (*NEJM* 2020) found no overall benefit of plasma exchange in severe ANCA vasculitis, narrowing its indications substantially. Antibiotics for the underlying infection in post-infectious and endocarditis-related disease, and antivirals for hepatitis-related disease. Kidney replacement therapy at end stage, and transplantation with awareness of recurrence risk, especially in focal segmental glomerulosclerosis and IgA nephropathy.

**Simple means.** Treating skin and throat infections, and treating scabies, prevents post-streptococcal glomerulonephritis. Benzathine benzylpenicillin is an EML-listed medicine in the Access group, section 6.2.1, with syphilis as its first-choice listed indication, and permethrin is an EML-listed medicine in section 13.5, scabicides and pediculicides, with scabies among its three indications; ivermectin is listed in section 6.6, medicines for ectoparasitic infections. All are cheap: the indicative UNICEF price for benzathine benzylpenicillin 2.4 MIU is US$29.49 per box of 50 vials, about US$0.59 a vial, October 2026, with the single-vial-with-solvent pack at US$3.01, five times as much per dose. This is how high-income countries eliminated the disease, and it needs no nephrology service at all.

Soap, water, housing and reduced crowding are the structural version of the same thing. Salt restriction reduces proteinuria and blood pressure and improves the response to ACE

inhibitors measurably. Dipstick urinalysis costs cents and is the only way most glomerulonephritis is found early; screening urinalysis in schoolchildren is credited with Japan's early detection of IgA nephropathy. Blood pressure measurement and cheap antihypertensives. Oedema management by salt and fluid restriction, elevation and careful diuretics. Prednisolone costs pennies and is curative in most childhood minimal change disease. Pneumococcal vaccination and infection vigilance in nephrotic patients, who are functionally immunosuppressed and at risk of peritonitis and sepsis.

The honest limit: diagnosis usually requires a kidney biopsy and histopathology, which is unavailable across much of the world. That absence, and not the cost of the drugs, is the binding constraint, since several of the effective drugs — prednisolone, cyclophosphamide — are extremely cheap.

**Gaps.** Biopsy and histopathology access is the dominant global inequity, so incidence data from Africa and much of Asia are unreliable and probably understate disease. Progression prediction is poor. Most immunosuppression regimens rest on small or old trials, and head-to-head comparisons are scarce. The new targeted agents have strong surrogate data on proteinuria and limited hard-outcome and long-term safety data, at very high prices, against cheap drugs with decades of use. PEXIVAS reversed plasma exchange practice and similar reversals may follow. Whether to screen urine at population level is unresolved outside Japan. Complement-targeted therapy is advancing faster than the evidence base for positioning it.

---

## Diabetic nephropathy

**What it is.** Long-standing diabetes damages the kidney's small blood vessels and filters. Protein appears in the urine and filtering slowly fails. It is the leading cause of kidney failure worldwide.

**Measured.** It develops in about 30 to 40 per cent of people with type 1 diabetes and about 20 to 40 per cent of those with type 2. It is the leading single cause of end-stage kidney disease globally, at about 30 to 50 per cent of incident dialysis and transplant patients in most countries, and higher in Mexico, Malaysia, Singapore and the Gulf states, above 50 to 60 per cent. GBD 2019 gave chronic kidney disease due to diabetes, types 1 and 2 combined, roughly 400,000 to 460,000 deaths a year†.

The denominator is contested, and the discrepancy matters because attributable burden is computed on it. The IDF Diabetes Atlas, eleventh edition, gives 589 million adults aged 20 to 79 with diabetes; this file's source dates that figure to 2024 and another chapter of this book dates the same figure and the same edition to 2025, in three places†. Same figure, same edition, two different years; both stand, unresolved. On the denominator itself, the IDF figure of 589 million adults aged 20 to 79 and the WHO figure of 830 million at all ages, 14 per cent of adults aged 18 and over†, are substantially different global figures, and two chapters of this book compute attributable burden on these incompatible denominators. Both stand, and the discrepancy is named rather than smoothed.

Age pattern reflects diabetes duration: typically more than ten years after onset in type 1, and often present at diagnosis in type 2 because of delayed diagnosis. Burden is concentrated in South and East Asia, the Middle East, Latin America, the Pacific Islands and Indigenous populations, where diabetes prevalence and genetic susceptibility combine.

**Where it starts.** Hyperglycaemia duration and severity is necessary and dose-dependent, and is the basis of the glycaemic control evidence from DCCT/EDIC and UKPDS. Hypertension is strongly synergistic, and the combination accelerates loss markedly.

Genetic susceptibility shows clear familial clustering independent of glycaemia, with heritability of diabetic nephropathy estimated at about 30 to 50 per cent and sibling risk substantially raised. *APOL1* variants raise risk in African-ancestry populations, and GWAS loci — *COL4A3*, *GLRA3* and others — have small effects. Ancestry: higher risk in African, South Asian, Hispanic, Pacific Islander, Indigenous American and Australian Aboriginal populations, beyond what glycaemia and access explain. Smoking; obesity; dyslipidaemia; male sex in type 1; puberty, which accelerates onset in type 1; and episodes of acute kidney injury.

What is not known is why 60 to 70 per cent of people with long-standing diabetes never develop nephropathy despite comparable glycaemic exposure, which is the strongest argu-

ment for genetic determination, though the genetics found so far explain little of it. Non-albuminuric diabetic kidney disease — progressive eGFR loss without proteinuria — is increasingly recognised, especially in type 2 diabetes and in women, does not fit the classical albuminuria-first model, has an unclear mechanism, and is missed by albuminuria-based screening. Why some patients regress from microalbuminuria spontaneously is unexplained.

**Cure status.** Three strata.

Diabetic kidney disease, medically managed: CONTROLLABLE, and now substantially more so than a decade ago. Established nephropathy with declining eGFR is not curable, but progression can be slowed enough to change outcomes substantially: combined ACE inhibitor or ARB, SGLT2 inhibitor and finerenone therapy roughly halves the rate of eGFR decline compared with historical controls.

Early microalbuminuria with tight glycaemic and blood pressure control: CURABLE, with regression occurring in a meaningful proportion, about 30 per cent over six years in the type 1 Joslin cohort, so early disease is partly reversible.

End-stage disease after transplantation: CONTROLLABLE, as for the transplant stratum of chronic kidney disease, since lifelong immunosuppression holds the state. Simultaneous pancreas-kidney transplantation in type 1 diabetes can replace both the diabetes and the kidney failure, and is the nearest thing to a complete cure available. Bariatric surgery in type 2 diabetes with obesity can induce diabetes remission and improve albuminuria, which is a partial reversal of the cause.

**Prevention.** Glycaemic control: STRONG. DCCT/EDIC in type 1 found intensive control reduced microalbuminuria by about 39 per cent and clinical albuminuria by about 54 per cent, with benefits persisting decades later, which is metabolic memory; UKPDS in type 2 gave about a 25 per cent reduction in microvascular endpoints. Blood pressure control: STRONG.

ACE inhibitors or ARBs once albuminuria is present: STRONG, reducing progression by about 30 per cent in proteinuric disease (RENAAL, IDNT). They do not prevent nephropathy in normoalbuminuric, normotensive patients, so they are not primary prevention.

SGLT2 inhibitors: STRONG — they both prevent and treat. Smoking cessation: MODERATE. Annual albuminuria and eGFR screening: STRONG — cheap, and the entry point to all the above. A urine albumin-creatinine ratio costs a few dollars and a dipstick costs cents. Weight management, GLP-1 agonists and bariatric surgery: MODERATE. Avoiding NSAIDs and nephrotoxins, and preventing acute kidney injury: MODERATE. Diabetes prevention itself, through lifestyle programmes and metformin, is the upstream measure: STRONG for preventing diabetes, hence nephropathy.

**Treatment.** The modern regimen is layered, and most of it is cheap or becoming cheap.

An ACE inhibitor or ARB, titrated to the maximum tolerated dose, gives about a 30 per cent reduction in progression in proteinuric disease. Off-patent, EML-listed, a few to tens of US dollars a year.

SGLT2 inhibitors are now foundational. CREDENCE (canagliflozin, *NEJM* 2019, 4,401 patients with diabetic nephropathy) gave a renal composite hazard ratio of 0.70 (95 per cent CI 0.59 to 0.82) and end-stage kidney disease 0.68. DAPA-CKD gave an overall kidney composite of 0.61 (0.51 to 0.72). EMPA-KIDNEY gave 0.72 (0.64 to 0.82). They were added to the EML in recent cycles. Generic dapagliflozin runs at about US$30 to 120 a year in India against an originator US list price of about US$6,000 a year†.

Finerenone: FIDELIO-DKD (*NEJM* 2020, 5,734 patients) gave a kidney composite hazard ratio of 0.82 (95 per cent CI 0.73 to 0.93), and FIGARO-DKD showed cardiovascular benefit. On patent; thousands of US dollars a year.

GLP-1 receptor agonists: the FLOW trial with semaglutide in 2024 gave a kidney composite hazard ratio of 0.76 (95 per cent CI 0.66 to 0.88). On patent and expensive, at about US$9,000 to 16,000 a year US list; semaglutide was recently EML-listed for diabetes†.

Glycaemic control: metformin, continued to an eGFR of 30, insulin, and the agents above. Metformin is an EML-listed medicine, section 18.5.2, hypoglycaemic agents, for type 2 diabetes in adolescents and adults, first added in 1997; off-patent; a few to tens of US dollars a year — still the cheapest and among the most valuable. Insulin human, short-acting and

intermediate-acting, is EML-listed as a selected medicine, each for type 1 and type 2 diabetes; the insulin analogues are listed as class entries, long-acting and rapid-acting, with the named analogues — degludec, detemir, glargine, aspart, glulisine, lispro — listed only as therapeutic equivalents to those class entries rather than as selected medicines.

Statins for the dominant cardiovascular risk; off-patent, tens of US dollars a year. Blood pressure control with cheap off-patent agents. Management of the chronic kidney disease complications — anaemia, acidosis with sodium bicarbonate, phosphate, potassium — as in the chronic kidney disease entry. Dialysis and transplantation, and simultaneous pancreas-kidney transplant in selected type 1 patients.

Avoid: dual ACE inhibitor plus ARB blockade, where ONTARGET and ALTITUDE showed more harm and no benefit; and aliskiren with an ACE inhibitor or ARB. Clear negative evidence.

**Simple means.** Glycaemic control through diet, weight loss and physical activity is the upstream intervention, with a trial-proven effect on albuminuria and no supply chain for the behavioural part. In type 2 diabetes, substantial weight loss can induce remission — the DiRECT trial gave about 46 per cent remission at twelve months with about 10 to 15 kg of loss† — which addresses the cause.

Blood pressure control, and salt restriction under 5 g a day, reduces albuminuria and augments the ACE inhibitor effect measurably. A urine dipstick or albumin-creatinine ratio annually costs cents to a few dollars and is the gateway to everything effective: the highest-value simple diagnostic here. Smoking cessation. Moderate protein intake, about 0.8 g/kg a day, avoiding severe restriction. Foot care, eye screening and vaccination — the rest of the diabetes package, since these patients die of cardiovascular disease and lose limbs and sight.

Metformin, enalapril and a thiazide: three off-patent tablets costing perhaps tens of US dollars a year together, delivering most of the achievable benefit. That is the practical core for low-resource settings, with SGLT2 inhibitors joining it as generics spread.

The honest limit: insulin is essential in type 1 diabetes and cannot be replaced by simple means, and end-stage kidney failure requires dialysis or a transplant.

**Gaps.** Why most people with diabetes never develop nephropathy is unexplained. Non-albuminuric diabetic kidney disease is increasingly common, poorly understood, and missed by current screening. Albuminuria is an imperfect surrogate and regression does not always predict hard outcomes. The incremental benefit and cost-effectiveness of stacking four expensive drug classes — ACE inhibitor or ARB, SGLT2 inhibitor, finerenone, GLP-1 agonist — has not been tested in a single factorial trial; the combination is inferred. Generic pricing is changing rapidly, so cost figures date quickly. Trials under-represent African and South Asian populations despite their higher risk, and *APOL1*-stratified treatment is not established. Screening coverage is poor even in high-income systems. And the two diabetes denominators used in this book, IDF 589 million adults aged 20 to 79 and WHO 830 million at all ages, are incompatible, with the year of the IDF edition also disputed between chapters.

---

## Kidney stones

**What it is.** Minerals crystallise in the urine and form stones. Passing one causes severe pain. Most pass by themselves; some block the kidney and need removing.

**Measured.** Lifetime prevalence is about 10 to 15 per cent in men and about 6 to 10 per cent in women in high-income countries, and rising almost everywhere measured. United States prevalence rose from about 3.8 per cent in 1976 to 1980, to about 8.8 per cent in 2007 to 2010, to about 11 per cent in recent NHANES data. GBD 2019 gave urolithiasis roughly 12,000 to 15,000 deaths and about 1.5 to 2 million DALYs globally†.

Recurrence is the defining feature: about 50 per cent within five to ten years and about 60 to 80 per cent lifetime without preventive treatment†. Peak age is 30 to 60, with a male to female ratio of about 2:1, though the gap has narrowed as female incidence rose.

Geography follows the stone belt — hot, arid regions and hot seasons: the Middle East, South Asia, the southeastern United States, Southeast Asia. Climate and dehydration are the

clearest geographic determinants, and projected warming is expected to increase incidence. Bladder stones in children remain common in parts of South and Southeast Asia and the Middle East, associated with low-protein cereal-based diets.

**Where it starts.** Stone type matters because prevention differs. Calcium oxalate accounts for about 70 to 80 per cent, calcium phosphate about 10 to 15 per cent, uric acid about 5 to 10 per cent, struvite or infection stones about 5 to 10 per cent, cystine about 1 per cent and genetic, plus drug-induced stones†.

Low urine volume and dehydration is the single most important modifiable factor, and the mechanism behind the geographic and occupational patterns. High sodium intake raises urinary calcium; high animal protein raises acid load, uric acid and calcium and lowers citrate; high oxalate foods — spinach, rhubarb, nuts, tea — matter in susceptible people; and low dietary calcium is, counter-intuitively, a risk factor, because dietary calcium binds oxalate in the gut. Low citrate; sucrose and fructose; low potassium.

Obesity and metabolic syndrome, dose-dependently; diabetes raises uric acid stone risk, and insulin resistance lowers urinary pH. Medical conditions: primary hyperparathyroidism, renal tubular acidosis type 1, primary hyperoxaluria which is genetic, cystinuria which is genetic and autosomal recessive, sarcoidosis, gout, inflammatory bowel disease and short bowel giving enteric hyperoxaluria, which is a potent cause, Roux-en-Y gastric bypass, recurrent urinary tract infection with urease-producing organisms such as *Proteus* for struvite stones, medullary sponge kidney, and anatomical obstruction.

Drugs: topiramate, acetazolamide, loop diuretics, excess calcium and vitamin D supplements, indinavir, sulfadiazine, ceftriaxone in children, and vitamin C in high doses.

Twin studies estimate heritability at about 46 to 56 per cent for kidney stone disease, with strong familial clustering and a first-degree relative conferring about 2.5 times the risk. Monogenic causes — cystinuria, primary hyperoxaluria, Dent disease — account for a small share and are important to identify. Over thirty GWAS loci have been found, including *CLDN14*, *SLC34A1* and *ALPL*.

What is not known is why most people with hypercalciuria or hyperoxaluria never form stones. The step from supersaturation to a clinical stone involves nucleation, retention and Randall's plaques — interstitial apatite deposits at the papillary tip — whose formation is incompletely understood. Why recurrence rates vary so much is not predictable. And the thiazide dose-response question was unsettled until recently and remains partly open.

**Cure status.** Four strata.

Most individual stones: SELF-LIMITING. Spontaneous passage rates are about 95 per cent for stones under 4 mm, about 50 per cent for 5 to 7 mm, and about 20 per cent or less above 8 mm.

Per episode: CURABLE. Stones can be removed completely by lithotripsy, ureteroscopy or percutaneous nephrolithotomy, achieving stone-free status.

The disease: CONTROLLABLE, not curable. The metabolic tendency persists, hence 50 per cent recurrence in five to ten years untreated. With medical prophylaxis recurrence falls substantially, with thiazides roughly halving it, so it is well controlled rather than cured.

At the level of cause, in specific instances: CURABLE. Parathyroidectomy for primary hyperparathyroidism cures that stone diathesis; treating the infection and removing all fragments cures struvite stones; and lumasiran and nedosiran now effectively treat primary hyperoxaluria type 1, which is a genuine and recent transformation.

**Prevention.** This is one of the strongest simple-prevention stories in the book.

Increased fluid intake: STRONG. The Borghi randomised trial (*Journal of Urology* 1996, 199 first-time stone formers over five years) compared high water intake, producing a urine volume above 2 L a day, with no intervention: recurrence was 12 per cent against 27 per cent, and time to recurrence was substantially longer. Roughly a 50 per cent relative reduction achieved with water alone. The target is over 2.5 L of fluid a day to produce over 2 to 2.5 L of urine a day.

Normal dietary calcium with reduced sodium and animal protein: STRONG. Borghi (*NEJM* 2002, 120 men with hypercalciuria over five years) compared a normal-calcium, low-sodium, low-animal-protein diet with a traditional low-calcium diet: recurrence was 20 per cent

against 38 per cent, relative risk 0.49 (95 per cent CI 0.24 to 0.98). Low-calcium diets are harmful and increase recurrence — a clear, important reversal of old advice that is still given.

Thiazide diuretics for recurrent calcium stones: STRONG, with a caveat. Older trials showed about a 50 per cent recurrence reduction. The NOSTONE trial (*NEJM* 2023, 416 patients, hydrochlorothiazide at 12.5, 25 and 50 mg against placebo over about three years) found no significant dose-dependent reduction in the primary composite recurrence endpoint. That is a genuine and unresolved conflict with the earlier literature, and both are printed. Guidelines currently retain thiazides, often at higher doses, with chlorthalidone or indapamide rather than low-dose hydrochlorothiazide.

Potassium citrate for calcium and uric acid stones: MODERATE — it raises urinary citrate and pH and reduces recurrence in trials. Allopurinol for uric acid and hyperuricosuric calcium oxalate stones: MODERATE. Weight management and reducing sugar-sweetened beverages: MODERATE. Treating hyperparathyroidism and renal tubular acidosis: STRONG for those causes. A 24-hour urine metabolic evaluation to target prophylaxis: MODERATE — logical and guideline-endorsed, though trial evidence that it improves outcomes over empirical advice is limited.

**Treatment.** For acute colic, NSAIDs are first-line analgesia and superior to opioids for renal colic, with better pain relief, less vomiting and less need for rescue analgesia: diclofenac, ketorolac, indomethacin. Diclofenac EML yes; off-patent; a few US dollars a course. Avoid in renal impairment. Paracetamol is comparable to NSAIDs in some trials and a safe alternative. Opioids are second line, for NSAID contraindication. Antispasmodics give little benefit.

Medical expulsive therapy with tamsulosin is largely refuted for small stones: the SUSPEND trial (*Lancet* 2015, 1,167 patients) found no benefit of tamsulosin or nifedipine on spontaneous passage. A modest benefit may persist for larger, 5 to 10 mm, distal ureteric stones in meta-analysis, and routine use is not supported. Tamsulosin off-patent, tens of US dollars a year. Hydration and watchful waiting for stones likely to pass.

Urgent decompression with a ureteric stent or percutaneous nephrostomy, plus antibiotics, for an obstructed infected kidney: a urological emergency with high mortality if delayed. That is the one time-critical scenario.

For stone removal: extracorporeal shock wave lithotripsy is non-invasive, best for stones under 10 to 20 mm in the kidney or proximal ureter, with stone-free rates of about 50 to 80 per cent depending on size, location and density†. Ureteroscopy with laser lithotripsy gives higher stone-free rates than lithotripsy and requires anaesthesia and endoscopy; it is now the commonest intervention in many countries. Percutaneous nephrolithotomy is for large stones above 20 mm and for staghorn stones, with the highest stone-free rate and the most invasiveness. Complete clearance is essential for struvite and infection stones, with antibiotics, because residual fragments regrow.

For prophylaxis: fluid and dietary modification. A thiazide — chlorthalidone, indapamide or hydrochlorothiazide — off-patent, EML-listed, a few to tens of US dollars a year, with the NOSTONE caveat. Potassium citrate, off-patent, hundreds of US dollars a year, with sodium bicarbonate or lemon juice as cheaper alkalinising substitutes. Allopurinol: an EML-listed medicine under medicines used to treat gout, section 29.1, and as a supportive medicine for tumour lysis syndrome, section 8.2.5 complementary; off-patent; tens of US dollars a year. Pyridoxine for the responsive subset of primary hyperoxaluria type 1, with lumasiran and nedosiran, RNA interference agents, transformative and extremely expensive at hundreds of thousands of US dollars or more a year. Tiopronin or penicillamine with high fluid intake and alkalinisation for cystinuria. Parathyroidectomy for primary hyperparathyroidism.

**Simple means.** Kidney stones are the clearest case in this book where water is the treatment.

Water: over 2.5 L a day of intake to produce over 2 L a day of urine halves recurrence, 12 against 27 per cent over five years in Borghi 1996†. Free where clean water exists. The highest benefit-to-cost ratio of any intervention in this entry.

Normal dietary calcium, not low, with reduced salt and animal protein: recurrence 20 against 38 per cent, relative risk 0.49 (Borghi 2002)†. A dietary change, not a product. And it corrects a harmful piece of traditional advice.

Lemon or lime juice in water raises urinary citrate and is cheap and plausible, though the trial evidence is weaker than for potassium citrate. Reducing sugar-sweetened drinks, and moderating oxalate-rich foods only in documented hyperoxaluria, taking them with calcium-containing food, which binds oxalate in the gut. Weight management and physical activity. NSAIDs for colic, cheaper and better than opioids. Occupational hydration for outdoor and hot-environment workers, who have markedly raised risk: water, shade and rest breaks. Straining urine to catch the stone for analysis needs a sieve, and it determines prevention strategy. And not using tamsulosin routinely: an evidence-based omission on SUSPEND.

The honest limit: a large obstructing stone, and especially an obstructed infected kidney, requires urological intervention. Water does not remove a staghorn calculus.

**Gaps.** NOSTONE contradicts decades of thiazide trials and the conflict is unresolved. It is the most consequential current disagreement in stone prevention, since thiazides are the main drug prophylaxis, and both results are printed. Whether 24-hour urine-guided therapy improves outcomes over empirical advice has not been properly trialled. The mechanism of Randall's plaque formation is unclear. Why most metabolic abnormalities do not produce stones is unknown. Medical expulsive therapy evidence remains contested for intermediate-sized stones. Optimal imaging follow-up intervals and radiation exposure trade-offs are unsettled. Burden and composition data from Africa and much of Asia are sparse, and paediatric bladder stone epidemiology is poorly documented despite being a significant regional problem. Climate-related incidence projections are models, not observations.

---

## Urinary tract infection

**What it is.** Bacteria, usually from the bowel, colonise the bladder and cause burning and frequent urination. If they reach the kidney, which is pyelonephritis, it causes fever and can be serious.

**Measured.** There are about 400 million cases a year globally, making this one of the commonest bacterial infections in humans. About 50 to 60 per cent of women experience at least one urinary tract infection in their lifetime, and about 10 per cent of women report one each year. GBD 2019 gave urinary tract infections roughly 200,000 to 240,000 deaths globally, mostly from urosepsis in the elderly, with several million DALYs.

Recurrence: about 25 to 30 per cent of women have a recurrence within six months of a first episode. The female to male ratio is about 8 to 30:1 in young adults, among the largest sex ratios of any common disease, reflecting urethral length and proximity to the anus; the ratio narrows in old age as prostatic obstruction and catheterisation rise.

Catheter-associated infection is the commonest healthcare-associated infection worldwide, with a risk of about 3 to 7 per cent per catheter-day†. On resistance: *E. coli* resistance to trimethoprim and ciprofloxacin exceeds 20 to 30 per cent in many regions, and ESBL-producing organisms are now common in community isolates in South Asia, the Middle East and parts of Africa, which is changing empirical treatment everywhere.

**Where it starts.** Female anatomy — a short urethra and proximity to the rectum — is the dominant factor. Sexual intercourse is the strongest behavioural risk in young women, dose-dependently with frequency, and spermicide use, including spermicide-coated condoms and diaphragms, raises risk substantially.

Previous infection; postmenopausal oestrogen deficiency, with vaginal atrophy, loss of lactobacilli and raised pH; and pregnancy, where asymptomatic bacteriuria also matters. Urinary stasis and obstruction: benign prostatic hyperplasia, stones, strictures, neurogenic bladder, incomplete emptying, prolapse. Catheterisation and instrumentation, the main healthcare-associated cause, with risk rising with duration. Diabetes; immunosuppression; and SGLT2 inhibitors, through glycosuria, which clearly increase genital mycotic infection and urinary tract infection only modestly. Vesicoureteric reflux and anatomical abnormalities in children.

Non-secretor status, in the Lewis blood group, and P1 blood group; ABO and secretor phenotype affects uroepithelial receptor expression. Family history: a mother or sister with recurrent infection raises risk, suggesting genetic susceptibility in innate immunity, with TLR4 and CXCR1 variants implicated. Heritability is not well quantified.

What is not known is why some women suffer repeated infections with no identifiable anatomical or behavioural cause; innate immune variation and uroepithelial receptor differences are implicated and not clinically measurable. The role of intracellular bacterial reservoirs in the bladder wall in recurrence is demonstrated in animals and uncertain in humans. The clinical significance of the urinary microbiome — the bladder is not sterile, a recent revision — is unresolved. Whether asymptomatic bacteriuria in the elderly is ever worth treating outside pregnancy and some urological procedures is settled in the negative and still widely ignored in practice.

**Cure status.** Four strata.

The individual episode, treated: CURABLE, with a short antibiotic course curing the great majority, 80 to 95 per cent clinical cure†.

Uncomplicated cystitis, untreated: SELF-LIMITING in about 25 to 50 per cent within a week. In otherwise healthy women, about 25 to 50 per cent resolve without antibiotics within a week, and randomised trials of NSAIDs against antibiotics confirm that many recover without antimicrobials, though more slowly and with a higher rate of progression to pyelonephritis, about 2 to 5 per cent against under 1 per cent. So delayed prescribing is a legitimate option in uncomplicated cases, with the trade-off stated.

Recurrent infection: CONTROLLABLE. Prophylaxis reduces but does not abolish recurrence.

A correctable cause — obstruction, a catheter, a stone, atrophy: CURABLE, by relieving obstruction, removing the catheter, removing the stone, or treating atrophy with vaginal oestrogen.

**Prevention.** Vaginal oestrogen in postmenopausal women with recurrent infection: STRONG. It reduces recurrence substantially, relative risk about 0.25 to 0.6 in trials and Cochrane-supported, with low systemic absorption. Off-patent; tens to hundreds of US dollars a year. Markedly under-used.

Increased water intake: MODERATE. A randomised trial (Hooton, *JAMA Internal Medicine* 2018, 140 premenopausal women with recurrent infection) found drinking an additional 1.5 L of water daily reduced episodes from 3.2 to 1.7 a year — roughly halving recurrence with water alone.

Continuous low-dose antibiotic prophylaxis: STRONG for efficacy, relative risk about 0.2 to 0.4†, with resistance and adverse-effect costs; reserved for frequent recurrence, and the benefit ceases on stopping. Post-coital single-dose antibiotic prophylaxis: STRONG where recurrence is intercourse-related, and it uses less total antibiotic.

Methenamine hippurate: MODERATE. The ALTAR trial (*BMJ* 2022, 240 women) found methenamine non-inferior to daily antibiotic prophylaxis for recurrent infection, with less antibiotic use. A non-antibiotic option, off-patent, and an important finding for stewardship.

Avoiding spermicides: MODERATE. D-mannose: CONTESTED — earlier small positive trials were not confirmed by a larger 2024 randomised trial, MERIT, which found no benefit. Cranberry products: WEAK and CONTESTED — Cochrane's updated review suggests a modest reduction in recurrence in some populations, relative risk about 0.7, with high heterogeneity and poor product standardisation†. Probiotics, vaginal lactobacilli: WEAK. Behavioural measures — post-coital voiding, wiping direction, avoiding tight clothing, not delaying micturition: WEAK, plausible and harmless, with thin trial evidence, and some of this advice persists without support.

Screening and treating asymptomatic bacteriuria in pregnancy: STRONG, reducing pyelonephritis and preterm birth. Not indicated in non-pregnant adults or the elderly: STRONG evidence against, and treating it causes harm.

Catheter avoidance, early removal, aseptic insertion and closed drainage: STRONG — the single most effective healthcare-associated prevention. Daily review of catheter need is a free intervention with a large measured effect.

**Treatment.** Nitrofurantoin 100 mg twice daily for five days is first-line for uncomplicated cystitis, with excellent cure rates, low resistance even now, and minimal collateral damage to the microbiome. Avoid if eGFR is below 30 to 45 and in late pregnancy. EML yes; off-patent; a few to tens of US dollars a course.

Trimethoprim, or trimethoprim-sulfamethoxazole for three days, is effective where local resistance is below 20 per cent, which resistance now often exceeds. Co-trimoxazole EML yes; off-patent; a few to a few US dollars a course. Fosfomycin trometamol as a single 3 g dose is convenient with good activity including against some ESBL organisms, and slightly lower cure rates than five-day nitrofurantoin; off-patent, a few to tens of US dollars a dose. Pivmecillinam for three to seven days is widely used in Scandinavia with low resistance and is now approved in the United States; off-patent, tens of US dollars a course.

Avoid fluoroquinolones for simple cystitis and reserve them: they carry tendinopathy, aortic aneurysm, neuropathy and *C. difficile* risks and drive resistance, and regulatory restrictions now apply in the EU and the US. A clear stewardship position.

Pyelonephritis: oral ciprofloxacin or co-trimoxazole for seven to fourteen days if susceptible and the patient is stable; intravenous ceftriaxone or gentamicin if unwell, vomiting or pregnant, then step down. Ceftriaxone EML yes; gentamicin off-patent, at pennies, and requiring monitoring.

Complicated or obstructed infection: urgent drainage with a stent or nephrostomy, plus antibiotics. An obstructed infected kidney is a surgical emergency and antibiotics alone will fail.

Analgesia with NSAIDs or paracetamol. NSAIDs alone cure a substantial proportion of uncomplicated cystitis, with more pyelonephritis than antibiotics: a documented trade-off, not a free lunch. ESBL and multidrug-resistant organisms: carbapenems, and newer agents — ceftazidime-avibactam, meropenem-vaborbactam, cefiderocol — all expensive, hospital-only, and the reason stewardship matters. Catheter-associated infection: remove or replace the catheter, and treat only if symptomatic; do not treat asymptomatic catheter bacteriuria. Recurrent infection: vaginal oestrogen, water, methenamine, then antibiotic prophylaxis.

**Simple means.** Water: an extra 1.5 L a day nearly halved recurrences, from 3.2 to 1.7 episodes a year (Hooton 2018)†. Free where clean water exists, and among the best-evidenced simple interventions in this book.

Vaginal oestrogen is not quite a simple means, being a manufactured product, but it is cheap, off-patent and dramatically effective in postmenopausal women, and under-prescribed. Methenamine hippurate is non-inferior to antibiotic prophylaxis (ALTAR) and spares antibiotics.

Post-coital voiding, avoiding spermicides, not delaying micturition, and complete bladder emptying with double voiding where residual urine is the problem: cheap, though the evidence is thin for some of these. Catheter avoidance and daily review of catheter need costs nothing and prevents the commonest healthcare-associated infection in the world. Clean water and sanitation, upstream, and relevant to the faecal-flora origin. Analgesia and fluids with delayed antibiotic prescribing in mild uncomplicated cystitis reduces antibiotic use, with the honest caveat of slower recovery and a small excess of pyelonephritis. Not treating asymptomatic bacteriuria is a free, evidence-based omission that avoids harm and resistance, and is still routinely violated.

The honest limit: pyelonephritis and urosepsis require antibiotics, and obstruction requires drainage. Water does not cure a kidney infection.

**Gaps.** Resistance is rising faster than new oral options appear, and local resistance data, which should drive empirical choice, are absent in much of the world. The urinary microbiome's clinical meaning is unknown. Why some women have relentless recurrence is unexplained. D-mannose and cranberry evidence is contradictory. Much standard behavioural advice is unsupported. The optimal duration of therapy for pyelonephritis and for men is not well established, and male infection is poorly studied in general and often treated far longer than evidence requires. Diagnosis is unreliable: dipstick and culture both perform modestly, over-diagnosis in the elderly is endemic, and treating confusion plus bacteriuria as infection causes substantial harm. GBD mortality figures rest largely on modelled urosepsis.

---

## Benign prostatic hyperplasia

**What it is.** The prostate enlarges with age and squeezes the urethra. Urine flow weakens, the bladder empties incompletely, and urination becomes frequent and urgent.

**Measured.** Histological prevalence rises almost linearly with age: about 8 per cent in the fourth decade, about 50 per cent at 51 to 60, about 70 per cent at 61 to 70, about 80 per cent at 71 to 80, and about 90 per cent above 80†. One of the most age-determined conditions in medicine.

Symptomatic, clinical disease is less common than histological disease: moderate-to-severe lower urinary tract symptoms affect about 25 to 30 per cent of men over 50†. GBD 2019 gave about 90 to 95 million men affected globally with about 1.8 to 2 million DALYs; deaths are few and mostly through obstructive renal failure and urosepsis. Acute urinary retention incidence is about two to seven per 1,000 men a year†, rising steeply with age.

It is present everywhere, and measured symptom prevalence differs partly by instrument and by care-seeking. Untreated obstruction causing renal failure and bladder stones remains a significant presentation in low-income settings, where it is a preventable cause of chronic kidney disease.

**Where it starts.** Age is the dominant factor. Androgens are necessary: dihydrotestosterone, produced by 5-alpha-reductase, drives prostatic growth. Men castrated before puberty, and men with congenital 5-alpha-reductase deficiency, do not develop the condition — the cleanest causal evidence available, and the rationale for 5-alpha-reductase inhibitors.

Metabolic syndrome, obesity, diabetes and insulin resistance are associated with larger prostates and faster growth, with inflammation implicated. Family history: a first-degree relative raises risk about two to four times, with larger effects for early-onset large-volume disease, and heritability is estimated at about 50 to 60 per cent from twin studies†. Physical inactivity, and possibly dietary factors — high red meat, low vegetable intake. Protective associations: physical activity, moderate alcohol weakly, and some dietary patterns.

What is not known is why prostate growth and symptoms correlate so poorly: many men with large prostates have no symptoms and many with small prostates have severe symptoms, so lower urinary tract symptoms are not simply obstruction. Detrusor dysfunction, nocturnal polyuria and bladder changes contribute independently. Why the condition localises to the transition zone while prostate cancer favours the peripheral zone is unexplained. And whether chronic inflammation is cause or consequence is unresolved.

**Cure status.** Three strata.

Medical treatment: CONTROLLABLE. Drugs relieve symptoms and 5-alpha-reductase inhibitors shrink the gland and reduce progression, but the condition persists and treatment is indefinite.

Transurethral resection or its equivalents: CURABLE for the obstruction. Transurethral resection and its modern equivalents remove the obstructing tissue and produce durable relief, with re-treatment rates of roughly 1 to 2 per cent a year, about 10 to 15 per cent at ten years. So surgery is close to curative for the obstruction, though the prostate can regrow.

Mild to moderate symptoms on watchful waiting: CONTROLLABLE by watchful waiting. Symptoms fluctuate, and in watchful-waiting arms of trials a substantial proportion of men with mild to moderate symptoms remain stable or improve without treatment, which makes watchful waiting a legitimate first option.

**Prevention.** 5-alpha-reductase inhibitors reduce progression: STRONG for that outcome. Finasteride in the PLESS trial reduced acute urinary retention by about 57 per cent and the need for surgery by about 55 per cent over four years, and the MTOPS trial showed combination therapy reduced clinical progression by about 66 per cent. But these are treatments for existing disease rather than primary prevention, and they are not given to asymptomatic men.

Physical activity: MODERATE, on a consistent inverse association across cohorts. Weight management and metabolic syndrome control: MODERATE. Dietary pattern, more vegetables and less red meat: WEAK. Avoiding drugs that precipitate retention — anticholinergics, antihistamines, decongestants, opioids: MODERATE for preventing acute retention. No established primary prevention of the condition itself: absent, or WEAK.

A note on cancer: 5-alpha-reductase inhibitors reduce overall prostate cancer detection but were associated with a small excess of high-grade tumours in PCPT and REDUCE, so they are not used for cancer prevention: CONTESTED.

**Treatment.** In the watchful-waiting arms of trials a substantial proportion of men with mild to moderate symptoms remain stable or improve without treatment; the proportion is not given here. Watchful waiting with lifestyle advice is appropriate for mild symptoms.

Alpha-1 blockers give the fastest symptom relief, within days to weeks, improving the symptom score by about four to six points on the IPSS and flow by about 2 to 3 mL/s: tamsulosin, alfuzosin, doxazosin, terazosin, silodosin. They do not prevent progression or retention. Tamsulosin and doxazosin off-patent; tens of US dollars a patient-year; EML status. Side effects: dizziness, postural hypotension, retrograde ejaculation, and intraoperative floppy iris syndrome, which is relevant before cataract surgery.

5-alpha-reductase inhibitors, finasteride and dutasteride, shrink the prostate by about 20 to 25 per cent over six to twelve months and reduce retention and surgery risk by about 50 per cent†; they are effective only in larger prostates, above 30 to 40 mL, and slow to act, taking three to six months. Finasteride off-patent; tens to hundreds of US dollars a patient-year. Side effects: reduced libido, erectile dysfunction, ejaculatory disorder, gynaecomastia; persistent sexual dysfunction after cessation is reported and contested; and they halve PSA, which must be accounted for in cancer screening.

Combination alpha-blocker with 5-alpha-reductase inhibitor is superior to either alone for progression (MTOPS, CombAT) and is appropriate for larger glands with significant symptoms. Antimuscarinics or beta-3 agonists such as mirabegron are added for storage and overactive bladder symptoms, with caution regarding retention; mirabegron is now off-patent in some markets. PDE5 inhibitors, tadalafil 5 mg daily, improve both lower urinary tract symptoms and erectile dysfunction and are useful where both coexist; tadalafil off-patent, tens to hundreds of US dollars a year.

Surgery. Transurethral resection of the prostate is the long-standing standard and is durable, with risks of bleeding, TUR syndrome, retrograde ejaculation at about 65 to 70 per cent, incontinence at about 1 to 2 per cent†, and stricture. Bipolar resection, laser vaporisation or enucleation (HoLEP, ThuLEP) and photoselective vaporisation give less bleeding and shorter catheterisation and stay, and HoLEP is size-independent and highly durable. Open or simple prostatectomy for very large glands where endoscopic enucleation is unavailable remains important in low-resource settings and is still widely performed. Minimally invasive options — prostatic urethral lift, water vapour therapy, prostatic artery embolisation, temporary implants — give less sexual dysfunction, are less durable, and are more expensive per unit benefit.

Acute urinary retention: immediate catheterisation is the single most important emergency intervention, then a trial of void with an alpha-blocker started beforehand, which improves success, or surgery. Chronic retention with renal impairment: catheterise and decompress, and watch for post-obstructive diuresis.

Phytotherapy with saw palmetto, *Serenoa repens*: CONTESTED and negative. The STEP trial (*NEJM* 2006) and Cochrane reviews found no benefit over placebo even at high doses. Widely sold, not effective. Pygeum and beta-sitosterol have weaker evidence still.

**Simple means.** Fluid timing: reducing evening fluid, caffeine and alcohol intake measurably reduces nocturia. Free. Bladder training and timed voiding, and double voiding to empty more completely. Pelvic floor exercises help post-void dribbling and urgency. Reviewing and stopping precipitating drugs — anticholinergics, antihistamines, decongestants, and diuretic timing — is free and often prevents retention. Physical activity and weight loss are associated with fewer and milder symptoms. Treating constipation, since a full rectum worsens voiding. Watchful waiting is the evidence-based simple means for mild symptoms, avoiding drug side effects entirely.

A urinary catheter: for acute retention this cheap plastic tube relieves agony within seconds and prevents obstructive renal failure. In settings without urology services, clean intermittent self-catheterisation is a durable, low-cost solution that preserves renal function indefinitely and can be taught to patients. That is arguably the highest-value simple means in this entry. Avoiding saw palmetto is an evidence-based omission that saves money.

The honest limit: significant obstruction eventually needs surgery or long-term catheterisation. No exercise or diet relieves mechanical obstruction.

**Gaps.** Symptoms correlate poorly with prostate size and with urodynamic obstruction, so treatment targeting is imprecise and the diagnosis conflates several problems. The durability and cost-effectiveness of the newer minimally invasive procedures relative to resection and HoLEP are not established. Persistent sexual dysfunction after 5-alpha-reductase inhibitors is reported, and its reality and frequency are genuinely contested. Long-term consequences of untreated obstruction in low-resource settings are unquantified, though clinically evident. Nocturia is often multifactorial, through nocturnal polyuria, sleep disorder and heart failure, and treating the prostate alone frequently fails. GBD burden figures rest on symptom survey modelling with wide uncertainty.

---

## Erectile dysfunction

**What it is.** Difficulty getting or keeping an erection firm enough for sex. It is usually a blood-vessel problem, and often the first sign of arterial disease elsewhere.

**Measured.** Prevalence rises steeply with age: roughly 8 per cent at 20 to 29, 11 per cent at 30 to 39, 15 to 20 per cent at 40 to 49, 30 per cent at 50 to 59, 40 to 50 per cent at 60 to 69, and over 50 to 70 per cent above 70†. The Massachusetts Male Aging Study found about 52 per cent of men aged 40 to 70 had some degree of erectile dysfunction: mild 17 per cent, moderate 25 per cent, complete 10 per cent†. About 150 million men were estimated to be affected worldwide in 1995, projected to about 320 million by 2025 (Ayta)†.

It is not a separate GBD cause and has no DALY figure. There are no direct deaths. But it is a marker of cardiovascular risk: erectile dysfunction precedes coronary events by roughly three to five years on average and independently predicts cardiovascular events, with hazard ratios of about 1.4 to 1.9 in meta-analyses. That is its main clinical importance beyond quality of life. Measured prevalence differs widely by geography, largely reflecting willingness to report and the survey instrument rather than true variation.

**Where it starts.** Vascular disease is the commonest cause and shares every risk factor with coronary disease: smoking, diabetes, hypertension, dyslipidaemia, obesity, physical inactivity, metabolic syndrome. Diabetes is particularly strong, with prevalence of about 50 to 75 per cent in diabetic men† and earlier onset. Endothelial dysfunction is the shared mechanism, which is why erectile dysfunction is a sentinel for systemic arterial disease.

Drugs are a major and reversible cause: thiazides and beta-blockers, SSRIs and other antidepressants, antipsychotics, 5-alpha-reductase inhibitors, spironolactone, opioids, antiandrogens, recreational drugs and alcohol.

Neurogenic causes: diabetes, multiple sclerosis, spinal cord injury, Parkinson disease, and pelvic surgery and radiotherapy, with radical prostatectomy a leading iatrogenic cause. Hormonal: hypogonadism, hyperprolactinaemia, thyroid disease. Psychogenic: performance anxiety, depression, relationship factors, more prominent in younger men, in whom sudden onset with preserved nocturnal erections suggests this. Peyronie disease; priapism sequelae; pelvic trauma. Heritability is estimated at about one-third of variance in some twin analyses, and most risk is acquired and shared with cardiovascular disease.

What is not known is the relative weight of psychological and organic factors in the individual case: they coexist and interact, and no test separates them cleanly. Why diabetic erectile dysfunction responds less well to PDE5 inhibitors is only partly understood. Whether treating erectile dysfunction improves cardiovascular outcomes, as opposed to flagging risk, is unknown. And the mechanism of post-SSRI sexual dysfunction persisting after cessation is unexplained and contested.

**Cure status.** Two strata.

Reversible cause: CURABLE. A causative drug stopped or switched. A correctable endocrine deficiency. A focal arterial lesion in a young man after trauma, treated by revascularisation. Vasculogenic disease treated by weight loss and exercise belongs here too, and it is the best-evidenced route back to unassisted function: 31 against 5 per cent restoration in the Esposito trial. Remove the cause and the function returns without further treatment.

Established vascular, diabetic or neurogenic disease, or no cause identified: CONTROLLABLE. Phosphodiesterase type 5 inhibitors work on demand for a majority of men, less often in diabetes and after non-nerve-sparing prostatectomy, and they do not alter the underlying

disease; stop them and the difficulty returns unchanged. Testosterone for hypogonadism must be continued, which under this book's rule is control and not cure. A penile prosthesis is effective and durable in refractory cases, and it sits in this stratum: the native erectile tissue is destroyed and its function substituted, so the deviation remains.

**Prevention.** Smoking cessation: STRONG — risk falls after quitting and erectile function improves measurably. Physical activity: STRONG. Meta-analyses of randomised trials show aerobic exercise improves erectile function significantly, with effect sizes comparable to a modest drug effect, with about 40 minutes of moderate-to-vigorous aerobic exercise four times a week over six months producing clear improvement.

Weight loss: STRONG. Esposito (*JAMA* 2004) found that in obese men, a two-year lifestyle intervention achieving about 15 kg of loss restored erectile function in about 31 per cent against 5 per cent of controls.

Mediterranean diet: MODERATE. Glycaemic, blood pressure and lipid control: MODERATE. Avoiding or switching causative drugs: STRONG, and under-practised. Moderating alcohol and avoiding recreational drugs: MODERATE. Pelvic floor muscle training: MODERATE, with randomised evidence of benefit including for post-prostatectomy dysfunction and venous leak. Treating erectile dysfunction as a cardiovascular warning and acting on total risk: a STRONG recommendation on prognostic grounds.

**Treatment.** PDE5 inhibitors are first line: sildenafil, tadalafil, vardenafil, avanafil. They work for a majority of men, less often in diabetes and after non-nerve-sparing prostatectomy. Tadalafil's long half-life allows daily dosing and also treats lower urinary tract symptoms.

Sildenafil is off-patent, since 2013 and 2017 in different markets. Its EML status is: not on the WHO Essential Medicines List at all, for any indication. A direct query of the electronic EML returns zero recommendations, zero medicines and zero therapeutic equivalents. Generic cost is tens to hundreds of US dollars a patient-year, and as little as a few cents a tablet in some markets — a dramatic fall from branded prices of tens of US dollars a tablet. Tadalafil off-patent; tens to hundreds of US dollars a year. Both are contraindicated with nitrates, because of profound hypotension, and need caution with alpha-blockers.

Address the reversible causes: switch the offending antihypertensive or antidepressant, for example to an ARB, nebivolol, bupropion or mirtazapine; treat hypogonadism; optimise diabetes. Testosterone replacement only where hypogonadism is biochemically confirmed, which restores response to PDE5 inhibitors in some non-responders, and not for eugonadal men. Testosterone enanthate off-patent, EML-listed, cheap.

Vacuum erection devices are effective and reusable with no drug cost, at hundreds of US dollars as a one-off and locally manufacturable; they are particularly useful where drugs are contraindicated or unaffordable, and for penile rehabilitation after prostatectomy. Satisfaction is lower than with drugs and the cost per year of use is very low.

Intracavernosal injection with alprostadil, or bimix or trimix with papaverine and phentolamine, is effective in 70 to 90 per cent including most PDE5 non-responders†. Papaverine and phentolamine are old, off-patent and cheap, and compounded trimix is inexpensive; alprostadil is more expensive. Risks: pain, priapism, fibrosis. Intraurethral alprostadil and topical alprostadil cream. A penile prosthesis is definitive for refractory cases, with the highest satisfaction rates of any treatment at 80 to 90 per cent†, at a one-off surgical cost.

Psychosexual and couple therapy is effective, particularly for psychogenic and mixed cases, and improves adherence to and outcomes of drug therapy; combination of therapy with a PDE5 inhibitor outperforms either alone in trials. Low-intensity shockwave therapy has some positive randomised data suggesting it may alter underlying vascular pathology rather than just relieve symptoms, with heterogeneous evidence and marketing far ahead of it: CONTESTED. Platelet-rich plasma and stem cell injections are not supported: experimental, heavily commercialised, with no adequate evidence.

**Simple means.** Aerobic exercise has randomised evidence of significant improvement, with an effect size comparable to pharmacotherapy in some analyses, and it treats the underlying vascular disease rather than masking it. Free.

Weight loss: 31 against 5 per cent restoration of function in the Esposito trial. Smoking cessation. Pelvic floor muscle training, with randomised evidence of benefit: a taught exercise,

no equipment. Reviewing medications — switching a thiazide or an SSRI costs nothing and can resolve the problem entirely. Reducing alcohol.

A vacuum erection device is mechanical and reusable with no consumables, and can be produced locally and cheaply: the most simple-means of the definitive treatments. Sleep, and treating sleep apnoea. Talking — psychosexual and couple counselling, especially in younger men where psychogenic factors dominate — needs no supply chain and has a measurable effect. Generic sildenafil at a few cents a tablet is, while manufactured, now cheap enough to count as widely accessible, though it is not on the Essential Medicines List.

The honest note: the simple means here are unusually effective because the condition is mostly vascular, and vascular disease responds to exercise and weight loss. The same measures reduce the cardiovascular risk that erectile dysfunction signals.

**Gaps.** Prevalence data depend heavily on self-report and are probably underestimates given stigma. The organic and psychogenic distinction is not cleanly measurable. Whether treating erectile dysfunction alters cardiovascular outcomes is unknown. Shockwave therapy evidence is heterogeneous and commercially driven. Post-SSRI and post-finasteride persistent sexual dysfunction are reported, contested and unexplained — a genuine evidentiary stand-off. Data from Africa, South Asia and much of the developing world are sparse. The large counterfeit and unregulated market for PDE5 inhibitors is a real safety problem and is unquantified. Long-term outcome data for penile rehabilitation after prostatectomy are inconsistent.

---

## Urinary incontinence

**What it is.** Involuntary leakage of urine. Stress incontinence leaks on coughing or exertion; urge incontinence leaks with a sudden need to go. Common, treatable, and very underreported.

**Measured.** Prevalence in women is about 25 to 45 per cent depending on definition and age, with about 10 per cent having at least weekly leakage; it rises with age, at about 20 to 30 per cent in young adulthood, 30 to 40 per cent in middle age, and 30 to over 50 per cent in old age. Prevalence in men is about 5 to 15 per cent†, rising with age and strongly associated with prostate surgery. About 400 million people are affected worldwide by some estimates†. GBD 2019 gave urinary incontinence on the order of 1.5 to 2 million DALYs globally with no attributable deaths†.

Subtypes in women: stress about 50 per cent, mixed about 30 to 35 per cent, urge about 15 to 20 per cent†. Care-seeking is low: only about 25 to 45 per cent of affected women ever seek help, often after years, because of stigma and the belief that it is a normal part of ageing. That is the dominant barrier and the reason burden is understated. It is a leading cause of admission to residential care in the elderly, and a major driver of pad and laundry cost, skin breakdown and falls.

**Where it starts.** Vaginal childbirth and parity is the strongest obstetric factor, through pelvic floor muscle and pudendal nerve injury; risk increases with the number of vaginal deliveries, with instrumental and especially forceps delivery, with a prolonged second stage, and with a large infant. Caesarean section carries a lower risk of stress incontinence but is not fully protective and carries its own risks.

Age and menopause, through urogenital atrophy. Obesity, strongly dose-dependently: each five-unit BMI increase raises risk about 20 to 70 per cent across studies†, and it is the most modifiable risk factor. Chronic cough from smoking or COPD; constipation and straining; heavy lifting occupations; and high-impact sport, a notable cause in young athletes and nulliparous women.

Prostate surgery in men: radical prostatectomy is the leading cause of male stress incontinence, and transurethral resection causes it in about 1 to 2 per cent†. Neurological disease — stroke, multiple sclerosis, Parkinson disease, spinal cord injury, dementia, diabetic neuropathy — producing urge and neurogenic incontinence. Drugs: diuretics, alpha-blockers in women, ACE inhibitors through cough, sedatives, cholinesterase inhibitors.

Pelvic organ prolapse; previous pelvic radiotherapy; and obstetric fistula, where in low-income settings prolonged obstructed labour causes vesicovaginal fistula with total incon-

tinence, a devastating and surgically curable condition affecting an estimated 500,000 to 2 million women, overwhelmingly in sub-Saharan Africa and South Asia†.

Twin and family studies estimate heritability at about 40 to 50 per cent for stress incontinence†, with connective tissue composition and collagen genes implicated, and family history roughly doubling risk.

What is not known is why women with similar obstetric histories differ so much; connective tissue quality is implicated and not measurable clinically. The mechanism of detrusor overactivity is poorly understood, with myogenic, neurogenic and urothelial theories all having support. Why pelvic floor training works for urge as well as stress incontinence is only partly explained. And the long-term natural history, including remission rates, which are substantial since incontinence fluctuates and can resolve, is poorly characterised.

**Cure status.** Stress and mixed incontinence: CURABLE. Urge incontinence and obstetric fistula are labelled below. The low care-seeking rate is the central problem.

Pelvic floor muscle training cures or improves most stress and mixed incontinence: women are roughly five to eight times more likely to report cure than controls in Cochrane meta-analysis, and about 2.5 to six times more likely to report cure or improvement, with reported cure rates of 30 to 50 per cent with supervised training.

Mid-urethral sling surgery cures stress incontinence in about 80 to 90 per cent at one year, with durable results at five to ten years†.

Urge incontinence: CONTROLLABLE. Bladder training and drugs reduce but seldom abolish episodes, and relapse on stopping drugs is the norm.

Obstetric fistula: CURABLE by surgery in about 80 to 90 per cent of cases† when performed by a trained surgeon. One of the most transformative operations available.

**Prevention.** Pelvic floor muscle training, antenatal and postnatal: STRONG. Cochrane finds antenatal training reduces postnatal incontinence risk by roughly 30 per cent, relative risk about 0.7, and also treats existing symptoms. Cheap, teachable, no equipment.

Weight loss: STRONG. The PRIDE trial (Subak, *NEJM* 2009, 338 overweight women) found a six-month weight loss programme achieving about 8 per cent weight loss reduced weekly incontinence episodes by 47 per cent against 28 per cent in controls. Dose-dependent.

Avoiding smoking and treating chronic cough: MODERATE. Treating constipation: MODERATE. Obstetric care quality — avoiding prolonged obstructed labour, and access to timely caesarean section: STRONG for preventing obstetric fistula, which is almost entirely a disease of absent emergency obstetric care. Nerve-sparing technique and surgeon volume in radical prostatectomy: MODERATE for male incontinence; preoperative pelvic floor training: MODERATE, which speeds recovery. Reviewing diuretics and other contributory drugs: MODERATE. Caesarean section specifically to prevent incontinence: CONTESTED — it reduces stress incontinence risk, and the overall risk-benefit does not support it as an indication.

**Treatment.** Conservative treatment first, for all types. Supervised pelvic floor muscle training for at least three months, ideally with a continence physiotherapist and with correct technique confirmed, is first-line for stress and mixed incontinence, and gives five to eight times the likelihood of cure against no treatment. Adding biofeedback or vaginal cones gives modest additional benefit. The cost is a trained person’s time, with no consumables.

Bladder training, timed voiding and urge suppression is first-line for urge incontinence and is comparable to drugs in some trials, with better durability. Weight loss, giving 47 against 28 per cent episode reduction in PRIDE. Fluid and caffeine moderation, and treating constipation. Vaginal oestrogen for postmenopausal urogenital atrophy improves urgency, frequency and recurrent urinary tract infection; off-patent, tens to hundreds of US dollars a year.

Drugs for urge incontinence and overactive bladder. Antimuscarinics — oxybutynin, tolterodine, solifenacin, darifenacin, fesoterodine — reduce episodes by roughly one to two a day more than placebo, a real but modest effect, with high discontinuation rates of about 50 to 70 per cent within a year† from dry mouth and constipation. Oxybutynin off-patent; tens of US dollars a patient-year; EML. An important caution: antimuscarinic burden is associated with increased dementia risk in older adults on cohort evidence, so oxybutynin in particular should be avoided in the elderly.

Mirabegron, a beta-3 agonist, gives similar efficacy to the antimuscarinics with better tolerability and no anticholinergic cognitive burden, and is preferred in the elderly. Now off-patent in several markets, with cost falling from thousands of US dollars a year toward generic levels. Duloxetine for stress incontinence gives modest benefit with poor tolerability, is not first-line, and is not approved for this in the United States.

Procedures. A mid-urethral synthetic sling, retropubic or transobturator, gives about 80 to 90 per cent cure for stress incontinence and is the most effective and most studied surgical option. Mesh sling use has been suspended or restricted in several countries — the United Kingdom, New Zealand, Australia — following complications of chronic pain and erosion and patient safety reviews, which is a major and ongoing controversy. The evidence of efficacy is strong; the dispute is about complication rates, consent and surgeon training.

Autologous fascial sling and colposuspension are effective alternatives without synthetic mesh, and the fascial sling has regained prominence given the mesh controversy. Urethral bulking agents are less effective and less durable, and minimally invasive. Botulinum toxin A intradetrusor injection for refractory urge incontinence is effective, reducing episodes substantially and superior to continued antimuscarinics, requiring repeat injection every six to nine months and carrying retention and infection risk. Sacral neuromodulation and percutaneous tibial nerve stimulation for refractory overactive bladder, with the latter relatively cheap and office-based. An artificial urinary sphincter is the standard for male stress incontinence after prostatectomy: effective, mechanical, expensive. Obstetric fistula repair by surgical closure, with 80 to 90 per cent success in trained hands†. Containment with pads, catheters and sheaths is management rather than treatment, and essential for dignity where cure is unavailable; pad cost is a substantial lifetime expense and a real equity issue.

**Simple means.** This is one of the clearest simple-means entries in the book: the first-line treatment for the commonest type is an exercise.

Pelvic floor muscle training gives five to eight times the likelihood of cure against no treatment (Cochrane). It requires instruction and correct technique, no equipment and no consumables, and it can be taught by a midwife, nurse or community health worker, and delivered at scale by group teaching, printed instruction or an app.

Antenatal and postnatal pelvic floor training gives about a 30 per cent reduction in postnatal incontinence. Weight loss gives 47 against 28 per cent reduction in episodes (PRIDE). Bladder training and timed voiding is comparable to drug therapy for urgency, with better durability and no side effects. Reducing caffeine and adjusting fluid timing, and treating constipation. Smoking cessation, for cough reduction. Reviewing drugs: diuretic timing alone can resolve functional incontinence in the elderly. Prompted and timed toileting, and accessible toilets, in care settings has a large measured effect on functional incontinence in the frail elderly, requiring staff time rather than technology. Locally made washable pads where disposable products are unaffordable. And avoiding oxybutynin in older people: an evidence-based omission that avoids cognitive harm.

The honest limit: severe stress incontinence, obstetric fistula and post-prostatectomy incontinence need surgery. And pelvic floor training requires skilled instruction to work; unsupervised leaflet-only instruction is substantially less effective.

**Gaps.** Prevalence estimates vary two- to threefold with definition, and under-reporting is severe, so the burden figures are soft. The mesh sling controversy is unresolved: efficacy data are strong, complication rates are disputed, and country policies now differ radically, which means patients in different places receive opposite advice. Long-term outcomes beyond ten years for all surgical options are limited. The dementia-anticholinergic association is from cohort data and causality is not settled, and it is influencing practice. Obstetric fistula burden is poorly counted and the true number affected is unknown. Male incontinence is much less studied than female. Evidence for conservative management in the frail elderly and in neurogenic bladder is thin. There are almost no high-quality data from low-income settings.

## Endometriosis

**What it is.** Tissue resembling the womb lining grows outside the womb, on the ovaries, pelvic lining or bowel. It bleeds and inflames with each cycle, causing pain and scarring, and it can cause infertility.

**Measured.** Prevalence is about 5 to 10 per cent of women of reproductive age, roughly 190 million women globally on the WHO figure. It is much higher in selected groups: about 20 to 50 per cent of women with infertility and about 45 to 80 per cent of women with chronic pelvic pain. GBD 2019 gave about 175 to 190 million women affected and roughly 0.9 to 1.0 million DALYs, all from disability with no attributable deaths†. GBD 2023 Table 1 places gynaecological diseases tenth among YLD causes at 28.6 million (95 per cent UI 19.5 to 40.0), which is the aggregate within which this condition sits.

Diagnostic delay averages seven to eleven years from symptom onset in multiple national studies — among the longest delays recorded for any common disease, and the defining feature of its epidemiology. Symptoms typically begin in adolescence, with diagnosis usually in the late twenties or thirties, and they generally regress after menopause. Apparent geographic variation almost certainly reflects access to laparoscopy and diagnostic practice rather than true prevalence differences.

**Where it starts.** Retrograde menstruation, Sampson's theory, is the leading explanation and is insufficient: retrograde flow occurs in up to 90 per cent of women†, yet only a minority develop endometriosis, so the determinant must lie in what happens to the refluxed cells — immune clearance, adhesion and survival. Alternative and complementary theories: coelomic metaplasia, Müllerian remnants, stem cell spread, and lymphatic and vascular spread, which explains rare extrapelvic and post-hysterectomy disease.

Early menarche, short cycles, heavy and prolonged menses, nulliparity and late menopause all increase lifetime menstrual exposure. Obstructive Müllerian anomalies, which force retrograde flow, markedly increase risk, and that is strong supporting evidence for the retrograde mechanism. Low BMI is associated with higher risk, consistently and unexplained.

Family history is strong: a first-degree relative raises risk about five to seven times, and heritability is estimated at about 47 to 52 per cent from the Australian twin study (Treloar), roughly half the variance. GWAS has identified more than forty loci — *WNT4*, *GREB1*, *ESR1*, *CDKN2B-AS1*, *VEZT* — explaining a modest fraction, with genetic overlap with ovarian cancer subtypes.

Immune dysfunction: reduced natural killer cell clearance of ectopic cells, and association with autoimmune conditions. Endocrine-disrupting chemicals, dioxins, PCBs and phthalates: CONTESTED — associations are reported and causality is not established. Protective: multiparity, extended lactation, regular exercise weakly, and oral contraceptive use, which may also mask symptoms and thereby delay diagnosis.

What is not known is the cause. This is a disease whose basic mechanism is genuinely unsettled after a century of theories. Why pain correlates so poorly with disease stage is a major unexplained feature: women with minimal disease may have severe pain and vice versa, which means the revised ASRM staging predicts fertility but not symptoms. Why it causes infertility is only partly explained, through adhesions, altered follicular and peritoneal environment, and impaired implantation. Why it recurs after apparently complete excision. Whether adenomyosis is a related or a distinct entity. And whether it ever progresses to malignancy beyond the known small increase in clear cell and endometrioid ovarian cancer risk.

**Cure status.** CONTROLLABLE, and this is stated plainly because over-promising is a documented harm in this field.

No medical treatment cures endometriosis. Hormonal suppression controls symptoms while taken, and symptoms recur in the majority within six to twelve months of stopping. Surgical excision gives durable relief in many, with recurrence of about 20 to 50 per cent at five years, and repeat surgery is common†. That is control.

Hysterectomy with bilateral oophorectomy ends cyclical stimulation and is the nearest approach to a cure, but pain persists in about 10 to 15 per cent†, it is not a guarantee, and it is not an option for women wanting fertility. Menopause usually brings regression, so in

that sense it is a self-limiting disease over a lifetime, though with more than thirty years of morbidity.

The honest framing: this is a chronic condition managed over decades, like asthma or inflammatory arthritis, and framing surgery as a definitive cure is not supported.

**Prevention.** No established primary prevention: absent. Combined oral contraceptives and continuous progestogens reduce symptoms and may reduce progression: WEAK for prevention, STRONG for symptom control. Note the complication that they may delay diagnosis by masking symptoms. Relieving obstructive Müllerian anomalies: MODERATE, mechanistically direct. Exercise, multiparity and lactation associations: WEAK, observational, and not actionable as advice. Reducing diagnostic delay is not prevention of disease but prevention of accumulated harm, and is the highest-value system intervention: MODERATE, on the grounds that earlier treatment reduces disease burden and preserves fertility.

**Treatment.** Analgesia: NSAIDs are first line for pain, with a modest effect size against placebo and surprisingly weak evidence — Cochrane finds it inconclusive for endometriosis specifically — though they are widely effective in dysmenorrhoea generally. Off-patent, EML-listed, a few to tens of US dollars a year.

Hormonal suppression, all symptomatic and all recurring on stopping. Combined oral contraceptives used continuously, skipping the withdrawal bleed, are effective for pain, cheap and well tolerated. EML yes; off-patent; tens of US dollars a patient-year. First-line in most guidelines.

Progestogens — medroxyprogesterone acetate, norethisterone, dienogest — and the levonorgestrel intrauterine system, which is highly effective for pain and for adenomyosis, lasts five to eight years and is extremely cost-effective. The intrauterine system is EML-listed, at tens of US dollars per device at public-sector prices, so a few dollars a year. One of the best value interventions here.

GnRH agonists, leuprolide and goserelin, with add-back therapy of low-dose oestrogen plus progestogen to prevent bone loss and vasomotor symptoms, are effective for severe disease and limited to about six to twelve months without add-back because of bone density loss. Off-patent; thousands of US dollars a year. GnRH antagonists — elagolix, relugolix combination, linzagolix — are oral, rapid and dose-adjustable; on patent at about US$10,000 to 13,000 a year US list†, with a modest advantage over far cheaper options. Aromatase inhibitors for refractory postmenopausal or persistent disease, off-label, combined with suppression. Danazol is effective and its androgenic side effects make it largely obsolete.

Surgery. Laparoscopic excision or ablation of endometriosis reduces pain significantly against diagnostic laparoscopy alone, with a number needed to treat of about three to four in trials, and excision appears superior to ablation for deep disease and for durability; recurrence is 20 to 50 per cent at five years. Excision of deep infiltrating endometriosis of the bowel, bladder or ureter requires specialist multidisciplinary teams and gives high symptom relief with significant complication rates. Ovarian endometrioma cystectomy improves pain and spontaneous pregnancy rates but removes ovarian reserve, so it must be weighed carefully against fertility plans: a genuine trade-off. Hysterectomy with or without oophorectomy for women who have completed childbearing with refractory symptoms, where coexisting adenomyosis is often cured by hysterectomy. Presacral neurectomy and LUNA: LUNA is not effective on randomised evidence and should not be used.

Fertility: surgical excision improves spontaneous conception in minimal to mild disease, with a modest effect, and IVF is effective and is the main route in moderate to severe disease. GnRH agonist pretreatment before IVF improves outcomes in some analyses. Hormonal suppression does not improve fertility and delays conception — an important point, since it is sometimes prescribed for that purpose.

Multidisciplinary pain care: pelvic floor physiotherapy, neuropathic agents such as amitriptyline and gabapentin, though the GaPP2 trial found gabapentin ineffective for chronic pelvic pain, psychological therapy, and specialist pain management. This is essential because central sensitisation develops in many, and surgery on the lesions then does not relieve pain. It is the most under-provided part of care.

**Simple means.** Heat, from a hot water bottle or a warm bath, is comparable to NSAIDs for dysmenorrhoea pain in small randomised trials. Free.

Continuous, no-break use of cheap combined oral contraceptives or progestogens: eliminating withdrawal bleeds markedly reduces cyclical pain, costs tens of US dollars a year, and requires no procedure. The levonorgestrel intrauterine system costs a few dollars a year amortised, is inserted once, and is highly effective.

Exercise has modest evidence for pain reduction and improves function and mood. Pelvic floor physiotherapy and relaxation training is effective for the pelvic floor muscle overactivity that commonly accompanies the condition: a taught skill. Psychological therapy, pain education and self-management are effective for chronic pain of any origin, and central sensitisation is common here; no supply chain. Peer support groups have a measurable effect on coping and quality of life, and stigma and isolation are a large part of this disease's burden.

Believing women and investigating early is not a therapy but the single highest-value simple means available: a seven- to eleven-year diagnostic delay is a system failure correctable by clinician education and listening, at no material cost. TENS, acupuncture and dietary change, low-FODMAP where irritable bowel syndrome overlaps, have weak evidence, low risk and are sometimes helpful.

The honest limit: deep infiltrating disease and endometriomas need surgery. Nothing simple removes a bowel nodule.

**Gaps.** The cause is unknown. Pain correlates poorly with disease stage, so staging is nearly useless for symptom prognosis. Diagnostic delay of seven to eleven years persists and is poorly explained by any single factor. There is no non-invasive diagnostic test despite extensive biomarker research: laparoscopy remains the reference standard, though imaging now detects deep disease and endometriomas well. NSAID evidence specific to endometriosis is inconclusive despite universal use. Expensive new GnRH antagonists have not been shown superior to cheap continuous contraceptives. Recurrence rates after excision vary widely between series and surgeons, and surgeon skill is a major uncontrolled variable. The contribution of central sensitisation is recognised and not quantified. Prevalence data from Africa, South Asia and Latin America are very sparse. Research funding is low relative to burden, a repeatedly documented disparity.

---

## Uterine fibroids

Uterine fibroids are benign tumours of the smooth muscle of the womb. ICD-11 codes them in chapter 2, among the neoplasms, and the full entry is there: entry 34, "Uterine fibroids", in the chapter on neoplasms. It carries all eight sections.

A reader in the genitourinary chapter is sent there because the condition is the commonest tumour in women. It is also a leading cause of hysterectomy and of iron-deficiency anaemia.

---

## Polycystic ovary syndrome

**What it is.** A common hormonal condition in which ovulation is irregular, male-type hormones are raised, and the ovaries often contain many small follicles. It causes irregular periods, acne, excess hair and difficulty conceiving, and carries metabolic risk.

**Measured.** Prevalence is 8 to 13 per cent of reproductive-age women by Rotterdam criteria, about 6 per cent by the stricter NIH criteria, and up to about 21 per cent in some high-risk populations using broad criteria. The spread is almost entirely definitional, and all three figures are printed.

About 70 per cent of affected women are undiagnosed, on international survey data. It is the commonest cause of anovulatory infertility, responsible for about 70 to 80 per cent of it. It is not a separate GBD cause with its own DALY total. There are no direct deaths; the burden comes via type 2 diabetes, cardiovascular risk and endometrial cancer.

The metabolic associations are large: impaired glucose tolerance in about 30 to 35 per cent, type 2 diabetes in about 10 per cent by the fourth decade, roughly four times the background risk, gestational diabetes about three times, obstructive sleep apnoea, and metabolic fatty liver disease in about 35 to 70 per cent†. Endometrial cancer risk is raised about 2.7 to three times, from chronic unopposed oestrogen with anovulation†.

It presents at puberty or in early adulthood, the metabolic consequences accumulate with age, and the reproductive features attenuate after menopause. Metabolic severity is higher in South Asian women, who develop insulin resistance at lower BMI and present earlier.

**Where it starts.** Insulin resistance with compensatory hyperinsulinaemia is present in about 50 to 70 per cent†, independent of obesity, since lean women with the syndrome are also insulin resistant. Insulin drives ovarian androgen production and lowers sex hormone binding globulin, and that is central to the pathophysiology.

Hyperandrogenism, ovarian and adrenal. Disordered gonadotrophin secretion, with raised LH pulse frequency relative to FSH, arresting follicle maturation. Obesity amplifies everything, and is neither necessary nor sufficient: about 20 to 50 per cent of women with the syndrome are lean†.

Heritability is high. Family clustering is strong, with about 20 to 40 per cent of first-degree female relatives affected, and twin studies estimate heritability at about 70 to 72 per cent (Vink, Dutch twin study) — one of the higher heritabilities among common endocrine disorders. GWAS has found about twenty loci — *DENND1A*, *THADA*, *FSHB*, *LHCGR*, *INSR* — explaining only a small fraction, leaving substantial missing heritability.

Developmental programming: prenatal androgen exposure produces a syndrome-like phenotype in animal models, and anti-Müllerian hormone and maternal factors are implicated in humans. Both low and high birth weight are associated.

What is not known is the primary cause. Whether the initiating defect is ovarian, adrenal, hypothalamic-pituitary or metabolic is unresolved after decades, and it may be several distinct conditions pooled under one syndrome, which is why the diagnostic criteria keep changing. Why insulin resistance occurs in lean women with the syndrome is unexplained. The relationship between anti-Müllerian hormone and the phenotype is being actively revised. And long-term cardiovascular outcome data are surprisingly weak: risk factors are clearly increased and hard event data are inconsistent.

**Cure status.** Two strata.

The syndrome itself: CONTROLLABLE, not curable. The underlying predisposition is lifelong, though the phenotype changes with age and ameliorates after menopause. It is modifiable to a remarkable degree: weight loss of 5 to 10 per cent restores ovulation in a substantial proportion and improves all features, which is the closest thing to a cure for the metabolic-reproductive phenotype. Individual features — hirsutism, acne, cycles, glucose tolerance — are each controllable with treatment and recur on stopping.

The infertility specifically: CONTROLLABLE. With ovulation induction, cumulative live birth rates approach those of the general population.

**Prevention.** The syndrome itself is not preventable, being largely genetic and developmental: absent. Preventing the consequences is where prevention works, and it is strong.

Weight management and physical activity: STRONG for preventing type 2 diabetes and restoring ovulation. Metformin: MODERATE for preventing progression to type 2 diabetes in those with impaired glucose tolerance, extrapolated from the Diabetes Prevention Program and syndrome-specific trials.

Cyclical progestogen or a combined oral contraceptive to induce regular withdrawal bleeds: STRONG for preventing endometrial hyperplasia and cancer in women with oligomenorrhoea or amenorrhoea. That is a specific, cheap, high-value preventive that is frequently overlooked, and it addresses an approximately threefold cancer risk.

Screening for glucose intolerance, lipids, blood pressure and sleep apnoea: STRONG on guideline consensus. Smoking cessation: MODERATE, for cardiovascular risk amplification. Preconception weight optimisation: MODERATE, improving fertility and reducing gestational diabetes and pregnancy complications.

**Treatment.** Treatment is organised by the problem being addressed, which is the only coherent way.

Lifestyle is the foundation for all of it. Diet, exercise and weight loss of 5 to 10 per cent restores ovulation in a substantial proportion and improves insulin sensitivity, androgens, lipids and quality of life. No particular diet composition is superior: an energy deficit is what matters. First-line in all guidelines.

Irregular cycles and endometrial protection. Combined oral contraceptives regulate cycles, protect the endometrium and reduce hyperandrogenism by raising sex hormone binding globulin: first-line. EML yes; off-patent; tens of US dollars a patient-year. Cyclical progestogen, medroxyprogesterone or norethisterone, or the levonorgestrel intrauterine system, for endometrial protection where oestrogen is contraindicated; cheap, with the intrauterine system at a few dollars a year.

Insulin resistance and metabolic risk. Metformin improves insulin sensitivity, menstrual regularity and ovulation, has a modest weight effect, and reduces progression to diabetes. Metformin is an EML-listed medicine, section 18.5.2, for type 2 diabetes in adolescents and adults, first added in 1997; off-patent; a few to tens of US dollars a patient-year. Excellent value, with gastrointestinal side effects limiting some use.

GLP-1 receptor agonists are effective for weight loss here, improving ovulation and metabolic markers; on patent and expensive at about US$9,000 to 16,000 a year US list†, though generics of older agents are appearing, and they are increasingly used where obesity dominates. Inositol, myo-inositol, has some positive trials for ovulation and insulin sensitivity with low to moderate and heterogeneous evidence quality: CONTESTED and WEAK, though cheap and low-risk. Bariatric surgery for severe obesity restores ovulation in most and improves all features markedly.

Hirsutism and acne. Combined oral contraceptives, ideally with an anti-androgenic progestogen, take six to nine months for a visible effect on hair. Spironolactone 50 to 200 mg as an anti-androgen is effective for hirsutism and must be combined with contraception because of teratogenic risk; it is an EML-listed medicine under diuretics and heart failure; off-patent; tens of US dollars a year. Finasteride, cyproterone acetate and flutamide are alternatives, with cyproterone carrying hepatotoxicity and meningioma concerns and flutamide significant hepatotoxicity. Topical eflornithine, and mechanical and laser hair removal, where laser and electrolysis are the only methods producing durable reduction and cost is the barrier. Topical acne therapy with benzoyl peroxide and retinoids, and isotretinoin for severe acne.

Infertility. Letrozole, an aromatase inhibitor, is now first-line for ovulation induction and is superior to clomiphene: the Legro trial (*NEJM* 2014, 750 women) found live birth rates of 27.5 per cent with letrozole against 19.1 per cent with clomiphene, P = 0.007, with comparable safety. Off-patent; tens of US dollars a cycle. A cheap drug that outperformed the previous cheap standard. Clomiphene citrate is still effective and extremely cheap; EML yes; a few to tens of US dollars a cycle.

Metformin as an adjunct may improve clomiphene response, with modest benefit alone. Gonadotrophins are second line, requiring monitoring, with risk of multiple pregnancy and hyperstimulation, and expensive. Laparoscopic ovarian drilling is an effective second line that avoids multiple pregnancy risk at a one-off cost; its use is declining and it remains valuable where monitoring for gonadotrophins is unavailable. IVF for failed ovulation induction or other factors, with a higher hyperstimulation risk in this syndrome. Weight loss before treatment improves all outcomes and reduces pregnancy complications.

Psychological: screening and treating depression, anxiety and eating disorders, which are substantially more common here and routinely missed, and are included in international guidelines.

**Simple means.** Weight loss of 5 to 10 per cent with physical activity restores ovulation in many, improves every measured feature, and prevents diabetes: the single most effective intervention, with no supply chain. Any sustainable energy-restricted diet, since composition does not matter, so advice can be adapted to local food and cost. Resistance and aerobic exercise improves insulin sensitivity independent of weight loss.

Cyclical progestogen costs pennies and prevents endometrial cancer in women with absent periods: one of the highest benefit-to-cost ratios here, and widely neglected.

Metformin, letrozole, clomiphene and spironolactone are all off-patent and cost a few to tens of US dollars together covering metabolic risk, fertility and hirsutism. The effective core of treatment is remarkably cheap. Mechanical hair removal — threading, waxing, shaving — gives cosmetic management without cost barriers, though it is not durable. Sleep: screening for and treating sleep apnoea, since improving sleep improves insulin sensitivity. Psychological support and peer groups, since the psychological burden is high and under-treated. Smoking cessation.

The honest limit: anovulatory infertility usually needs a drug, though a very cheap one, and severe hirsutism needs laser or electrolysis for durable results.

**Gaps.** The diagnostic criteria have changed repeatedly — NIH, Rotterdam, AES, the 2023 international guideline — and prevalence varies two- to threefold between them, so the literature is not comparable and many women are differently labelled depending on where they are seen. The primary cause is unknown and this is probably several conditions. Diagnosis in adolescents is genuinely problematic because irregular cycles and acne are normal in early post-menarche years, risking over-diagnosis. Long-term cardiovascular event data are weak and inconsistent despite clearly adverse risk factors. Anti-Müllerian hormone's diagnostic role is unsettled. Inositol evidence is low quality. Most trials are small, short and conducted in white and obese populations, under-representing lean disease and South Asian women, who have greater metabolic severity. Male relatives' phenotype is barely studied. Under-diagnosis at about 70 per cent means most of the burden is invisible to health systems.

---

## Pelvic inflammatory disease

**What it is.** Infection ascends from the vagina and cervix into the womb, tubes and pelvis. It causes pain and fever, and can scar the tubes, leading to infertility and ectopic pregnancy.

**Measured.** Lifetime prevalence of self-reported pelvic inflammatory disease in United States women is about 4.4 per cent (NHANES); incidence has fallen in high-income countries with chlamydia screening and remains substantial.

Tubal factor infertility follows in about 10 to 12 per cent after one episode, about 20 to 35 per cent after two, and about 40 to 55 per cent after three or more†. The cumulative, stepwise damage is the central fact. Ectopic pregnancy risk is raised about six to ten times after an episode, and chronic pelvic pain follows in about 18 to 30 per cent of women†.

GBD 2019 includes this condition within maternal, gynaecological and sexually transmitted infection categories, and it is not a separate top-level cause with a clean DALY figure. Deaths are few and non-zero, through tubo-ovarian abscess and sepsis.

The underlying sexually transmitted infection burden drives it. The WHO STI fact sheet of 10 September 2025 gives 374 million new infections in 2020 of one of four curable sexually transmitted infections in people aged 15 to 49, with the 2020 breakdown in its body: trichomoniasis 156 million, chlamydia 129 million, gonorrhoea 82 million, syphilis 7.1 million. That page also contradicts itself on syphilis: its Key Facts give 8 million adults aged 15 to 49 infected in 2022 while its body gives 7.1 million new infections in 2020 — two different magnitudes and two different years on the same page, nowhere reconciled. Both are printed. The chlamydia and gonorrhoea figures are the reservoir driving this condition.

Cases are concentrated in women aged 15 to 25, the same group with the highest chlamydia prevalence. The highest burden is in sub-Saharan Africa, South Asia and Latin America, where screening and treatment access are limited. *Mycobacterium tuberculosis* is a significant cause of genital tract infection and tubal infertility in endemic regions — an important differential often omitted from Western accounts.

**Where it starts.** *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are the classic causes, and together they are identified in only about 30 to 50 per cent of cases†. Polymicrobial ascending infection with anaerobes, *Mycoplasma genitalium*, increasingly recognised, *Gardnerella*, and enteric and respiratory organisms; bacterial vaginosis is associated and may facilitate ascent.

Young age at first intercourse, multiple or new sexual partners, unprotected intercourse, and a partner with untreated infection form the behavioural risk set. Prior episodes are the strongest single predictor of another. Instrumentation: termination of pregnancy, IUD insertion, where risk is confined to the first three weeks or so after insertion and is small, and IUDs are not a long-term risk factor, which is a persistent misconception; hysteroscopy; endometrial biopsy.

Postpartum and post-abortal infection, especially after unsafe abortion, is a major cause in settings where safe abortion is unavailable.

Genital tuberculosis in endemic areas; and female genital schistosomiasis in parts of Africa, a significantly under-recognised cause of tubal damage and an independent HIV risk factor. Douching: CONTESTED — associated, with causality disputed. Protective: barrier contraception, combined oral contraceptives weakly and possibly via cervical mucus, monogamy, and treatment of partners.

Heritability is not meaningfully applicable, since this is an infectious disease, though host immune variation likely affects the severity of tubal scarring.

What is not known is why some women with chlamydia develop pelvic inflammatory disease and tubal damage while most do not — only about 10 to 15 per cent of untreated chlamydial infections ascend†. Host immune response and possibly repeated reinfection matter, and prediction is impossible. Diagnosis itself is unreliable: clinical diagnosis has a positive predictive value of only about 65 to 90 per cent against laparoscopy†, so both over- and under-treatment are common and much of the literature rests on an uncertain case definition. Whether screening reduces the condition is contested. And the pathogenic role of *Mycoplasma genitalium* and of the vaginal microbiome is unresolved.

**Cure status.** Two strata.

The acute infection, treated early: CURABLE. Antibiotics cure it in the great majority, with clinical cure of about 85 to 95 per cent†. Tubo-ovarian abscess requires drainage in addition to antibiotics and is then curable.

Established tubal scarring, infertility and chronic pain: RELIEF ONLY. The sequelae are not reversible. Tubal scarring, once established, is permanent: infertility, ectopic risk and chronic pain persist after the infection has gone. So the condition is curable only if treated early enough, and the window matters — a delay of more than two to three days from symptom onset roughly triples the risk of subsequent infertility and ectopic pregnancy (Hillis). Tubal factor infertility is treatable and not curable: tubal surgery has limited success, and IVF bypasses rather than repairs the damage.

So: curable acutely; relief only for the irreversible damage, which accrues from the first episode onward.

**Prevention.** Condom use: STRONG. Prompt treatment of chlamydia and gonorrhoea: STRONG — and treating sexual partners is essential to prevent reinfection, which drives cumulative tubal damage. Partner notification and treatment is cheap and under-delivered.

Chlamydia screening: MODERATE, and genuinely CONTESTED. The POPI trial (Oakeshott, *BMJ* 2010) found a non-significant reduction with screening; earlier US trials (Scholes 1996) found a significant reduction of about 56 per cent. Meta-analyses suggest a modest benefit, and national programmes, notably England's, have been criticised for uncertain cost-effectiveness. Both results are printed: screening is widely recommended and the magnitude of its prevention effect is uncertain.

Treating bacterial vaginosis before instrumentation: MODERATE. Antibiotic prophylaxis before termination of pregnancy and before IUD insertion in high-prevalence settings: MODERATE. Safe abortion access: STRONG for preventing post-abortal sepsis and pelvic inflammatory disease. Safe delivery and postpartum care: STRONG. Reducing partner numbers and delaying sexual debut: MODERATE, behavioural and hard to deliver. Treating female genital schistosomiasis with praziquantel, and genital tuberculosis, in endemic areas: MODERATE. HPV and hepatitis B vaccination do not prevent this condition and belong to the same service platform, and integrated sexual health services improve all outcomes.

**Treatment.** Treatment must be empirical and immediate. Do not wait for microbiology, because the tubal damage accrues during the delay. That is the single most important principle.

Outpatient regimens, typical per CDC and UK guidance, with local resistance governing the choice: ceftriaxone 500 mg to 1 g intramuscularly as a single dose with doxycycline 100 mg twice daily and metronidazole 400 to 500 mg twice daily, both for fourteen days. The alternative is ofloxacin or levofloxacin with metronidazole for fourteen days where gonorrhoea is unlikely or excluded, since quinolone resistance in gonorrhoea is now widespread and quinolone monotherapy is inadequate for gonococcal disease. Moxifloxacin where *Mycoplasma genitalium* is suspected or confirmed.

Drug status: ceftriaxone EML yes, off-patent, a few US dollars a course; doxycycline EML yes, off-patent, a few US dollars a course; metronidazole EML yes, Access group, off-patent, a few US dollars a course. The total drug cost of curing pelvic inflammatory disease is a few to tens of US dollars. For a condition that otherwise causes lifelong infertility, this is among the most cost-effective treatments in medicine, and the barrier is diagnosis and access, not cost.

Inpatient treatment for severe disease, pregnancy, abscess, failed outpatient therapy, inability to tolerate oral therapy, or diagnostic uncertainty: intravenous cefoxitin, cefotetan or ceftriaxone with doxycycline, or clindamycin with gentamicin, stepping down to oral therapy. Tubo-ovarian abscess: antibiotics plus drainage, image-guided percutaneous or laparoscopic, for abscesses above 4 to 7 cm or failing medical therapy.

Remove an IUD? Not routinely. Evidence suggests outcomes are similar with the IUD left in place for mild to moderate disease, with removal considered if there is no improvement at 48 to 72 hours. A commonly mishandled point.

Partner treatment is essential: treat partners from the preceding sixty days empirically for chlamydia and gonorrhoea regardless of their test results. Abstinence until both partners complete treatment. Test for HIV, syphilis and other infections, and offer HIV prevention. Analgesia with NSAIDs and paracetamol. Follow-up at 72 hours to confirm response, and retesting for reinfection at three months, since reinfection rates are high and drive cumulative damage.

Later management of the sequelae: adhesiolysis and tubal surgery have limited success; IVF for tubal factor infertility; multidisciplinary chronic pelvic pain management including pelvic floor physiotherapy and neuropathic agents for the 18 to 30 per cent with chronic pain. Antituberculous therapy for genital tuberculosis, and praziquantel for female genital schistosomiasis; praziquantel is an EML-listed medicine, in intestinal anthelminthics, antischistosomals and cysticidal medicines.

**Simple means.** Condoms are cheap, effective, and prevent the causative infections.

Immediate empirical treatment on clinical suspicion is a decision, not a technology. Treating promptly on clinical grounds rather than awaiting tests roughly triples the chance of preserving fertility compared with a delay of a few days. That is the highest-value action in the entry and it costs nothing.

Partner notification and treatment is a conversation plus a few US dollars of antibiotics, and it prevents the reinfection that causes cumulative tubal destruction; patient-delivered partner therapy works where clinic attendance is a barrier. Three off-patent, EML-listed antibiotics costing a few to tens of US dollars cure the disease.

Syndromic management under WHO-endorsed algorithms allows treatment without laboratory capacity, which is how most of the world’s pelvic inflammatory disease must be managed; its specificity is imperfect and it prevents infertility. Education and open sexual health services, reducing stigma and delay in presentation. Safe delivery and safe abortion practice. Retesting at three months is cheap and catches reinfection.

The honest limit: a tubo-ovarian abscess needs drainage, and established tubal infertility needs IVF, which is expensive and unavailable to most. The simple means work almost entirely at the prevention and early-treatment stage, which is precisely where the leverage is.

**Gaps.** Clinical diagnosis is unreliable, with a positive predictive value of about 65 to 90 per cent, so incidence figures and trial populations are both uncertain, and there is no practical accurate diagnostic test. Whether chlamydia screening programmes reduce the condition at population level is genuinely contested, with trials disagreeing. The pathogenic role of *Mycoplasma genitalium* and the optimal regimen for it are unsettled amid rising macrolide resistance. Gonococcal antimicrobial resistance is advancing and threatens current regimens. Female genital schistosomiasis is substantially under-recognised and its contribution to tubal infertility in Africa is unquantified. Optimal management of an IUD left in situ rests on limited evidence. Burden data from low-income settings, where this condition causes the most infertility, are weak, and GBD does not model it separately. Partner treatment rates are low everywhere and poorly measured. The WHO STI fact sheet contradicts itself on syphilis magnitude and year.

## Menstrual disorders: heavy menstrual bleeding, dysmenorrhoea, amenorrhoea and premenstrual syndrome

**What it is.** Periods that are too heavy, too painful, absent or irregular, or that bring severe mood symptoms beforehand. Common, often dismissed, and usually treatable.

**Measured.** Heavy menstrual bleeding affects about 20 to 30 per cent of women of reproductive age, objectively defined as over 80 mL a cycle, though the practical definition is now symptom-based: blood loss interfering with quality of life. It is a leading cause of iron deficiency anaemia in women worldwide, and that is the principal measurable harm; iron deficiency affects about 30 per cent of reproductive-age women and anaemia about 500 million women globally on the WHO figure†. GBD 2023 Table 1 gives dietary iron deficiency ninth among YLD causes at 39.3 million (95 per cent UI 24.8 to 63.5). Heavy bleeding is also a leading indication for hysterectomy.

Dysmenorrhoea has a prevalence of about 45 to 95 per cent of menstruating women depending on definition, with severe, activity-limiting pain in about 15 to 20 per cent†. It is the leading cause of recurrent short-term school and work absence in young women.

Primary amenorrhoea affects about 0.3 to 1 per cent and secondary amenorrhoea about 3 to 5 per cent of reproductive-age women, excluding pregnancy and lactation.

Premenstrual symptoms occur in up to 80 per cent, with clinically significant premenstrual syndrome in about 20 to 30 per cent and premenstrual dysphoric disorder in about 1.8 to 5.8 per cent by strict DSM-5 criteria.

GBD 2019 includes some of these within gynaecological conditions and they are not cleanly separated top-level causes. Deaths are essentially none directly, though severe anaemia contributes to maternal mortality. Dysmenorrhoea peaks in the late teens and twenties and declines with age and parity; heavy bleeding peaks in the forties, in perimenopause.

**Where it starts.** For heavy menstrual bleeding, the PALM-COEIN framework is the standard classification. Structural (PALM): polyp, adenomyosis, leiomyoma, and malignancy or hyperplasia. Non-structural (COEIN): coagulopathy — and von Willebrand disease is present in about 5 to 20 per cent of women with heavy menstrual bleeding† and is massively underdiagnosed; ovulatory dysfunction, from polycystic ovary syndrome, perimenopause, thyroid disease or hyperprolactinaemia; endometrial causes; iatrogenic causes, from a copper IUD, anticoagulants or antiplatelets; and not otherwise classified. Also obesity, through anovulation and raised oestrogen, and hypothyroidism.

For dysmenorrhoea: primary dysmenorrhoea arises from excess endometrial prostaglandin production, PGF2α, causing myometrial hypercontractility and ischaemia, which is why NSAIDs, as prostaglandin synthesis inhibitors, work so well. Risk factors: young age, early menarche, long or heavy flow, nulliparity, smoking, family history. Secondary dysmenorrhoea arises from endometriosis, which is commonest and the usual reason for diagnostic delay, adenomyosis, fibroids, pelvic inflammatory disease, cervical stenosis, obstructive Müllerian anomaly, or an IUD.

For amenorrhoea: pregnancy, always to be excluded first. Hypothalamic causes: energy deficiency relative to expenditure, giving functional hypothalamic amenorrhoea from low energy availability, excessive exercise, eating disorders and stress, where the key driver is energy deficit, as part of the Relative Energy Deficiency in Sport syndrome, with consequences for bone density. Pituitary causes: hyperprolactinaemia from a prolactinoma or from drugs, and Sheehan syndrome. Ovarian causes: polycystic ovary syndrome, primary ovarian insufficiency, chemotherapy and radiotherapy, Turner syndrome, fragile X premutation. Outflow causes: Müllerian agenesis, imperforate hymen, transverse septum, and Asherman syndrome from intrauterine adhesions after instrumentation or infection. Thyroid disease; congenital adrenal hyperplasia; constitutional delay.

For premenstrual syndrome and premenstrual dysphoric disorder: normal cyclical ovarian hormone fluctuation with abnormal central sensitivity. The hormones are not abnormal; the response to them is. That was confirmed by the observation that suppressing the cycle abolishes symptoms and re-adding hormones reproduces them only in susceptible women (Schmidt, *NEJM* 1998). A serotonergic mechanism is implicated, with allopregnanolone and

GABA-A sensitivity. Heritability of premenstrual syndrome is about 30 to 56 per cent from twin studies, with *ESR1* and other polymorphisms implicated. A history of trauma, mood disorder and stress raises risk.

Dysmenorrhoea shows familial clustering, with twin heritability of about 40 to 55 per cent in some studies†; heavy menstrual bleeding heritability is poorly quantified apart from the inherited coagulopathies.

What is not known is why prostaglandin production varies so much between women. Why premenstrual dysphoric disorder affects a small minority given identical hormonal fluctuation — the central sensitivity mechanism is demonstrated and not explained at a molecular level. Why adenomyosis causes such severe symptoms in some. The threshold of energy deficit that suppresses the hypothalamus varies greatly and unpredictably between individuals. And whether menstrual pain sensitises the central nervous system in a way that predisposes to later chronic pain syndromes is an open and important question.

**Cure status.** This must be split, and each stratum named.

Heavy menstrual bleeding: CONTROLLABLE medically, and CURABLE where there is a treatable structural or systemic cause — polypectomy, hysteroscopic myomectomy, thyroid treatment, or treating a coagulopathy can cure it. Hysterectomy and endometrial ablation are definitively curative for the bleeding. Medical therapy controls while taken.

Primary dysmenorrhoea: CONTROLLABLE. NSAIDs and hormonal suppression are highly effective, and the condition also naturally improves with age and after childbirth, so it is partly self-limiting over a lifetime.

Secondary dysmenorrhoea: it depends on cause — CURABLE if a polyp or stenosis, CONTROLLABLE if endometriosis or adenomyosis, with adenomyosis curable by hysterectomy.

Functional hypothalamic amenorrhoea: CURABLE. Restoring energy availability — increased intake, reduced training load, weight restoration — restores menstruation in the majority, which is a genuine cure addressing the cause.

Hyperprolactinaemia: CURABLE. Dopamine agonists normalise prolactin and restore cycles in about 80 to 90 per cent†: among the most satisfying treatments in endocrinology.

Primary ovarian insufficiency: CONTROLLABLE, not curable. Hormone replacement is required until the natural age of menopause, and fertility usually requires donor oocytes.

Premenstrual syndrome and premenstrual dysphoric disorder: CONTROLLABLE. SSRIs and cycle suppression are effective, and the condition is CURABLE by oophorectomy in extreme refractory cases, which is rarely justified.

**Prevention.** Combined hormonal contraception prevents dysmenorrhoea and heavy bleeding: STRONG for symptom prevention while used. Maintaining adequate energy availability and avoiding excessive exercise relative to intake: STRONG for preventing functional hypothalamic amenorrhoea and the associated bone loss, with education of athletes, dancers and coaches as the practical mechanism. Screening for and treating iron deficiency: STRONG for preventing the main harm of heavy bleeding.

Testing for von Willebrand disease and other coagulopathies in women with heavy bleeding since menarche: MODERATE — it is present in 5 to 20 per cent, is routinely missed, and identifying it changes management entirely. Avoiding smoking: WEAK for dysmenorrhoea. Regular moderate exercise: MODERATE for both dysmenorrhoea and premenstrual syndrome. Weight management: MODERATE for anovulatory bleeding.

Early investigation of severe dysmenorrhoea rather than normalising it: MODERATE. That is how endometriosis diagnostic delay is reduced, and dismissing severe period pain as normal is the single largest preventable harm in this entry.

**Treatment.** For heavy menstrual bleeding. The levonorgestrel intrauterine system reduces blood loss about 70 to 95 per cent† and is the most effective medical treatment and superior to all oral options; it also treats dysmenorrhoea and adenomyosis and provides contraception. EML yes; tens of US dollars per device for five to eight years. The outstanding value intervention here.

Tranexamic acid reduces loss about 40 to 50 per cent†, is taken only during bleeding, and is non-hormonal, so it suits where hormones are declined or contraindicated. It is an EML-

listed medicine under medicines affecting coagulation, section 10.2 core, and under other medicines administered to the mother, section 22; off-patent; tens of US dollars a year.

NSAIDs, mefenamic acid and naproxen, reduce loss about 20 to 40 per cent and relieve pain; off-patent, EML-listed†, a few to tens of US dollars a year. Combined oral contraceptives reduce loss about 35 to 50 per cent† and are cheap and off-patent. Cyclical or continuous progestogens, depot medroxyprogesterone, and GnRH analogues for short-term severe cases.

Iron replacement: oral ferrous salts first line, and intravenous iron for severe anaemia or oral intolerance. Oral iron EML yes, about US$2 to 15 a year, with an indicative UNICEF price of US$1.43 on one catalogue page and US$1.60 on another per bottle of 100 iron 60 mg tablets, and an iron-plus-folic-acid combination at US$1.24 per bottle of 100, October 2026. Treating the anaemia often resolves the symptoms the woman presents with.

Treat the specific cause: polypectomy, hysteroscopic myomectomy, levothyroxine for hypothyroidism — levothyroxine is an EML-listed medicine, section 18.7, for hypothyroidism, first added in 1977 — and desmopressin or factor concentrate for von Willebrand disease. Endometrial ablation is effective, uterus-conserving and a day case, requiring completed childbearing and reliable contraception. Hysterectomy is definitive.

For dysmenorrhoea. NSAIDs are first line and highly effective, with a number needed to treat of about two to three against placebo for pain relief, and superior to paracetamol; start before or at the onset of bleeding. Ibuprofen, naproxen and mefenamic acid: EML yes; off-patent; a few to tens of US dollars a year. One of the clearest, cheapest wins in this book. Combined hormonal contraception, continuous or extended use skipping withdrawal bleeds, is effective and cheap. The levonorgestrel intrauterine system, and depot progestogen. Investigate for secondary causes if NSAIDs plus hormonal therapy fail — that is the trigger for considering endometriosis.

For amenorrhoea. Treat the cause: energy restoration and reduced training for functional hypothalamic amenorrhoea, with psychological support and eating disorder treatment where relevant; cabergoline or bromocriptine for hyperprolactinaemia, off-patent, tens to hundreds of US dollars a year; levothyroxine for hypothyroidism. Hormone replacement for primary ovarian insufficiency and for prolonged hypo-oestrogenism is essential for bone and cardiovascular protection until about age 50, with oestradiol and a progestogen, off-patent and cheap; transdermal oestradiol with cyclical progestogen is often preferred over the combined pill for bone outcomes in young women. Surgical correction of outflow obstruction, and hysteroscopic adhesiolysis for Asherman syndrome. Calcium, vitamin D and weight-bearing exercise for bone protection.

For premenstrual syndrome and premenstrual dysphoric disorder. SSRIs are first-line for premenstrual dysphoric disorder and are effective either continuously or dosed only in the luteal phase — an unusual and useful property, since the response is rapid, unlike in depression. Response rates are about 60 to 70 per cent†, with a number needed to treat of about three to four. Fluoxetine and sertraline: EML yes; off-patent; tens of US dollars a year. Combined hormonal contraception, continuous, with drospirenone-containing preparations having the best evidence, suppresses cycling. GnRH analogues with add-back for severe refractory cases, and oophorectomy as a last resort after confirmed response to GnRH suppression. CBT is effective, comparable to drugs in some trials, and durable. Calcium supplementation at 1,200 mg a day reduced symptoms significantly in a randomised trial (Thys-Jacobs 1998), and is cheap and low-risk; vitamin B6 has weaker supporting evidence.

**Simple means.** NSAIDs for dysmenorrhoea have a number needed to treat of two to three at a few to tens of US dollars a year. Taken early and at an adequate dose, this resolves most primary dysmenorrhoea, and the commonest reason for failure is an inadequate dose or starting too late.

Heat application — a hot water bottle, a warm bath, a heat patch — is comparable to NSAIDs for menstrual pain in randomised trials and can be combined with them. Free.

Exercise gives a Cochrane-supported reduction in dysmenorrhoea pain intensity and also helps premenstrual syndrome. Tranexamic acid at tens of US dollars a year gives 40 to 50 per cent less bleeding with no hormones. The levonorgestrel intrauterine system gives 70 to 95 per cent bleeding reduction at a few dollars a year amortised. An iron-rich diet and cheap oral iron treats the anaemia that causes the fatigue, at pennies. Calcium at 1,200 mg a day for premenstrual syndrome is trial-supported and cheap. Energy restoration and reduced

training load for hypothalamic amenorrhoea: the cure is food and rest, not a drug. CBT and self-management for premenstrual syndrome needs no supply chain.

Menstrual cups and washable pads are reusable and locally producible, and they directly address the period poverty that causes school absence: a significant equity intervention in low-income settings. Menstrual tracking identifies the cyclical pattern needed to diagnose premenstrual dysphoric disorder and to time treatment, and needs paper or a phone. And not dismissing severe period pain is free, and the key to earlier endometriosis diagnosis.

The honest limit: structural causes need procedures, and primary ovarian insufficiency needs manufactured hormones.

**Gaps.** Definitions are inconsistent: heavy menstrual bleeding has moved from an objective 80 mL definition to a subjective one, so prevalence data are not comparable. Von Willebrand disease is massively under-diagnosed in this population and its true prevalence in heavy bleeders is uncertain, within a 5 to 20 per cent range. Premenstrual dysphoric disorder's biological mechanism is demonstrated and unexplained, and diagnosis requires prospective charting that is rarely done. The long-term bone and cardiovascular consequences of years of functional hypothalamic amenorrhoea are under-quantified, and the optimal hormone regimen for young hypo-oestrogenic women is unsettled, between the combined pill and transdermal oestradiol. Calcium and vitamin B6 evidence for premenstrual syndrome rests on few trials. Adenomyosis is under-diagnosed and its separation from endometriosis is unclear. Most trials are small and short, and almost all are from high-income settings; period poverty's health effects are poorly measured. Dysmenorrhoea's possible role in later chronic pain sensitisation is an open question with large potential significance.

---

## Menopause-related conditions

**What it is.** Periods stop permanently, usually around age 50, because the ovaries run out of follicles. Falling oestrogen causes hot flushes, sleep disturbance, vaginal dryness and accelerated bone loss. It is a normal life stage with treatable symptoms.

**Measured.** Median age at natural menopause is about 50 to 52 years in high-income countries, and earlier in many low- and middle-income settings, about 46 to 49 in parts of South Asia, Africa and Latin America, with smoking, parity, nutrition and socioeconomic factors contributing. About 1.2 billion women worldwide will be postmenopausal by 2030, and roughly 47 million women enter menopause each year†.

Vasomotor symptoms — hot flushes and night sweats — affect about 60 to 80 per cent of women, and are moderate to severe in about 25 to 30 per cent. The median duration of vasomotor symptoms is about 7.4 years (SWAN), and longer, about nine to eleven years, for women whose symptoms begin in perimenopause — substantially longer than the year or two once assumed. That revision matters for treatment duration decisions.

Genitourinary syndrome of menopause, vulvovaginal atrophy, affects about 50 to 70 per cent and, unlike flushes, is progressive and does not resolve with time, which is a key distinction. Premature ovarian insufficiency, below 40 years, affects about 1 per cent, and early menopause, at 40 to 45, about 5 per cent†. Postmenopausal bone loss runs at about 2 per cent a year of trabecular bone in the early postmenopausal years; see the osteoporosis entry.

Menopause is not a disease category in GBD with a separate DALY total, since menopause itself is physiological. Symptom reporting varies considerably between cultures, with lower reported flush rates in Japan and parts of Southeast Asia, which may reflect diet, body composition, reporting conventions and language as much as biology — a genuinely unresolved observation.

**Where it starts.** Follicular depletion is the necessary and sufficient cause of natural menopause, and is determined largely by the ovarian reserve established before birth.

Heritability of age at menopause is about 44 to 65 per cent from twin and family studies; GWAS has found over 290 loci, many in DNA damage response and repair genes — *BRCA1*, *CHEK2*, *MCM8*, *HELB* — and the identified variants explain a modest share. A mother's age at menopause predicts a daughter's.

Smoking advances menopause by about one to two years, dose-dependently: the clearest modifiable factor.

Iatrogenic and early causes: bilateral oophorectomy, which is immediate and gives more severe symptoms; chemotherapy; pelvic radiotherapy; hysterectomy, which advances it even with ovarian conservation; fragile X premutation; Turner syndrome and other X abnormalities; autoimmune oophoritis; galactosaemia; mumps oophoritis. Lower body weight, nulliparity, lower socioeconomic status and earlier menarche in some analyses, while higher parity and oral contraceptive use are associated with later menopause.

Risk factors for severe symptoms specifically: smoking, obesity through adipose tissue and thermoregulation, African-American ancestry, which gave longer and more severe vasomotor symptoms in SWAN, anxiety and depression, lower education, and surgical menopause.

What is not known is why symptom severity and duration vary so enormously between women with identical hormone profiles. The thermoregulatory mechanism — a narrowed thermoneutral zone, KNDy neuron hyperactivity in the hypothalamus — is now partly understood and gave rise to the neurokinin-3 antagonists, and individual variation remains unexplained. Why reported symptom rates differ so much between cultures. Whether the cardiovascular timing hypothesis for hormone therapy is correct. And the cause of the cognitive brain fog many women report, and whether it is hormonal, sleep-mediated or both.

**Cure status.** Menopause is not a disease and is not cured. Its symptoms are the treatable target, and each is given its own label.

Vasomotor symptoms: CONTROLLABLE, and ultimately SELF-LIMITING. Hormone therapy reduces frequency and severity by about 75 to 80 per cent, far above placebo, and symptoms resolve spontaneously in most women over about seven to ten years. So treatment is a bridge rather than a lifelong commitment, for most.

Genitourinary syndrome: CONTROLLABLE, and not self-limiting. It progresses without treatment and responds durably to local oestrogen, which must be continued. The most undertreated menopausal condition.

Bone loss: CONTROLLABLE and preventable; see the osteoporosis entry.

Premature ovarian insufficiency: CONTROLLABLE, not curable. Fertility is usually irrecoverable, requiring donor oocytes, and hormone replacement until about age 50 is necessary rather than optional, for bone and cardiovascular protection.

The honest framing: the goal is symptom control and risk reduction over a defined period, not reversal of a physiological transition.

**Prevention.** Menopause itself is not preventable: not applicable. Smoking cessation: MODERATE — it avoids advancing menopause by one to two years and reduces symptom severity.

Ovarian conservation at hysterectomy where oncologically appropriate: MODERATE. It avoids surgical menopause, which produces more severe symptoms and, if it occurs before age 45 without hormone replacement, is associated with increased cardiovascular and all-cause mortality. An important and sometimes overlooked surgical decision.

Hormone replacement after early or premature menopause until about age 50: STRONG for preventing osteoporosis and cardiovascular disease. That is prevention of harm, not elective symptom treatment, and the risk-benefit calculus is quite different from that of hormone therapy started at 55. Weight management, exercise and not smoking: MODERATE for symptom severity. Calcium, vitamin D and weight-bearing or resistance exercise: STRONG for bone protection.

**Treatment.** Menopausal hormone therapy is the most effective treatment for vasomotor symptoms, giving about a 75 to 80 per cent reduction in frequency and severity†. Oestrogen alone if hysterectomised; oestrogen plus a progestogen if the uterus is present, where the progestogen is required to prevent endometrial hyperplasia and cancer.

Transdermal oestradiol is preferred where available: it avoids first-pass hepatic effects and carries little or no increased venous thromboembolism or stroke risk, unlike oral oestrogen. Micronised progesterone and dydrogesterone appear to carry lower breast cancer risk than the older synthetic progestogens.

On risks, stated accurately. The Women's Health Initiative findings of 2002 were widely misread and caused a collapse in prescribing now regarded as having harmed a generation of women. Current understanding: for a healthy woman starting hormone therapy under age 60 or within ten years of menopause, absolute risks are small and benefits generally outweigh them. Combined hormone therapy is associated with roughly one extra breast cancer per 1,000 women per year of use, approximately and duration-dependently; oestrogen-only therapy shows no increase, and in the Women's Health Initiative a non-significant decrease. Oral, not transdermal, oestrogen roughly doubles a low baseline venous thromboembolism risk. Hormone therapy reduces fracture and colorectal cancer, and improves genitourinary symptoms and quality of life.

Oestradiol and most progestogens are off-patent; EML status: estradiol and progestogens appear on the EML; tens to hundreds of US dollars a patient-year generically, and cheaper in some markets. Contraindications: oestrogen-sensitive cancer, active venous thromboembolism, active liver disease, unexplained vaginal bleeding, recent stroke or myocardial infarction.

Vaginal, local oestrogen for genitourinary syndrome is highly effective with minimal systemic absorption, and safe for long-term use including, with specialist input, in many breast cancer survivors. It treats dryness, dyspareunia, urgency and recurrent urinary tract infection. Off-patent; tens to hundreds of US dollars a year. Grossly under-prescribed relative to the 50 to 70 per cent prevalence: the biggest care gap in this entry.

Vaginal moisturisers and lubricants are effective for dryness and dyspareunia, cheap, available without prescription, and first-line for those avoiding hormones; ospemifene and vaginal DHEA, prasterone, are alternatives.

Non-hormonal drugs for vasomotor symptoms, for women who cannot or will not take hormones. SSRIs and SNRIs — paroxetine, venlafaxine, escitalopram — reduce flushes about 40 to 65 per cent against about 30 per cent for placebo†; off-patent; tens of US dollars a year. Note that paroxetine interferes with tamoxifen metabolism, which is relevant in breast cancer. Gabapentin and pregabalin are effective and useful for night sweats; off-patent, cheap. Clonidine is modestly effective, off-patent and very cheap, with side effects limiting use. Oxybutynin is effective in trials, with anticholinergic burden a concern. Fezolinetant and elinzanetant, neurokinin-3 receptor antagonists, are a new non-hormonal class targeting the KNDy pathway directly and reduce flush frequency significantly, with fezolinetant giving about a 60 per cent reduction against about 45 per cent for placebo in the SKYLIGHT trials; on patent at about US$6,000 a year US list†, with liver monitoring required. Effective and very expensive relative to the off-patent alternatives.

CBT and mindfulness are effective for the bother and impact of flushes and for sleep, and are recommended in NICE and international guidance; they do not reduce flush frequency much and substantially reduce distress. No supply chain beyond a trained therapist, and deliverable as self-help or group work.

Bone protection with calcium, vitamin D, and resistance and weight-bearing exercise, with bisphosphonates where indicated; see the osteoporosis entry, and note that no bisphosphonate is on the EML for osteoporosis. Hormone therapy itself prevents fracture. Cardiovascular risk management — blood pressure, lipids, glucose, smoking: the menopause consultation is a valuable opportunity for this, and arguably matters more for lifespan than symptom control.

Testosterone for persistent low sexual desire after other causes are addressed: the evidence supports benefit for sexual function, and there is no licensed female preparation in most countries, so off-label male preparations are used at a fraction of the dose.

Not supported or CONTESTED: compounded bioidentical hormones, which are unregulated, of inconsistent dosing and without safety data, and are distinct from regulated body-identical oestradiol and micronised progesterone, which are evidence-based; black cohosh, red clover, evening primrose and phytoestrogen supplements, with inconsistent trial results and generally no better than placebo; ovarian rejuvenation; and vaginal laser therapy for atrophy, where randomised trials have been negative or no better than sham and regulators have warned about it.

**Simple means.** Layered clothing, a lower room temperature, fans, cool drinks, and avoiding triggers — alcohol, caffeine, spicy food, hot drinks — are simple thermoregulatory measures with modest but real effect and no cost.

CBT, paced breathing and mindfulness have trial-supported reduction in symptom bother and improve sleep. Regular exercise improves sleep, mood, bone and cardiovascular risk, while the effect on flush frequency itself is modest or absent, which should be stated honestly. Weight loss where overweight reduces flush frequency and severity measurably. Smoking cessation.

Vaginal lubricants and moisturisers, including plain, cheap options, give immediate relief of dyspareunia and are available without a prescription. Regular sexual activity or vaginal dilator use maintains vaginal calibre and elasticity in genitourinary syndrome. Pelvic floor muscle training for the urinary symptoms that accompany menopause. Sleep hygiene, and treating sleep apnoea, which increases after menopause. A calcium-rich diet, vitamin D from sunlight where feasible, and resistance and weight-bearing exercise give bone protection at essentially no cost.

Accurate information: much of the distress attached to menopause comes from the post-WHI misinformation about hormone therapy and from the framing of menopause as decline. Correcting that costs nothing.

The honest note: the cheap off-patent hormones — oestradiol, micronised progesterone, vaginal oestrogen — deliver most of the achievable benefit at tens to hundreds of US dollars a year, against thousands of US dollars a year for the newest non-hormonal agents.

**Gaps.** The Women's Health Initiative's interpretation and the timing hypothesis remain contested: whether hormone therapy started early is cardioprotective, neutral, or simply not harmful is not settled, and the definitive trial has not been done. Absolute risk figures for breast cancer differ between the WHI, the Million Women Study and the 2019 *Lancet* collaborative meta-analysis, and the differences between progestogen types are inferred from observational data. Long-term safety of the new neurokinin-3 antagonists is unknown. The reason for cross-cultural differences in symptom reporting is unexplained. Cognitive symptoms are poorly characterised and under-researched. Data on menopause in low- and middle-income countries, including age at menopause and symptom burden, are sparse, despite most postmenopausal women living there. Testosterone use in women lacks licensed preparations and long-term data. Vaginal laser was adopted commercially well ahead of evidence that has since been largely negative. And perimenopause, when symptoms often begin and contraception is still needed, is less studied than postmenopause.

---

## Infertility, female and male

**What it is.** Failure to conceive after a year of regular unprotected intercourse. The cause may lie with either partner or both, and in a substantial minority no cause is found.

**Measured.** About 17.5 per cent of adults, roughly one in six, experience infertility during their lifetime (WHO, 2023 report), with little difference between high- and low-income regions. The WHO infertility fact sheet, printed 28 November 2025, gives a lifetime prevalence of approximately one in every six people of reproductive age worldwide, states that infertility affects millions of people with no exact count given on the page, and gives no period prevalence and no regional figures. It defines infertility as failure to achieve pregnancy after twelve months or more of regular unprotected sexual intercourse, notes that assisted reproductive technology has been available for more than three decades, and records that WHO issued its first global guideline on infertility on 28 November 2025.

Point prevalence of twelve-month infertility is about 12.6 per cent, against a lifetime figure of 17.5 per cent, and period prevalence figures vary with definition†. About 48 to 50 million couples are affected at any time globally, with earlier estimates of about 186 million people†. Both are printed.

Cause distribution, approximate and overlapping. Male factor contributes to about 40 to 50 per cent of cases and is the sole factor in about 20 to 30 per cent†. Ovulatory disorders about 25 per cent, with polycystic ovary syndrome dominant†. Tubal factor about 11 to 20 per cent, higher in sub-Saharan Africa, where pelvic inflammatory disease and unsafe abortion raise

it substantially. Endometriosis about 5 to 15 per cent; uterine and cervical causes about 5 per cent†. Unexplained about 15 to 30 per cent† — a large and uncomfortable category.

It is not a GBD cause with mortality, and GBD 2019 estimated infertility DALYs on the order of about one million, disability only. Geography: sub-Saharan Africa has the highest secondary infertility rates, driven by infection — pelvic inflammatory disease, post-abortal and postpartum sepsis, genital tuberculosis, female genital schistosomiasis — that is, largely preventable causes. Meanwhile high-income countries face age-related infertility from delayed childbearing. The two epidemiologies are quite different and need different responses. Access to treatment is extremely unequal: IVF is available and affordable to a small minority globally, and in many countries is entirely out of pocket.

On sperm counts: meta-regression (Levine 2017, with a 2023 update) reported a decline of about 50 to 62 per cent in mean sperm concentration between 1973 and 2018 worldwide. This is CONTESTED — methodological criticisms concern the selection of studies, changing counting methods and population sampling — and the finding has been replicated with broader data and is taken seriously. The finding is published and replicated; its validity is disputed. Both positions are printed.

**Where it starts.** For women: age is the dominant factor in high-income settings. Fecundability falls from the early thirties and steeply after 35; by 40 to 41, per-cycle chance and IVF live birth rates fall markedly, driven mainly by oocyte aneuploidy, which rises with maternal age and is not correctable. That is the single hardest biological constraint in the field.

Ovulatory disorders: polycystic ovary syndrome, commonest, then hypothalamic amenorrhoea from energy deficit, hyperprolactinaemia, thyroid disease and primary ovarian insufficiency. Tubal damage: pelvic inflammatory disease and chlamydia, where risk rises stepwise with episodes, previous ectopic pregnancy, pelvic surgery, genital tuberculosis, schistosomiasis, endometriosis. Uterine causes: submucosal fibroids, polyps, Asherman syndrome, congenital anomalies, adenomyosis. Endometriosis. Obesity, which reduces fecundability and IVF success dose-dependently, and underweight. Smoking, which reduces fecundability by about 13 to 25 per cent† and advances menopause. Alcohol. Chemotherapy and radiotherapy. Coeliac disease.

For men: varicocele, present in about 15 per cent of men and about 35 to 40 per cent of men with primary infertility†; a history of cryptorchidism; testicular trauma or torsion; mumps orchitis; infection with chlamydia, gonorrhoea or tuberculosis. Obstruction: vasectomy, congenital bilateral absence of the vas from *CFTR* mutations in cystic fibrosis carriers, postinfective epididymal obstruction. Genetic causes: Klinefelter syndrome, 47,XXY, in about 10 to 12 per cent of men with azoospermia; Y chromosome microdeletions in the AZF regions in about 5 to 10 per cent of severe oligospermia or azoospermia†; *CFTR*; Kallmann syndrome.

Heat, occupational, from saunas or from a laptop; smoking; alcohol; anabolic steroids and testosterone use, which is a major and growing iatrogenic and self-inflicted cause, since exogenous testosterone suppresses spermatogenesis; opioids; cannabis; chemotherapy; sulfasalazine; some antifungals. Obesity; diabetes; endocrine disruptors and pesticides, which are CONTESTED, with associations reported and causation not established. Paternal age has a real but much smaller effect than maternal age.

Male infertility has a substantial genetic contribution, with sperm count heritability estimated at about 30 to 40 per cent in some analyses†. For female infertility, heritability operates largely through the conditions: polycystic ovary syndrome at about 70 per cent, endometriosis at about 50 per cent, and age at menopause at about 44 to 65 per cent†.

What is not known is the cause in the 15 to 30 per cent labelled unexplained — a large category that represents genuine ignorance rather than a diagnosis. In male infertility, about 30 to 50 per cent of cases remain idiopathic after full evaluation†. Whether and why sperm counts are declining. The functional significance of most sperm DNA fragmentation and of many genetic variants. Why some women with apparently normal investigations and young oocytes still fail to conceive, including with IVF, since implantation failure is poorly understood. And the endometrial receptivity window and recurrent implantation failure are areas of much commercial activity and little established science.

**Cure status.** This splits by cause, and the honest headline is that treatment often bypasses rather than cures.

CURABLE: ovulatory disorders, where ovulation induction restores fertility and cumulative live birth rates approach normal in polycystic ovary syndrome; hyperprolactinaemia, with dopamine agonists; hypothalamic amenorrhoea, by energy restoration, which is a true cure addressing the cause; thyroid disease; obstructive azoospermia, by surgical reconstruction or sperm retrieval; submucosal fibroids and polyps, by hysteroscopic removal; Asherman syndrome; varicocele repair, which improves parameters and pregnancy rates in selected men; and stopping exogenous testosterone or anabolic steroids, which often restores spermatogenesis over months.

RELIEF ONLY: tubal factor infertility, where IVF bypasses the tubes and the tubes remain damaged; severe male factor, where intracytoplasmic sperm injection bypasses almost every sperm defect, with a single sperm sufficient; and unexplained infertility treated by IVF.

RELIEF ONLY: age-related oocyte aneuploidy, the central unsolved problem, where no treatment restores oocyte quality and donor oocytes are the only effective route; primary ovarian insufficiency; and non-obstructive azoospermia with no retrievable sperm, where donor sperm or adoption are the options.

Unexplained infertility managed expectantly: SELF-LIMITING in the couples who conceive without treatment.

**Prevention.** This is where the greatest unexploited gain lies, especially globally.

Preventing and promptly treating sexually transmitted infections: STRONG — chlamydia and gonorrhoea treatment, partner treatment, condoms. Tubal factor infertility is largely preventable, and in sub-Saharan Africa it is the dominant preventable cause. Immediate empirical treatment of suspected pelvic inflammatory disease roughly triples the chance of preserving fertility compared with a few days' delay.

Safe abortion and safe delivery services: STRONG — post-abortal and puerperal sepsis are major preventable causes of secondary infertility. Smoking cessation: STRONG, affecting both sexes. Weight management: MODERATE, in both partners, improving fecundability and treatment success. Avoiding anabolic steroids and exogenous testosterone: STRONG — an increasingly common, entirely preventable cause. Treating genital tuberculosis and schistosomiasis in endemic areas: MODERATE. Mumps and rubella vaccination: MODERATE, for mumps orchitis. Early orchidopexy for cryptorchidism, and prompt treatment of testicular torsion: STRONG.

Fertility awareness, specifically about the effect of age: MODERATE as information, though the social and economic determinants of delayed childbearing are not individually solvable. Oocyte cryopreservation before about age 35 preserves options and is expensive and not a guarantee. Fertility preservation before gonadotoxic cancer treatment: STRONG — sperm, oocyte, embryo or ovarian tissue cryopreservation, frequently not offered, which is a documented care failure. Reducing occupational heat and toxin exposure: MODERATE. Limiting avoidable pelvic surgery and using minimally invasive techniques: MODERATE.

**Treatment.** A substantial proportion of couples with unexplained infertility conceive spontaneously with expectant management, which is why immediate intervention is not always correct, and why trials must have untreated comparison arms; the proportion is not given here. Investigation first: semen analysis, ovulation confirmation, tubal patency by hysterosalpingography or laparoscopy, ovarian reserve, and a sexual history including coital frequency and timing. Semen analysis is cheap and must come first: it is irrational to investigate a woman extensively before examining the man's contribution, yet this happens routinely.

For women. Ovulation induction with letrozole first-line: live birth 27.5 per cent against 19.1 per cent for clomiphene in polycystic ovary syndrome (Legro, *NEJM* 2014). Letrozole off-patent, tens of US dollars a cycle; clomiphene EML yes, off-patent, a few to tens of US dollars a cycle. Both extremely cheap and highly effective. Metformin as an adjunct in polycystic ovary syndrome; off-patent, a few to tens of US dollars a year, and an EML-listed medicine. Gonadotrophins second line, needing ultrasound monitoring, with risk of multiple pregnancy and ovarian hyperstimulation, at hundreds to thousands of US dollars a cycle. Dopamine agonists, cabergoline, for hyperprolactinaemia restore ovulation in 80 to 90 per cent†; off-patent, cheap. Weight loss and energy restoration.

Surgery: hysteroscopic polypectomy or myomectomy, adhesiolysis, endometriosis excision, tubal surgery with limited success, where IVF is usually preferred, and salpingectomy for hydrosalpinx before IVF, which improves IVF outcomes markedly.

IVF for tubal factor, failed ovulation induction, endometriosis, unexplained infertility and the age factor. The live birth rate per cycle is strongly age-dependent: roughly 35 to 45 per cent under 35, about 25 to 30 per cent at 35 to 37, about 15 to 20 per cent at 38 to 40, about 5 to 10 per cent at 41 to 42, and about 1 to 4 per cent above 42, using the woman's own oocytes. Cost thousands to tens of thousands of US dollars a cycle depending on country. Low-cost IVF protocols — simplified culture systems, mild stimulation, reduced monitoring — have achieved delivery in sub-Saharan Africa and Europe at a small fraction of standard cost, with the Walking Egg project reporting comparable outcomes at a few hundred dollars for laboratory costs. That is the main hope for access.

Donor oocytes are the effective treatment for age-related infertility and premature ovarian insufficiency, with live birth rates reflecting donor age rather than recipient age.

Not supported, and low-value add-ons: most IVF add-ons lack evidence of improved live birth. Preimplantation genetic testing for aneuploidy does not improve cumulative live birth rates in unselected patients (STAR and subsequent trials); endometrial scratching does not work, with a large randomised trial negative; and assisted hatching, immunotherapy, intralipids, time-lapse imaging and endometrial receptivity arrays lack supporting outcome evidence. The HFEA traffic-light system rates most as having no evidence of benefit. A significant consumer-protection problem: CONTESTED and negative.

For men. Treat the reversible causes: stop anabolic steroids and testosterone, treat infection, correct endocrine abnormality, stop gonadotoxic drugs where possible, reduce heat exposure. Varicocele repair improves semen parameters and increases pregnancy rates in men with clinical varicocele and abnormal semen, with odds ratios for pregnancy of about 1.5 to 2.6 in meta-analyses: a one-off low-cost operation. Gonadotrophin therapy for hypogonadotrophic hypogonadism is highly effective and restores spermatogenesis. Intrauterine insemination for mild male factor and unexplained infertility, often with ovarian stimulation, is far cheaper than IVF at hundreds to thousands of US dollars a cycle and is appropriate as a first step in many couples. Intracytoplasmic sperm injection bypasses nearly all sperm defects, a single viable sperm suffices, and it has transformed severe male infertility; it requires IVF infrastructure. Surgical sperm retrieval — PESA, TESA, TESE, micro-TESE — for obstructive and some non-obstructive azoospermia, with micro-TESE retrieving sperm in about 40 to 60 per cent of non-obstructive cases†. Vasectomy reversal is effective and often cheaper than IVF with intracytoplasmic injection and retrieval. Donor sperm where no sperm are retrievable. Antioxidants for male infertility: CONTESTED and WEAK — Cochrane suggests possible benefit, the evidence quality is low, and the large MOXI trial was negative. Widely sold, poorly supported.

For both: expectant management with timed intercourse for a defined period in young couples with unexplained infertility of short duration, since spontaneous conception is common and this avoids cost and risk. Psychological support: infertility carries high rates of depression, anxiety and relationship strain, and in many societies, particularly for women, it brings social exclusion, abandonment and violence. Counselling and peer support are part of care, not an optional extra.

**Simple means.** Correct timing and frequency of intercourse — every one to two days around the fertile window. Many couples presenting with infertility have mistimed or infrequent intercourse, and simple advice resolves it. Free, and the first thing to establish. Fertility awareness methods, using cervical mucus and basic cycle tracking, identify the fertile window without any device, and urinary LH kits are cheap where available.

Smoking cessation in both partners. Weight loss where overweight, and weight gain with reduced exercise where underweight: energy restoration cures functional hypothalamic amenorrhoea, and weight loss restores ovulation in many women with polycystic ovary syndrome. Food and rest as treatment. Reducing alcohol, and stopping cannabis and anabolic steroids. Avoiding testicular heat — loose clothing, no laptop on the lap, avoiding saunas and hot occupational exposure.

Letrozole or clomiphene at a few to tens of US dollars a cycle are cheap manufactured drugs that cure the commonest treatable female cause. Semen analysis needs a microscope and a

trained technician, and is the cheapest and highest-yield investigation, and it prevents needless invasive investigation of the woman. Prompt empirical treatment of pelvic inflammatory disease with a few to tens of US dollars of antibiotics is the single most cost-effective fertility-preserving action available globally. Condoms and partner treatment prevent the infections that cause tubal infertility. Low-cost IVF protocols bring assisted reproduction within reach at a fraction of conventional cost. Declining unproven IVF add-ons saves thousands of dollars with no loss of success. Counselling and peer support.

The honest limit: tubal blockage, azoospermia and age-related oocyte aneuploidy cannot be addressed by simple means. IVF and intracytoplasmic sperm injection require laboratories, and no intervention reverses oocyte ageing.

**Gaps.** Between 15 and 30 per cent of infertility is unexplained, and 30 to 50 per cent of male infertility is idiopathic: large admissions of ignorance. The sperm count decline is reported, replicated and genuinely contested, and its cause, if real, is unknown. Age-related oocyte aneuploidy has no treatment and is the field's central unsolved problem. Most IVF add-ons are marketed far ahead of evidence, and some — preimplantation genetic testing for aneuploidy, endometrial scratching — have been shown not to work after wide adoption, a continuing consumer-protection failure. Endometrial receptivity and recurrent implantation failure are poorly understood. The long-term health of children conceived by intracytoplasmic sperm injection, and the transmission of male infertility, need longer follow-up. Access data and outcome registries are absent for most of the world, and the WHO one-in-six figure rests on heterogeneous surveys with varying definitions; the WHO fact sheet itself gives no exact count, no period prevalence and no regional figures. Male infertility is under-researched relative to its 40 to 50 per cent contribution, and men are often not investigated at all. Fertility preservation before cancer treatment is inconsistently offered. The social consequences of infertility, particularly for women in low-income settings, are documented qualitatively and barely quantified.

# What no longer holds

Two things recur across these three chapters often enough to be set down together, because each of them appears in four or five entries and neither is a finding about one disease.

## Structural findings on imaging are largely age-normal

The same result has been found at four sites, by different investigators, with the same shape: abnormality is common in people without symptoms, prevalence rises with age, and the presence of the finding does not establish it as the cause of the pain.

**The spine.** In asymptomatic adults, disc degeneration is present in about 37 per cent at age 20 and about 96 per cent at 80; disc bulges in about 30 per cent at 20 and about 84 per cent at 80; disc protrusions in about 29 per cent at 20 and about 43 per cent at 80 (Brinjikji, *AJNR* 2015, systematic review of imaging in asymptomatic populations).

**The cervical spine.** Cervical disc degeneration is present in the majority of asymptomatic adults over 40, approaching 90 per cent and above in the elderly†.

**The rotator cuff.** Full-thickness tear prevalence in population imaging runs at roughly 10 per cent under 50, 20 to 25 per cent over 60, 30 to 50 per cent over 70 and over 50 to 60 per cent over 80 — and about a third to two-thirds of these tears are painless (Yamamoto, Minagawa).

**The knee.** Radiographic knee osteoarthritis affects over 30 per cent of those over 60, while symptomatic disease is less common, and radiographic and symptomatic disease correlate only moderately.

**Tendons.** Asymptomatic tendons frequently show marked abnormality on ultrasound and MRI, and pathology on imaging correlates poorly with symptoms.

The consequence is the same in each case. Imaging early, in the absence of red flags, does not improve outcomes; it drives surgery, and it labels an age-normal finding as a disease. That is why routine imaging is recommended against for low back pain, for neck pain, and before a trial of conservative management in shoulder disease — and why those recommendations are among the most widely violated in medicine.

Read in the net: what the scan shows is the depth at which the strand has been read, not the depth at which the pain is generated. A finding that is present in nearly everyone of a given age is a property of the age, not of the complaint. This is a reading, not a mechanism.

## Widely used treatments that failed good trials

Ten named trials in these three chapters tested a standard treatment against placebo, sham or an active comparator and found no benefit, or found harm. Several of the treatments continue in widespread use.

| Trial | Treatment tested | Result |
|---|---|---|
| **FIDELITY** (Sihvonen, *NEJM* 2013) | Arthroscopic partial meniscectomy for degenerative meniscal tear | No benefit over sham surgery |
| **CSAW** (Beard, *Lancet* 2018, 313 patients) | Arthroscopic subacromial decompression | No better than arthroscopy alone, placebo surgery; the difference against no treatment was not clinically important |

| Trial | Treatment tested | Result |
|---|---|---|
| **FIMPACT** (Paavola, *BMJ* 2018, 210 patients) | Subacromial decompression | No better than sham diagnostic arthroscopy at 2 years, and neither beat exercise therapy |
| **HALT-IT** (*Lancet* 2020, 12,009 patients) | Tranexamic acid for gastrointestinal bleeding | No reduction in death; increased venous thromboembolism, 0.8 vs 0.4 per cent, and seizures |
| **PRESERVE** (*NEJM* 2018, 5,177 patients) | N-acetylcysteine, and sodium bicarbonate, for contrast-associated kidney injury | No benefit over saline |
| **GAIT** (*NEJM* 2006, 1,583 patients) | Glucosamine and chondroitin for knee osteoarthritis | Neither, alone or combined, superior to placebo in the overall cohort |
| **STEP** (*NEJM* 2006) | Saw palmetto for benign prostatic hyperplasia | No benefit over placebo, even at high doses |
| **SUSPEND** (*Lancet* 2015, 1,167 patients) | Tamsulosin, and nifedipine, for spontaneous passage of ureteric stones | No benefit |
| **RESTORE** (*JAMA* 2021, 288 patients) | Platelet-rich plasma for knee osteoarthritis | No better than saline for knee pain or cartilage structure at 12 months |
| **Coombes** (*JAMA* 2013, 165 patients) | Corticosteroid injection for lateral elbow tendinopathy | Better at 4 weeks; significantly *worse* complete recovery at 1 year, 83 vs 96 per cent, with higher recurrence |

Four more belong beside them, from the same chapters. **PACE** (*Lancet* 2014, 1,643 patients) found paracetamol identical to placebo for acute low back pain, with a median seventeen days to recovery in both arms. **SPACE** (*JAMA* 2018, 240 patients) and **OPAL** (*Lancet* 2023, 347 patients) found opioids no better than non-opioid analgesics and no better than placebo respectively, with worse pain at one year in both. And **Kearney** (*JAMA* 2021) found platelet-rich plasma no better than sham for Achilles tendinopathy. A further randomised trial, **RESTORE** in low back pain (*Lancet* 2023, 492 patients), is positive rather than negative, and shares its name with the platelet-rich plasma trial above; it found cognitive functional therapy gave clinically meaningful improvement sustained at 52 weeks.

Two patterns run through the negative list. First, the cheap thing often won: exercise beat decompression in FIMPACT, physical therapy was non-inferior to meniscectomy in METEOR, and education plus exercise beat corticosteroid injection in LEAP. Second, several of the failed treatments are still performed in volume. Arthroscopic meniscectomy and subacromial decompression continue at scale after sham-controlled negative trials; platelet-rich plasma is heavily marketed after adequately powered negative trials at three sites; glucosamine and saw palmetto are sold over the counter worldwide. Those are gaps between practice and evidence, not gaps in evidence.

One negative finding in this chapter runs the other way, and belongs here for completeness. Diverticulitis was treated with antibiotics for seventy years. DIABOLO and AVOD together tested that, found no demonstrated benefit on recovery, complications, recurrence or surgery in immunocompetent patients with CT-confirmed uncomplicated disease, and found hospital stay shorter without them. The guidelines changed. The treatment was not just ineffective in the trials; its failure put the underlying infective model of the disease in doubt, and that question is still open.

---

## Appendix to this chapter: where the checked figures came from

The front matter explains how figures are marked in this book. This note records which sources the checked figures in this chapter were read from.

No figure in this chapter is an unsourced estimate. The order-of-magnitude price estimates in the underlying material were either replaced by a sourced figure, kept with their market range stated, or written out in words.

The figures read off their sources in this chapter rest on: the GBD 2021 low back pain condition paper, read for the full set of low back pain figures with their uncertainty intervals; the GBD 2023 capstone Table 1, read for the YLD ranking and counts; the electronic WHO Essen-

tial Medicines List, 24th List (2025), queried medicine by medicine; NICE NG147, read live for the diverticular disease guideline text; the WHO fact sheets on musculoskeletal health, osteoarthritis, low back pain, kidney disease, oral health, infertility, abortion, falls, physical activity and sexually transmitted infections, read 19 October 2026; the named primary papers for the diverticular disease entry — Granlund 2012, Crowe 2011, Peery 2012, Strate 2008, Strate 2011, Daniels 2017; and the UNICEF Supply Catalogue indicative prices, read 19 October 2026 and printed as indicative and dated rather than as prices.

Four WHO pages in this chapter contradict themselves, and both figures are printed in each case: musculoskeletal health, on a headline of 1.71 billion against a component total of about 2.5 billion; osteoarthritis, on the age share, 73 per cent against 70 per cent; low back pain, on the age of greatest prevalence, up to 80 years against 80 to 85 years; and sexually transmitted infections, on syphilis, 8 million in 2022 against 7.1 million in 2020. One published paper in this chapter contradicts itself, and both figures are printed: Crowe 2011, on the fibre hazard ratio, 0.59 (0.46 to 0.78) in the abstract against 0.58 (0.46 to 0.73) in the results.

---

*End of chapter.*

# Chapter 17 — Reproduction, the Perinatal Period, Developmental Anomalies, and Injury

### ICD-11 chapters 18, 19, 20 and 22

---

## Introduction

Four ICD-11 chapters are set together here because they share a population and a logic. Chapter 18 covers pregnancy, childbirth and the weeks after. Chapter 19 covers what happens to a baby in its first month. Chapter 20 covers the things that form wrongly before birth. Chapter 22 covers injury and poisoning, which is what kills the young adults the first three chapters produced. Forty-nine entries follow.

The logic they share is that almost nothing in them is a slow disease. These are conditions with a window. A postpartum haemorrhage is decided in an hour, an obstructed labour in a day, a neural tube in the fourth week after conception, a drowning in four minutes, a crush injury in the second the slab comes off. The clinical question in this chapter is rarely what to give. It is whether anything at all is within reach while the window is open.

Asking that question across all forty-nine entries produces one finding that reorganises the chapter, and arguably the book. **Three measures with large reported effects in these four chapters are not clinical.** They are a pesticide ban, a flour additive and a veterinary vaccination campaign. None is delivered by a clinician to a patient.

**Sri Lanka’s pesticide regulation.** Successive bans from 1984 onward removed named agents from the national market. The suicide rate had risen about eight-fold from 1950 and peaked at 47 per 100,000 in 1995†, with pesticide poisoning accounting for more than two-thirds of suicides at that peak. The overall rate then fell 70 per cent over roughly two decades†, and fell by half again after the 2008 to 2011 bans on dimethoate, fenthion and paraquat†. The reported result is **about 93,000 lives saved over twenty years at a direct government cost of under US$50 per life saved**†. Pesticide use rose over the same period, from 1,571 tons in 1990 to 2,260 tons in 2018†, so the measure removed specific agents rather than reducing agricultural chemical use. The source does not state which study reports the 70 per cent decline, the 93,000 lives or the cost per life saved, and the primary papers could not be fetched.

**Folic acid fortification of flour.** A neural tube closes by the twenty-eighth day after conception, before most pregnancies are recognised, so a supplement a woman takes when she knows she is pregnant is already late. Putting the vitamin in the flour removes the timing problem entirely. The measured result is a **25 to 50 per cent fall in neural tube defect prevalence in every country that has done it**: the United States from 10.8 to 6.9 per 10,000 births, a fall of 36 per cent; Chile from 17.1 to 9.7, 43 per cent; Canada 46 per cent†. The cost is **of the order of one to ten cents per person per year**. The intervention is a decision taken at a mill.

**Mass dog vaccination against rabies.** Rabies is essentially always fatal once symptomatic, and dogs transmit 99 per cent of human cases. Vaccinating **70 per cent of the dog population interrupts transmission**†, at **about a dollar or less per dog**. Human post-exposure prophylaxis, the alternative, has an average cost of US$108 per course in 2018, according to the WHO rabies fact sheet and must be given to every exposed person for as long as the dogs remain unvaccinated. Canine rabies has been removed from Europe, most of the Americas and parts of Asia by vaccination; three countries have been validated as having eliminated dog-mediated human rabies.

None of the three falls inside a health-service budget. A pesticide ban is agriculture and justice, flour fortification is food regulation and industry, dog vaccination is veterinary. This is a recurring reason they are underfunded relative to their measured effect.

Below them come the cheap clinical measures, and several are the best-evidenced interventions in the book. **Kangaroo mother care** reduced 28-day mortality in low birth weight infants from 15.7 to 12.0 per cent, a relative risk of 0.75 (95 per cent CI 0.64 to 0.89), number needed to treat about 27, across 3,211 infants in five countries. It costs a length of cloth. **Magnesium sulfate** reduced eclampsia from 1.9 to 0.8 per cent, a relative reduction of 58 per cent (40 to 71), number needed to treat 91, across 10,141 women in 33 countries; a UNICEF indicative price in October 2026 put the 5 g ampoule at about US$0.33. **Antenatal dexamethasone** costs under a dollar a course, and US$0.24 a tablet at the same indicative prices. **Ponseti casting** corrects about 90 per cent of clubfeet initially at US$22.46 per DALY averted from one source and about US$109 from arithmetic on another source's figures, five-fold apart, and the clubfoot entry prints a relapse rate, using plaster and water. **Tranexamic acid within three hours** of injury reduced all-cause trauma mortality from 16.0 to 14.5 per cent, relative risk 0.91 (0.85 to 0.97), number needed to treat about 67, across 20,211 patients in 40 countries, at about one to two dollars a gram†. And **fifteen minutes of soap and water after an animal bite** substantially reduces rabies risk before any vaccine is involved; there the intervention is knowledge.

Against that list, set the expensive items. **Surfactant** costs hundreds to thousands of US dollars a dose and is the most effective specific treatment for neonatal respiratory distress syndrome. **Brexanolone** launched in the United States at US$34,000 a course and **zuranolone** at US$15,900, for a condition whose highest measured prevalence is in countries where neither is available. **Heat-stable carbetocin** solves the cold chain problem that limits oxytocin, and its access price is not public. These are not bad drugs. They are effective drugs that do not reach the populations carrying the burden, and the pattern is consistent enough across the chapter to be worth stating once: in these four chapters, several of the cheapest interventions are old and off-patent. Listing on the WHO Essential Medicines List is not checked in this chapter, and each such claim is to be read as carrying a dagger.

**On the figures in this chapter.** The dossier these entries were built from carried no per-figure provenance marks. Under the book's convention a figure therefore carries a dagger unless the source and year are named in the text. Figures were read off their source only where they came from a WHO page or a primary report in the retrieval round of October 2026. The effect is that a great deal of this chapter either names a source that was not opened again or carries a dagger. That is the honest state of the material and not a defect in it.

---

## ICD-11 Chapter 18 — Pregnancy, childbirth or the puerperium

---

Thirteen entries. The chapter-level denominators are these. Maternal deaths in 2023: **about 260,000** on the UN interagency estimate, a global maternal mortality ratio of **197 per 100,000 live births**, with low-income countries at 346 and high-income at 10. Sub-Saharan Africa carries about **182,000** of those deaths, roughly 70 per cent of the global total. Five complications account for about **75 per cent** of maternal deaths — severe bleeding,

**Sources disagree on the maternal death count.** The UN Maternal Mortality Estimation Inter-Agency Group gives about 260,000 for 2023. GBD 2023 gives **239,900 (95 per cent uncertainty interval 207,800 to 280,300)** maternal-disorder deaths for the same year, down 39.5 per cent from 396,700 in 2000. The two rest on different models and different cause definitions: GBD’s maternal disorders group counts late and indirect

## Postpartum haemorrhage

**What it is.** Heavy bleeding from the womb after a baby is born. Most often the womb fails to contract down after the placenta separates, so the vessels that supplied the placenta stay open. The standard definition is 500 mL or more of blood lost after vaginal birth, and 1,000 mL or more is severe.

**Measured.** Maternal haemorrhage deaths in 2023: **52,000 (35,800 to 70,000)**, down **61.2 per cent** since 2000. This is the largest single maternal cause in the GBD series and the largest decline in it. WHO names severe bleeding among the five complications accounting for about 75 per cent of maternal deaths, without a per-cause share.

No global incidence estimate for postpartum haemorrhage was found in a WHO or GBD source. The range of 5 to 15 per cent of births† that circulates rests on facility series of varying quality, not on a global estimation exercise, and is not asserted here.

The geography is simple. The deaths are where birth happens without a skilled attendant and without an intact uterotonic in the room. Sub-Saharan Africa carries about 70 per cent of all maternal deaths.

**Where it starts.** Uterine atony — the womb not contracting — is the mechanism in the large majority. The clinical four-cause scheme of tone, tissue, trauma and thrombin is a convention, not a measured partition.

Established risks: prolonged or obstructed labour, multiple pregnancy, high parity, a previous haemorrhage, a large baby, induced or augmented labour, retained placenta. Maternal anaemia does not cause the bleed. It converts a survivable bleed into a fatal one, because there is less reserve.

What is genuinely not known is why one woman's uterus contracts after delivery and another's does not. Most cases occur in women with no identified risk factor. That is why risk-factor screening fails as a triage tool and why prophylaxis is given to everyone. There is no validated predictive test.

**Cure status.** CURABLE. The bleed is an acute event with a defined endpoint: the uterus contracts, the bleeding stops, the woman recovers fully. One injection of a cheap off-patent drug at the moment of birth prevents most of it. A second cheap off-patent drug treats it. Where both fail, mechanical and surgical measures stop it. Nothing persists once the bleeding is stopped and the blood volume restored.

**Prevention.** - **A uterotonic to every woman in the third stage of labour — STRONG.** Oxytocin 10 IU intramuscularly or intravenously is the WHO first choice. This is the intervention behind the measured 61.2 per cent fall in deaths. - **Skilled birth attendance — STRONG.** Someone present who can give the uterotonic, massage the uterus and recognise the bleed. No single trial effect size exists; the evidence is the association across the interagency series and the fact that nothing below can be delivered without an attendant. - **Antenatal correction of anaemia — MODERATE** for death, not for the bleed. It raises the volume a woman can lose before she decompensates. - **Delayed cord clamping — does not prevent it,** and does not increase maternal bleeding either. It is safe alongside active third-stage management and benefits the baby. - **Controlled cord traction — WEAK.** WHO lists it as optional where a skilled attendant is present. The uterotonic carries the effect.

**Treatment. 1. Oxytocin**, 10 IU intramuscularly or intravenously, for prevention and first-line treatment. On the WHO Essential Medicines List under Uterotonics, for postpartum haemorrhage, injection 10 IU/mL, first listed 1977. Off-patent. A UNICEF indicative price in October 2026 works out at **about US$0.24 per ampoule**. The decisive limit is the cold chain: oxytocin degrades at ambient tropical temperatures, so the drug that works is routinely the drug that has already spoiled by the time it reaches the birth.

**2. Heat-stable carbetocin**, the answer to that limitation. The CHAMPION trial randomised **29,645 women** at 23 sites in 10 countries after vaginal birth. For blood loss of 500 mL or more, or use of additional uterotonics: **14.5 per cent carbetocin against 14.4 per cent oxytocin, relative risk 1.01 (0.95 to 1.06)**, meeting the non-inferiority margin of 1.16. For blood loss of 1,000 mL or more: **1.51 against 1.45 per cent, relative risk 1.04 (0.87 to 1.25)**, which did not meet the 1.23 margin; the authors attributed that to low event rates and insufficient power rather than to observed inferiority. Carbetocin 100 µg/mL is EML-listed under Uterotonics. The heat-stable formulation is not off-patent. Ferring holds it and has

committed to an access price in public-sector markets in low- and middle-income countries, so the price is a negotiated arrangement rather than a generic market, and it is not published.

**3. Misoprostol**, 600 µg oral for prevention and 800 µg sublingual for treatment. On the EML under Uterotonics and for medical abortion, oral solid 200 µg. Off-patent, cents a tablet. The decisive property is that it is a tablet: no cold chain, no needle, no skilled injector. It is less effective than intact oxytocin given by someone who can inject. At a home birth with no refrigerator the comparison is against nothing, and there it is the only uterotonic that can be present. It causes more shivering and fever than oxytocin.

**4. Tranexamic acid**, 1 g intravenously, repeated if bleeding continues. Treatment, not prevention. The WOMAN trial enrolled **20,060 women** at 193 hospitals in 23 countries. **Death due to bleeding: 155 of 10,036 (1.5 per cent) against 191 of 9,885 (1.9 per cent), relative risk 0.81 (0.65 to 1.00, p = 0.045)**, an absolute reduction of 0.4 percentage points and a number needed to treat of **267**; adjusted for baseline risk, 0.78 (0.62 to 0.98). The fragility index on that outcome is **0**: one event flips the significance, and that must be said plainly. Timing is the finding that matters: **within three hours, 1.2 against 1.7 per cent, relative risk 0.69 (0.52 to 0.91); after three hours, 2.6 against 2.5 per cent, relative risk 1.07 (0.76 to 1.51) — no benefit**. The composite primary endpoint of death from any cause or hysterectomy was null at 5.3 against 5.5 per cent, relative risk 0.97 (0.87 to 1.09). No excess of thrombotic events. On the EML, section 10.2 and under medicines administered to the mother, for haemorrhage and postpartum haemorrhage, injection 100 mg/mL. Off-patent, about one to two dollars a gram.

**5. Mechanical and surgical measures, escalating.** Uterine massage and bimanual compression, intrauterine balloon tamponade, uterine artery ligation, a B-Lynch or other compression suture, and hysterectomy as the last resort.

**Simple means.** This condition is unusually rich in them. - **Uterine massage.** Rubbing up the fundus through the abdominal wall makes the uterus contract. Two hands and nothing else, and it is a standard part of active third-stage management. - **Bimanual uterine compression.** One hand in the vagina, one on the abdomen, compressing the uterus between them. No equipment. - **Aortic compression.** A fist above the umbilicus, as a holding measure during transfer. - **The non-pneumatic anti-shock garment.** A neoprene and velcro compression suit applied from the ankles up, which shunts blood from the legs and pelvis to the vital organs and buys hours during transfer. Reusable for dozens of applications on manufacturer figures, with no power and no cold chain, and it is taught by demonstration. The evidence is positive and not definitive: observational and pre-post studies report reduced mortality and measured blood loss, while the cluster-randomised mortality evidence is weaker. Unit cost in the published literature is in the low hundreds of US dollars, amortised over many uses. - **Condom-catheter balloon tamponade.** A condom tied over a urinary catheter and inflated with saline inside the uterus. Case series from Bangladesh and elsewhere report it effective, at the cost of a condom, a catheter and a bag of saline. The evidence is case series, and one cluster-randomised trial in Africa raised concern about harm where it displaces definitive care. It is a bridge to surgery. - **Misoprostol tablets**, the only uterotonic that works as a simple means. - **Early breastfeeding and skin-to-skin contact**, which release endogenous oxytocin. No trial has isolated an effect on haemorrhage, so this is listed as practice rather than as a measured intervention.

The minimum chain: nothing at all for massage, compression and positioning; a condom and a catheter for tamponade; one tablet for misoprostol.

**Gaps.** No global incidence estimate exists from WHO or GBD. The interagency and GBD maternal death totals disagree, at 260,000 against 239,900 for 2023, and so does their cause attribution. The WOMAN trial's fragility index is 0 on its one significant outcome and its composite primary endpoint was null; the honest statement is that early tranexamic acid reduces death from bleeding, the effect is real and modest at a number needed to treat of 267, and the headline significance is fragile. Carbetocin's access price is not public, so whether it displaces oxytocin at scale is a procurement question with no published data. The anti-shock garment's effect size is unsettled between study designs. Measured blood loss is itself unreliable: visual estimation underestimates, the 500 mL threshold is a convention, and trials using calibrated drapes and trials using estimation are not measuring the same thing.

## Pre-eclampsia and eclampsia

**What it is.** A disorder of pregnancy in which blood pressure rises and organs begin to fail, usually after 20 weeks. Pre-eclampsia is the state. Eclampsia is when it progresses to seizures. Delivery of the baby and the placenta ends it.

**Measured.** Maternal hypertensive disorder deaths in 2023: **48,200 (37,300 to 59,900)**, down **30.0 per cent** since 2000. Second-largest maternal cause in the GBD series, and a notably slower decline than haemorrhage at 61.2 per cent or sepsis at 38.7 per cent†. The 2015 round of the same series gave 46,900 deaths.

Pre-eclampsia affects approximately **2 to 8 per cent of pregnancies worldwide**†. That range is wide enough to be a statement about measurement rather than about disease.

**Eclampsia incidence is 0.56 per 1,000 pregnant women in developed countries, and roughly 10 to 30 times that in low-income countries**†. This gradient is the central measured fact about the condition. The disease occurs everywhere. The seizure and the death occur where magnesium sulfate and timely delivery are not.

Regionally, hypertensive disorders account for nearly a tenth of maternal deaths in Africa and Asia and about a quarter in Latin America. In high-income settings the incidence is rising, attributed to more chronic hypertension, diabetes and obesity.

**Where it starts.** Chronic pre-existing hypertension carries **7 to 8 times** the risk†. A first-degree relative with pre-eclampsia doubles it. A mother herself born small for gestational age has 50 per cent higher risk, and if both parents were born small, three times the risk. Obesity, diabetes, maternal age over 35, first pregnancy, twin pregnancy, kidney disease and antiphospholipid antibody syndrome are all established and none is quantified in the sources reached.

A history of pre-eclampsia **doubles later cardiovascular mortality risk**. That is a consequence, not a cause: the condition marks a vascular phenotype that outlasts the pregnancy.

The cause is not known. The leading account is abnormal placentation with incomplete remodelling of the spiral arteries, followed by release of anti-angiogenic factors into the maternal circulation. That describes a sequence. It does not identify a first cause, and it does not explain why the same placental findings appear without disease or why some cases present after delivery. There is no accepted aetiology, no preventive treatment that works for most women, and no treatment that resolves the condition short of ending the pregnancy. The screening algorithms predict. They do not explain.

**Cure status.** CURABLE — by delivery, and the cure is the end of the pregnancy. Delivery of baby and placenta is definitive and the disease resolves over days to weeks. Nothing else removes it. Antihypertensives control the pressure; magnesium sulfate prevents the seizure; neither touches the disorder. The qualification belongs in the label's reading rather than in the label: the only curative intervention is iatrogenic delivery, which before term transfers the whole burden of prematurity to the baby. That trade-off is the whole of clinical management.

**Prevention.** - **Low-dose aspirin in high-risk women — STRONG.** The ASPRE trial gave aspirin 150 mg daily at bedtime from before 16 weeks to screened at-risk women and **reduced preterm pre-eclampsia before 37 weeks by 62 per cent and early pre-eclampsia before 32 weeks by 80 per cent, with no change in term pre-eclampsia**. Note the shape of that: it prevents the early, severe, dangerous form and does nothing for the mild term form. Combined screening on maternal history, mean arterial pressure, uterine artery Doppler and placental growth factor identified over 75 per cent of the women who went on to develop the condition. Across unselected populations the figure is a much smaller 1 to 5 per cent absolute reduction†. Both are printed; they are not in conflict, they are different populations. Aspirin is EML-listed, off-patent and costs cents a course. - **Calcium supplementation — CONTESTED.** WHO recommended at least 1 g daily in 2011, particularly where dietary calcium is low. Updated evidence indicates calcium may have little or no effect on preventing pre-eclampsia or its complications, with the observation that most trials began supplementation in the second trimester and may have started too late. Both positions printed. - **Antioxidant vitamins C, D and E — no effect, and not recommended**. A settled

negative. - **Salt restriction, bed rest, exercise and diuretics — no proven preventive benefit**. - **Antenatal care itself — STRONG**, for the outcome rather than the incidence. A blood pressure and a urine protein measured at a visit is how the condition is found before it seizes. The 10-to-30-fold eclampsia gradient is the measured consequence of its absence.

**Treatment. 1. Magnesium sulfate**, the anticonvulsant, and the clearest large-effect cheap-drug result in obstetrics. The Magpie trial randomised **10,141 women** — 5,071 to magnesium and 5,070 to placebo — at 175 hospitals in 33 countries, with 99.7 per cent analysed†. **Eclampsia: 0.8 per cent on magnesium against 1.9 per cent on placebo, a relative risk reduction of 58 per cent (40 to 71), number needed to treat 91 (63 to 143)**†. Maternal death was 0.2 against 0.4 per cent, a relative reduction of 45 per cent (−14 to 74) and **not statistically significant**†. Infant death among the 8,775 women randomised before delivery was 12.7 against 12.4 per cent, not significant†. Serious maternal morbidity was 3.9 against 3.6 per cent, not significant†. The published assessment of the trial doses was that their safety is beyond dispute.

Magnesium sulfate is also superior to diazepam and to phenytoin for treating established eclampsia, and WHO recommends it both to prevent and to treat. It is EML-listed under anti-seizure medicines, with the restrictive note that it is for eclampsia and severe pre-eclampsia and not for other convulsant disorders; the listed forms are 500 mg/mL in a 2 mL ampoule intravenously and 500 mg/mL in a 10 mL ampoule intramuscularly. It is an inorganic salt and there is no patent to hold. A UNICEF indicative price in October 2026 works out at **about US$0.33 per 5 g ampoule**, so a full loading and maintenance course costs a few dollars.

This is the per-euro benchmark for the chapter: a 58 per cent reduction in eclampsia at a number needed to treat of 91, from a drug costing a few dollars, needing no cold chain, and administered intramuscularly where no intravenous line is possible.

**2. Delivery**, which is definitive. Timing follows severity and gestational age: expectant management, induction, or caesarean. Where preterm delivery is chosen, antenatal corticosteroids for fetal lung maturity and magnesium sulfate for fetal neuroprotection both apply.

**3. Antihypertensives** for severe hypertension, at a systolic of 160 mmHg or more or a diastolic of 110 or more. **Labetalol, hydralazine, nifedipine and methyldopa** are the standard agents and **no evidence favours one over another**; choice follows experience, cost and availability. A proposed target is 140 to 160 systolic and 90 to 105 diastolic. Hydralazine, methyldopa and nifedipine are EML-listed, all off-patent, cents to a few dollars a course. **ACE inhibitors and angiotensin receptor blockers are contraindicated in pregnancy.**

**Simple means.** - **A blood pressure cuff and a urine protein dipstick.** This is the detection technology for the entire condition. An aneroid or automated cuff needs manufacture but no supply chain beyond itself, and dipsticks are cheap consumables. Boiling urine to look for coagulated protein is the no-consumable fallback described in the older field literature. - **Left lateral positioning, airway protection and padding during a seizure.** Standard first aid, no equipment, and it prevents aspiration and injury. - **Intramuscular magnesium sulfate.** The regimen is designed to work without an infusion pump or reliable intravenous access: a loading dose into each buttock plus intravenous where possible, then intramuscular maintenance. A syringe, a needle and ampoules of a salt. This is why magnesium reaches places where almost nothing else does. - **Transfer with magnesium already given.** The point from Magpie is that the drug works where it is given, not where the woman arrives.

The minimum chain: a cuff, a syringe and ampoules of a salt. Nothing refrigerated, nothing powered.

**Gaps.** The aetiology is unknown, and that is an absent evidence base rather than a thin one. Magpie did not demonstrate a mortality benefit, at a relative reduction of 45 per cent with an interval from −14 to 74; sources reporting magnesium sulfate as proven to reduce maternal death overstate the trial. WHO 2011 and the updated reviews disagree on calcium, and both are printed. ASPRE's 62 and 80 per cent figures apply to a screened high-risk population, and the screening algorithm they depend on — placental growth factor and uterine Doppler — is unavailable in most settings carrying the mortality, so the intervention with the large effect and the population with the deaths are not currently the same population. Eclampsia incidence in low-income countries is given as a multiple, not as a rate, and no direct rate

was located. Why the hypertensive-disorder death decline lags haemorrhage by half is not explained in any source reached.

---

## Obstructed labour

**What it is.** The baby cannot pass through the pelvis, however hard the womb contracts. The labour stops progressing and stays stopped. Without intervention the uterus may rupture, the baby dies, and the pressure of the head against the pelvis destroys the tissue between bladder, vagina and rectum.

**Measured.** Obstructed labour and uterine rupture deaths in 2023: **12,200 (7,500 to 18,400)**, down 44.8 per cent since 2000†. About **6.5 million** cases of obstructed labour or uterine rupture were counted for 2015†.

**The death figures disagree sharply across rounds of the same series, and not monotonically.** GBD 2015 gives about **23,000** maternal deaths; GBD 2013 gives about **19,000** for 2013; GBD 2023 gives **12,200** for 2023. The cause definition has moved between rounds and ill-defined codes have been redistributed differently. All three are printed. None is a count, and the series cannot be read as a trend.

Obstructed labour accounts for about **8 per cent** of pregnancy-related maternal deaths† and affects roughly **2 to 5 per cent of deliveries** in Africa and Asia†. It is the leading cause of uterine rupture worldwide and one of the leading causes of stillbirth. Where caesarean section is available within hours it is an operative indication rather than a cause of death.

**Where it starts.** Fetal factors: a large baby, abnormal position or presentation, shoulder dystocia, and in humans broad fetal shoulders.

Maternal pelvic factors: a small pelvis shaped by malnutrition, vitamin D deficiency and calcium deficiency in the mother's own childhood. The pelvis that obstructs the labour was formed by the nutrition of the girl twenty years earlier. Young maternal age, where pelvic growth may be incomplete, carries the same mechanism, and child marriage and adolescent pregnancy are the upstream exposure. Birth canal obstruction can follow female genital mutilation or tumours. No effect sizes for any of these were located.

There is no validated way to predict cephalopelvic disproportion before labour. Pelvimetry, whether radiographic or clinical, has repeatedly failed as a screening test and is not recommended. Maternal height is a weak proxy. The diagnosis is made in labour, by the labour failing. That is why the intervention has to be available at the place of birth rather than arranged in advance.

**Cure status.** CURABLE. Caesarean section resolves it definitively and both mother and baby survive with normal subsequent life. Vacuum extraction resolves a subset. Symphysiotomy resolves it where no operating theatre exists. There is no chronic phase once the obstruction is relieved. Its sequelae are separate conditions with their own status: prolonged obstruction before relief causes obstetric fistula, and may cause stillbirth or neonatal encephalopathy, and relieving the obstruction does not cure those.

**Prevention.** - **Skilled birth attendance with access to operative delivery — STRONG**, and it is the only thing that is. A facility that can perform caesarean section is a facility where obstructed labour does not kill. - **Improving female nutrition before and during pregnancy — MODERATE**, with an effect a generation long. No effect size located. - **Preventing adolescent pregnancy and child marriage — MODERATE.** Mechanistically direct through incomplete pelvic growth, and unquantified. - **Contraception and family planning — MODERATE.** Fewer pregnancies, fewer exposures. - **Partograph use — CONTESTED.** The partograph is standard WHO practice for tracking labour progress and may identify obstruction, but **no outcome data showing that partograph use reduces mortality or complications** were found in the sources reached, and WHO's more recent labour-care guidance has moved away from the classical fixed progress lines. It is unproven for the outcome. - **Ending female genital mutilation — STRONG** for the canal-obstruction subset, on mechanism; no effect size located.

**Treatment.** No drug treats obstructed labour. Augmenting contractions with oxytocin against a true obstruction causes uterine rupture, so this is the one place in obstetrics where the cheap effective uterotonic of the haemorrhage entry is contraindicated.

**1. Caesarean section.** Often the only option that saves both mother and infant. The inputs are an operating theatre, an anaesthesia provider, a surgeon or trained non-physician clinician, sterile instruments and blood. It is one of the three **Bellwether procedures** of the Lancet Commission on Global Surgery.

**2. Vacuum extraction**, where the obstruction is relative and the cervix fully dilated. A hand pump and a cup, reusable, no power.

**3. Symphysiotomy** — surgical division of the pubic symphysis to enlarge the pelvis. It is faster than caesarean, needs no anaesthesia beyond local, and leaves no uterine scar, which matters where a scarred uterus in a place without surgery jeopardises the next pregnancy. It has been largely abandoned in high-income practice and is historically associated with pain and gait disturbance. The published position is that it retains a place where caesarean is unavailable.

**4. Supportive care:** hydration, and antibiotics if membranes have been ruptured for more than 18 hours†.

**5. Maternal position change**, which can help labour progress before surgery is considered.

**Simple means.** - **Changing the mother's position** — upright, all-fours, lateral, the Gaskin manoeuvre. Free, immediate, and it resolves a proportion of malpositions. - **The shoulder dystocia manoeuvres** — McRoberts position, suprapubic pressure, delivery of the posterior arm, all-fours. Hands only, and they resolve the majority at the bedside. - **Hydration and oral fluids** during prolonged labour. - **Recognising it and moving.** The measured determinant of survival is the interval between obstruction and operative delivery, so a transport arrangement is a simple means. - **Symphysiotomy** is the simple-means operative answer: a scalpel, local anaesthetic and someone trained. No theatre, no general anaesthesia, no blood bank. - **A partograph** is a sheet of paper, with the outcome evidence noted above.

What cannot be improvised: for the irreducible cases, a caesarean section, which requires surgery, anaesthesia and blood. There is no simple means that substitutes. This is the condition where the Lancet Commission's finding bites hardest.

**Gaps.** The death figures disagree across GBD rounds, at about 23,000 for 2015, about 19,000 for 2013 and 12,200 for 2023, in a way that is not monotonic; the cause definition and the redistribution of ill-defined codes both moved. The partograph has no demonstrated mortality effect despite being near-universal practice, and that is a live gap rather than a settled negative. No effect sizes were located for any risk factor or any preventive measure. Symphysiotomy's evidence base is old and contested, with thin long-term maternal outcome data, and sources recommending it for low-resource settings and sources treating it as obsolete are both current. Cephalopelvic disproportion has no antenatal predictor, so no screening intervention is available even in principle.

---

## Maternal sepsis

**What it is.** Infection of the womb and surrounding tissues during pregnancy, labour or after birth, spreading into the bloodstream. It usually enters during or after delivery. It begins with fever and abdominal pain and progresses to organ failure.

**Measured.** Maternal sepsis and other pregnancy-related infections, deaths in 2023: **26,700 (19,000 to 37,100)**, down **38.7 per cent** since 2000. The decline is slower than haemorrhage and faster than hypertensive disorders. WHO names infection among the five complications accounting for about 75 per cent of maternal deaths, describing infections as usually occurring after childbirth, without a per-cause share.

No global incidence estimate was located. The WHO Global Maternal Sepsis Study of 2017 was a facility-based prevalence study rather than a global incidence estimate. The deaths are concentrated where delivery is unclean, where caesarean section is performed without sterile technique or prophylactic antibiotics, and where postpartum follow-up does not exist.

**Where it starts.** Caesarean section is the dominant procedural risk factor for postpartum endometritis. Prolonged rupture of membranes, prolonged labour, multiple vaginal examinations in labour, retained placental tissue and obstructed labour all raise risk. Unclean delivery — unwashed hands, non-sterile instruments, contaminated surfaces — is the classical

route, and unsafe abortion is a distinct one. Anaemia and undernutrition act as susceptibility factors. GBD counts maternal deaths aggravated by HIV separately at **1,700 (1,000 to 2,300)** in 2023, down 38.9 per cent. No effect sizes for these were located.

What is not known is which women with the same exposures progress to sepsis. There is no useful predictive test. The organisms are heterogeneous — group A and B streptococci, *E. coli*, anaerobes, *Staphylococcus aureus*, and in some settings *Clostridium* — so no pathogen-directed strategy covers the condition. Early recognition criteria are also poorly calibrated, because the physiological changes of pregnancy and the puerperium move pulse, temperature and white-cell count, and the standard sepsis scores perform worse here than in the general population.

**Cure status.** CURABLE. Antibiotics plus removal of the source — retained tissue, or drainage of an abscess — resolves it, and recovery is complete. The determinants of survival are the interval to antibiotics and whether a source needs surgical removal. Nothing persists after cure, except fertility consequences where the uterus or tubes are damaged or removed.

**Prevention.** - **Clean delivery practice — STRONG.** Handwashing, sterile or clean instruments, a clean surface, clean cord cutting. This is the oldest measured result in the field: Semmelweis's handwashing intervention at the Vienna lying-in hospital in 1847 took maternal mortality on the affected ward from the high teens in percentage terms to low single figures within a year. The modern effect size for the bundle in current practice was not retrievable. - **Prophylactic antibiotics before caesarean section — STRONG.** A single pre-incision dose substantially reduces postpartum endometritis and wound infection, on Cochrane-level evidence. The pooled relative risk was not retrievable here. The drugs are cheap, off-patent and EML-listed. - **Skilled birth attendance — STRONG**, as the delivery vehicle for everything above. - **Avoiding unnecessary vaginal examinations and unnecessary caesarean — MODERATE.** - **Active management of the third stage, and ensuring the placenta is complete — MODERATE**, retained tissue being a nidus. - **Safe abortion access — STRONG** for the abortion-related subset. - **A postpartum follow-up contact in the first week — MODERATE.** Most postpartum sepsis presents after discharge.

**Treatment. 1. Broad-spectrum antibiotics, early.** WHO's standard combination for severe puerperal sepsis is **ampicillin plus gentamicin plus metronidazole**, started on clinical suspicion without waiting for cultures. All three are EML-listed and off-patent, and a full parenteral course costs a few US dollars. No randomised comparison against no antibiotic exists or could ethically exist; the evidence is the historical case-fatality change and the dose-response with time to antibiotic observed in sepsis generally.

**2. Source control.** Manual or surgical removal of retained products, drainage of an abscess, and hysterectomy where the uterus itself is the source and cannot be salvaged.

**3. Supportive care.** Intravenous fluids, oxygen, and vasopressors where available. In settings without critical care, fluids and antibiotics are the whole of what can be given.

**4. Tetanus prophylaxis** where the entry route suggests it.

**Simple means.** - **Handwashing with soap and clean water.** The single highest-yield act in the history of this condition, and it requires soap. - **A clean delivery kit.** Soap, a clean plastic sheet, clean string, a sterile razor blade, clean gloves. Packaged and distributed at near-zero unit cost, and designed precisely to be a simple means. - **Clean cord cutting and cord care**, which prevents neonatal tetanus and neonatal sepsis by the same act. - **Boiling instruments.** Sterilisation without an autoclave. - **Oral antibiotics where parenteral is impossible**, as a holding measure during transfer. Less effective, and better than the interval. - **Recognition teaching for the family.** Fever, foul discharge or abdominal pain in the first week after birth means go now. It costs nothing and addresses the dominant delay. - **Oral fluids** during transfer.

The minimum chain: soap for prevention, manufactured antibiotics for treatment. There is no simple-means substitute for the antibiotic. Prevention is nearly free and cure is not improvisable.

**Gaps.** No global incidence estimate was located: the deaths are estimated and the incidence is not published. No effect sizes were retrievable for prophylactic antibiotics at caesarean or for the clean-delivery bundle, both of which are standard of care on evidence that exists

and was not reachable here. Sepsis definitions changed during the period the trend covers — Sepsis-3 in 2016 and WHO's maternal sepsis definition in 2017 — so part of the measured 38.7 per cent fall may be definitional. The organism mix is not globally characterised, because blood-culture capacity is absent in most settings carrying the mortality, so the pathogen distribution where women die is substantially unknown. Antimicrobial resistance in maternal sepsis is poorly quantified and is the clearest threat to the CURABLE classification; no figures were located.

---

## Unsafe abortion complications

**What it is.** Injury, bleeding and infection following an abortion performed by someone without the skills, or in an environment not meeting minimal medical standards, or both. The complications, not the procedure, are the condition coded here.

**Measured.** Maternal abortive outcome deaths in 2023: **19,600 (12,200 to 30,800)**, down 54.8 per cent since 2000†. That line also contains spontaneous abortion, so it cannot be read as deaths from unsafe abortion.

Induced abortions worldwide: **about 73 million a year**, which is 29 per cent of all pregnancies and 61 per cent of unintended pregnancies. **About 45 per cent of induced abortions** fell into the unsafe category on global estimates for 2010 to 2014, and one third of unsafe abortions were performed under the least safe conditions. A review covering 2009 to 2020 linked **8 per cent of maternal deaths** to abortion, and WHO notes these are often misclassified and underreported.

**The central measured fact is a two-orders-of-magnitude gradient. Death rates are below 1 per 100,000 for safe abortion and above 200 per 100,000 abortions where unsafe abortion is common**.

In 2012, **7 million women a year** in developing countries were treated in hospitals for complications of unsafe abortion. Cost estimates from 2006 put post-abortion treatment in developing countries at **US$553 million a year**, with households losing **US$922 million** in income to related long-term disability.

Over half of unsafe abortions occur in Asia, mostly in south and central Asia. In Latin America and Africa roughly **three in four** abortions were unsafe, and in Africa nearly half of all abortions occurred under the least safe conditions.

**Where it starts.** Legal restriction is the dominant determinant, and the finding is specific. WHO states that restricting access **does not reduce the number of abortions**, and that the share which are unsafe is significantly higher in countries with highly restrictive laws. The law determines the safety, not the frequency.

Beyond that: unmet need for contraception, absent trained providers, absent misoprostol and mifepristone, cost, stigma, distance, and conscientious objection without referral. Adolescence and poverty act as access barriers. No effect sizes beyond the legal association were located.

What is genuinely not known is the true numbers. WHO states plainly that abortion-related maternal deaths are often misclassified and underreported. Where the act is criminal it is not recorded, so incidence, complication rate and death rate in exactly the settings that matter most are the least reliably measured quantities in maternal health. The 45 per cent unsafe figure derives from a 2010 to 2014 estimation exercise and had not been updated on the fact sheet current in December 2025.

**Cure status.** CURABLE. The complications — incomplete abortion, haemorrhage, sepsis, uterine or bowel perforation — are each curable with standard treatment: uterine evacuation, antibiotics, transfusion, and surgery for perforation. Recovery is complete in the large majority treated in time. Infertility and chronic pelvic infection follow a minority. The classification is unambiguous. The problem is entirely one of reaching treatment, and of whether reaching it is legally safe for the woman.

**Prevention.** - **Access to safe abortion — STRONG.** The measured effect is the gradient above: under 1 per 100,000 against over 200 per 100,000. This is the largest single preventive effect size in this chapter for any condition, and it is achieved by changing who performs

the procedure and where, not by any new technology. - **Contraception — STRONG.** It prevents the unintended pregnancy upstream. No single effect size located; the arithmetic link is that 61 per cent of unintended pregnancies end in abortion. - **Misoprostol and mifepristone availability — STRONG.** WHO's consolidated guideline holds that first-trimester medical abortion can be self-managed with accurate information and quality medicines, with a trained health worker available if needed. That moves the procedure out of the unsafe category without requiring a facility. - **Post-abortion care provided without legal jeopardy — STRONG** for death among those who already have the complication. - **Comprehensive sexuality education — MODERATE.** - **Legal restriction as prevention — contradicted.** WHO's position is explicit.

**Treatment. 1. Uterine evacuation for incomplete abortion. Misoprostol** 600 µg oral, with regimens varying — tablets, no cold chain, EML-listed for spontaneous abortion incomplete without complication, off-patent, cents a tablet. **Manual vacuum aspiration**, a hand-held syringe and cannula needing no electricity, reusable, and preferred over sharp curettage, which carries higher perforation and intrauterine adhesion risk. Electric vacuum aspiration where power and a facility exist.

**2. Antibiotics for sepsis** — ampicillin, gentamicin and metronidazole, all EML-listed, all off-patent, a few dollars a course.

**3. Blood transfusion** for haemorrhage. Tranexamic acid has not been trialled in this indication specifically, though the bleeding mechanism is the one the WOMAN trial addressed.

**4. Laparotomy** for perforation of uterus or bowel. A Bellwether requirement.

**5. Anti-D immunoglobulin** where indicated and available, and **contraception provided before discharge**, which is the measured intervention against the repeat event.

**Simple means.** - **Manual vacuum aspiration.** A hand-powered syringe. No electricity, no theatre, reusable after cleaning, and usable under local anaesthesia and paracervical block by a trained mid-level provider. This is among the clearest cases in the chapter of a simple means that is also the standing best treatment. - **Misoprostol tablets.** Shelf-stable, oral, cents each, effective for both evacuation and bleeding. Their existence is why medical abortion and post-abortion care can happen without a facility. - **Oral rehydration and oral antibiotics** as holding measures during transfer. - **Accurate information.** WHO's own position is that first-trimester medical abortion can be self-managed given accurate information and quality medicines. Information is the lowest-chain intervention there is. - **Bimanual compression and uterine massage** for the bleeding.

The minimum chain: two tablets and a plastic syringe. This is one of the shortest supply chains of any curative intervention in this book.

**Gaps.** The numbers are the weakest in the chapter and WHO says so: criminalisation and misclassification make incidence, complication rate and death rate systematically undermeasured where they are highest. The 45 per cent unsafe figure is from 2010 to 2014 and was not updated on the fact sheet current in December 2025. The cost figures are from 2006 and the 7-million-complications figure from 2012; none has been refreshed. GBD's maternal abortive outcome line is not coextensive with unsafe-abortion complications, since it includes spontaneous abortion, and ectopic pregnancy is counted separately, so the 19,600 figure cannot be read as deaths from unsafe abortion. Legal change as an intervention has not been and cannot be randomised; the evidence is the cross-national association WHO reports, which is strong, consistent and observational.

---

## Obstetric fistula

**What it is.** A hole between the vagina and the bladder or rectum, torn open by days of obstructed labour pressing the baby's head against the mother's pelvis until the tissue dies. Urine or faeces then leaks continuously and uncontrollably. The baby is almost always already dead.

**Measured.** Women and girls living with fistula: **about 500,000** across the Arab States, Asia, Latin America and the Caribbean, and sub-Saharan Africa. New cases are given only as thousands each year, with no number published. No annual incidence estimate was located from any source.

**About 90 per cent of women who develop fistula deliver a stillborn baby**. Repairs directly supported by UNFPA number more than **153,000**, and the Campaign to End Fistula is active in more than **55 countries**.

The condition is concentrated among the poorest and most marginalised women, especially far from medical services, and is **virtually eliminated in high-income countries**.

No GBD cause series exists for obstetric fistula as a separate entity. Its mortality is carried inside obstructed labour, and its years lived with disability are largely uncounted.

**Where it starts.** Prolonged obstructed labour without operative delivery is the cause. It is a single-cause condition and the cause is the absence of a caesarean section.

Upstream: child marriage, adolescent pregnancy with incomplete pelvic growth, malnutrition and stunting, poverty, distance from a facility, and female genital mutilation. Iatrogenic fistula from surgical injury at caesarean or hysterectomy is a separate and, in some series, increasing minority route. No effect sizes were located.

What is not known is how many women have it. The 500,000 figure is an estimate of unknown vintage repeated across agency documents, and no incidence estimate exists. Women with fistula are commonly divorced, expelled from their households and socially hidden, which is precisely why they are not counted. **The size of this condition is not known to within a factor of two.**

**Cure status.** Localized, with access to reconstructive surgery: CURABLE — closure in 80 to 90 per cent of first repairs of simple fistula†. Without access to surgery: RELIEF ONLY.

Reconstructive surgery closes the fistula and continence returns. Published surgical series report closure rates commonly in the 80 to 90 per cent range for first repairs of simple fistula, with lower rates for complex and repeat cases and residual stress incontinence in a minority after successful closure. UNFPA's own page gives no success rate and no cost figure, and an authoritative pooled figure was not retrievable. The condition does not heal spontaneously once established, which is why the second stratum is RELIEF ONLY rather than SELF-LIMITING.

**Prevention.** - **Skilled birth attendance with timely access to caesarean section — STRONG.** This prevents essentially all obstetric fistula, and the measured evidence is the near-total absence of the condition in countries with universal access. - **Preventing child marriage and adolescent pregnancy — MODERATE.** Mechanistically direct, unquantified. - **Family planning to reduce early and closely spaced pregnancies — MODERATE**. - **Addressing malnutrition and stunting in girls — MODERATE**, with a generation-long effect. - **Partograph and labour monitoring — CONTESTED** on outcome evidence, as in obstructed labour. - **Ending female genital mutilation — STRONG** for the subset it causes.

UNFPA names skilled birth attendance including midwives, timely emergency obstetric care, modern family planning, and addressing poverty, gender inequality, child marriage and adolescent pregnancy. None of these carries an effect size on that page.

**Treatment. 1. Surgical repair**, by the vaginal or abdominal route depending on site and complexity. No drug treats this. The inputs are a trained fistula surgeon, an operating theatre, anaesthesia, and post-operative catheter care for one to several weeks. Surgical volume and surgeon experience are the strongest predictors of closure in published series, which is why the condition is managed in dedicated centres and campaigns rather than in general surgical services.

**2. Continuous bladder catheterisation in the first weeks after a fresh fistula.** A proportion of early small fistulae close spontaneously with catheter drainage alone. This is the cheapest curative intervention available for the condition, and it requires a catheter and a drainage bag.

**3. Physiotherapy and pelvic floor rehabilitation** for residual incontinence after closure.

**4. Treatment of associated conditions** — nerve injury causing foot drop, which is common after prolonged obstructed labour, amenorrhoea, secondary infertility, vaginal stenosis, and dermatitis from constant wetting.

**5. Social reintegration support.** Not medical, and UNFPA and the published programmes treat it as part of the intervention because the condition's burden is largely social.

**Simple means.** - **Early continuous catheterisation.** A Foley catheter and a bag can close a fresh small fistula without any surgery. The limiting factor is that the woman must reach a health worker within days, which is the same failure that caused the fistula. - **Barrier creams and skin care** for the excoriation caused by constant urine contact. This prevents the secondary dermatitis that makes the condition unbearable. - **Perineal hygiene, frequent washing, absorbent cloth**, changed often. Relief rather than cure, and it is what most affected women have. - **Case-finding by community health workers and by radio.** The main constraint on fistula campaigns is that affected women do not know repair exists. Announcing it is close to free and is the measured bottleneck in campaign throughput. - **Transport support to a repair campaign.** The surgery is free at campaigns. The bus fare is often what prevents it. - **Nutritional support before surgery.**

The minimum chain: a catheter for the earliest cases, and for the rest an operating theatre and a trained surgeon. There is no simple-means substitute for fistula repair.

**Gaps.** The prevalence figure of 500,000 has no stated date or method and is repeated across agency documents, and no incidence estimate exists at all; this is the least-measured condition in the chapter. No GBD cause series covers it, so its years lived with disability are absent from the global burden accounts. UNFPA publishes no success rate and no cost per repair, and published series range widely by fistula complexity and surgeon volume. The share that is iatrogenic rather than obstructed-labour in origin is not globally quantified and appears to be rising in some settings. Long-term outcomes after successful closure — continence at five years, subsequent fertility, subsequent delivery outcomes — are thinly reported.

---

## Gestational diabetes mellitus

**What it is.** Blood sugar that rises above normal during pregnancy in a woman who did not have diabetes before. The placenta's hormones make the mother's tissues resist insulin, and if her pancreas cannot compensate, glucose rises. It usually resolves after delivery.

**Measured.** There is **no global figure.** The WHO diabetes fact sheet publishes none for gestational diabetes. GBD does not report it as a separate cause: it has no deaths line and no DALY rank of its own.

Published prevalence estimates range from roughly **2 per cent to over 20 per cent** of pregnancies, and the range is driven mainly by which diagnostic criteria are used rather than by real population differences. Adopting the IADPSG and WHO 2013 thresholds roughly doubles the measured prevalence in the same population. No single global estimate is asserted here.

The trend is rising, tracked to rising maternal age and maternal obesity, and not quantified in a reachable source. The highest reported prevalences are in South Asia, the Middle East and North Africa, and that comparison is confounded by criteria.

**Where it starts.** Established: maternal overweight and obesity before pregnancy, and excessive gestational weight gain; maternal age; previous gestational diabetes or a previous macrosomic baby; family history of type 2 diabetes; South Asian, East Asian, Middle Eastern, Hispanic and Indigenous ancestry, which carry higher risk at lower body mass index than European ancestry; and polycystic ovary syndrome. No effect sizes were located from a reachable authoritative source.

Two things are genuinely unsettled. First, whether gestational diabetes is a distinct condition or simply the detection of pre-existing impaired glucose tolerance under the stress test of pregnancy: a substantial share of women diagnosed have abnormal glucose handling that persists or recurs, and the condition strongly predicts later type 2 diabetes. Second, where the threshold should be drawn. The glucose-to-outcome relationship is continuous with no inflection, so the diagnostic cut-off is a decision about how many women to treat rather than a discovery about a disease boundary. That is the main reason the prevalence figures cannot be compared.

**Cure status.** The hyperglycaemia of this pregnancy: SELF-LIMITING — the placenta is the cause and its delivery removes it. The consequences for this birth: CONTROLLABLE — treating the hyperglycaemia measurably reduces macrosomia, shoulder dystocia and pre-eclampsia, so intervention is not without value. The woman's elevated lifetime risk of type 2 diabetes: not removed by anything done in the pregnancy.

**Prevention.** - **Pre-pregnancy weight management — MODERATE.** Mechanistically direct; trials of pre-conception weight loss are small. - **Diet and physical activity in pregnancy — MODERATE.** Meta-analyses of exercise and dietary interventions report relative reductions in incidence of the order of 20 to 40 per cent, with substantial heterogeneity†. An exact pooled figure was not retrievable. - **Metformin for prevention — CONTESTED.** Trials in obese pregnant women reduced gestational weight gain and did not consistently reduce incidence. - **Myo-inositol, probiotics, vitamin D — WEAK.** Signals in small trials, not replicated at scale. - **Screening is not prevention.** Universal against risk-factor-based screening changes who is diagnosed, not who develops the condition, and which approach improves outcomes is itself contested.

**Treatment. 1. Diet and exercise.** First line and sufficient in the majority, commonly reported as 70 to 85 per cent of cases controlled without drugs†. Not a drug, and no supply chain beyond advice and food.

**2. Insulin.** The standard pharmacological treatment and the one with the longest safety record in pregnancy. Human insulin, short-acting and intermediate-acting, is EML-listed for type 1 and type 2 diabetes; the analogue entries are listed as classes, and the named analogues — degludec, detemir, glargine, aspart, glulisine, lispro — are listed only as therapeutic equivalents to those class entries, not as selected medicines. Human insulin is off-patent and remains expensive relative to its production cost, and its price is a standing access problem; it is EML-listed partly for that reason. Insulin requires a cold chain, injection equipment and glucose self-monitoring: three supply chains at once.

**3. Metformin.** EML-listed for type 2 diabetes mellitus, oral solid 500 mg, first added 1997. Off-patent, cents a day, oral, no cold chain. It crosses the placenta and long-term offspring follow-up is reassuring to date and not complete. It is increasingly used first-line where insulin's cold chain is unavailable, which is the relevant consideration for most of the world.

**4. Glibenclamide.** Oral, cheap, EML-listed, off-patent. Inferior to insulin and to metformin on neonatal outcomes in head-to-head trials, and a third-line option.

**5. Delivery timing and mode.** Induction at or near term where macrosomia is suspected; the trade-offs are not settled.

**6. Postpartum glucose testing at 6 to 12 weeks and lifelong thereafter.** The intervention with the largest long-term value, and the one most often omitted.

**Simple means.** - **Dietary change.** Reducing refined carbohydrate and spacing intake across the day controls the majority of cases with no manufactured input whatever. This is the primary treatment and it is a simple means. - **Walking after meals.** Measured postprandial glucose reductions from short post-meal walks are consistent across small trials. Free. - **Fasting and post-prandial glucose measured with a strip meter.** A meter and strips are a manufactured consumable chain, and a small and cheap one, and they convert the condition into something manageable at home. Urine glucose dipsticks are the lower-chain fallback and are much less sensitive. - **Breastfeeding after delivery**, associated with lower subsequent maternal type 2 diabetes incidence in cohort studies, and free. - **Weighing the mother** and tracking gain.

The minimum chain: for most women, nothing manufactured. For the minority needing drugs, metformin tablets are the short chain and insulin is the long one.

**Gaps.** There is no global prevalence figure, and WHO says so; any number quoted is a modelled estimate over incommensurable diagnostic criteria. The diagnostic threshold is unsettled and the choice of criteria changes measured prevalence roughly two-fold, which is the single largest source of disagreement in the field. Whether screening and treating mild gestational diabetes improves outcomes enough to justify universal screening is contested, with professional bodies in different countries reaching different conclusions on the same evidence. No effect sizes for risk factors or for lifestyle prevention were retrievable from a primary source. GBD does not carry the condition as a cause, so it has no place in the global burden accounts despite affecting a large share of pregnancies. Long-term offspring outcomes after in-utero metformin exposure are not yet complete.

## Hyperemesis gravidarum

**What it is.** Vomiting in pregnancy severe enough to cause dehydration, weight loss and electrolyte disturbance. Far beyond ordinary morning sickness. It can prevent a woman eating or drinking at all for weeks.

**Measured.** Prevalence is given as **0.3 to 2.0 per cent** of pregnant women, with some sources as high as 3 per cent†. A second figure on the same page gives **0.3 to 1.5 per cent**†, and an infobox on it gives **about 1 per cent**†. All are printed; the sources disagree within a narrow band and none is a measurement, because ascertainment depends on whether admission is recorded.

It is the **second most common reason for hospital admission in the first half of pregnancy**, after preterm labour, with no hospitalisation rate given. United States hospitalisation costs have been estimated at **US$3 billion a year**†.

There is no deaths line in the GBD maternal series. It is not a notable cause of maternal death where intravenous fluids are available. Historically it was.

Onset is typically at 5 to 6 weeks gestation, β-hCG peaks around 8 to 12 weeks, and most women improve by the early second trimester; some continue throughout pregnancy and occasionally after birth.

**Where it starts.** The substantive finding is recent. A *Nature* paper of December 2023 linked hyperemesis gravidarum to **abnormally high levels of GDF15 and to increased maternal sensitivity to that hormone**. GDF15 is produced by the placenta and acts on the hindbrain, and maternal pre-pregnancy GDF15 exposure appears to determine sensitivity. No effect size is reported on the source consulted. This is the most substantive aetiological finding the condition has ever had.

Also established: first pregnancy, multiple pregnancy, obesity, and trophoblastic disorder. Family history is strong and long-observed — family members with hyperemesis make the diagnosis more likely. Associations with *H. pylori* infection, raised thyroid hormone production, low maternal age and low pre-pregnancy body mass index are reported. No effect sizes are given for any risk factor.

Until the GDF15 work nothing about the mechanism was established, and the condition was for decades attributed to maternal psychology — a misattribution that caused measurable harm through undertreatment. The GDF15 finding has not yet produced a treatment, the quantitative relationship between level, sensitivity and severity is uncharacterised, and why some women with high GDF15 are unaffected is not known.

**Cure status.** The emesis: SELF-LIMITING — it ends with the pregnancy and in most women well before it, typically early in the second trimester. No treatment removes it. The thiamine deficiency it produces: CURABLE, and it must be treated. Untreated, it causes Wernicke's encephalopathy, which is permanent brain injury. Vitamins A and B are depleted within about two weeks of poor intake.

So self-limiting must not be read as intervention adding nothing. Everything in the treatment section is symptom control and replacement of what has been lost, except the thiamine, which prevents a non-self-limiting disease.

**Prevention.** - **Nothing prevents it.** No intervention has been shown to prevent hyperemesis gravidarum in a woman who is going to develop it. That belongs stated plainly rather than filled in. - **Early treatment of nausea and vomiting of pregnancy — MODERATE** for preventing progression to the severe form. The observational basis is that early antiemetic treatment reduces hospitalisation; no trial has established that it prevents the severe syndrome. - **Thiamine supplementation — STRONG** for preventing Wernicke's encephalopathy, which is the preventable catastrophe. - **Prophylactic antiemetics in a woman with prior hyperemesis — WEAK.** Common practice, thin evidence. - GDF15-directed prevention does not exist.

**Treatment. 1. Rehydration and electrolyte replacement.** Intravenous fluids with potassium as needed. This is the intervention that changed hyperemesis from a fatal to a survivable condition, and it is not a drug.

**2. Thiamine, which is the non-negotiable item.** Thiamine must be supplemented to reduce the risk of Wernicke's encephalopathy, and it must be given **before or with** any

glucose-containing fluid, because glucose without thiamine precipitates the encephalopathy. EML-listed, off-patent, cents a dose; UNICEF indicative prices in October 2026 for thiamine were printed at US$1.29, US$1.42 and US$5.55 for the same material number on different pages, which is why these are indicative figures and not a price. **A few cents prevents permanent brain injury,** and it is routinely omitted.

**3. Pyridoxine with doxylamine.** Effective for nausea and vomiting of pregnancy, with some question over its effectiveness in hyperemesis specifically; a Cochrane review found limited evidence for vitamin B6 on outcomes. Pyridoxine is EML-listed, off-patent, cents.

**4. Metoclopramide.** Used and relatively well tolerated. EML-listed, off-patent, cents a course.

**5. Ondansetron.** May be beneficial, and the evidence is limited. Concerns exist about an association with **cleft palate**: the signal is observational, the absolute risk increase reported is small, and professional positions differ. EML-listed as an antiemetic for chemotherapy-induced emesis, off-patent, low cost now generic.

**6. Corticosteroids.** The evidence is weak. They may slightly raise the risk of cleft lip and palate and suppress fetal adrenal activity; hydrocortisone and prednisolone are inactivated by the placenta and may be used after 12 weeks†. A later-line option.

**7. Enteral or parenteral nutrition** in refractory cases.

Negatives, reported as such: acupuncture is ineffective. Ginger has limited and inconsistent evidence. Medicinal cannabis has been used and has no trial evidence.

**Simple means.** - **Oral rehydration solution**, sipped in small volumes where it can be kept down. Sugar, salt and water, and the first-line simple means for the central problem. UNICEF indicative prices put low-osmolarity sachets at **US$0.048 each** in October 2026. - **Dry, bland food, small and frequent.** Named as first line on the source consulted. - **Thiamine tablets** where parenteral is unavailable — a tablet costing a fraction of a cent, preventing permanent neurological injury. - **Cold foods**, since odour is a dominant trigger, with avoidance of cooking smells and ventilation. - **Rest in a dark quiet room**, and removal of trigger exposures. - **Pyridoxine tablets and ginger** — cheap, oral, weakly evidenced, harmless. - **Being believed.** The condition's documented history of psychological misattribution is itself a source of undertreatment, and the measured consequence of undertreatment is in the gaps below.

The minimum chain: oral rehydration salts and thiamine tablets carry mild and moderate cases. Severe cases need intravenous fluids, and there is no simple-means substitute for an intravenous line and a bag of saline.

**Gaps.** The prevalence sources disagree at 0.3 to 2.0 per cent, 0.3 to 1.5 per cent and about 1 per cent, and none is a measurement. The GDF15 finding is recent and has produced no treatment and no quantified risk model. Ondansetron's cleft palate signal is unresolved: observational, small in absolute effect, inconsistent across studies, and professional bodies differ. Corticosteroid evidence is weak and the teratogenicity signal unquantified. On offspring outcomes, children of mothers with **undertreated** hyperemesis had about **four-fold higher neurobehavioural diagnoses** in one observational study; that single study has obvious confounding and is also the only quantified statement available on the consequences of undertreatment — it cannot bear weight and should not be discarded. Maternal outcomes include lower miscarriage risk and higher preterm birth risk, and severe cases with under 7 kg weight gain have been linked to lower birth weight and small-for-gestational-age infants; both observational. No cost-effectiveness analysis of any treatment was located.

---

## Preterm labour

**What it is.** Labour starting before 37 completed weeks of pregnancy. The womb begins contracting and the cervix opens while the baby is still immature. The labour itself is the condition coded here; the consequences for the baby belong to the perinatal chapter.

**Measured.** An estimated **13.4 million babies were born preterm in 2020, more than 1 in 10 of all babies**. The rate ranged from **4 to 16 per cent** of births by country.

**WHO's own fact sheet gives two different global figures.** The body text gives 13.4 million; the page metadata gives **15 million**. Both are printed, and the disagreement is internal to one page.

Deaths: about **900,000 children died in 2019** from preterm birth complications, and WHO states that **three-quarters of those deaths could be prevented with current, cost-effective interventions**. GBD 2023 gives **623,300 (509,700 to 735,000)** deaths from neonatal preterm birth complications in 2023, down 41.4 per cent since 2000. The two do not reconcile beyond the difference in year and model, and both are printed.

**Prematurity is the leading cause of death in children under 5**. WHO describes the number of preterm births as rising, gives no year-by-year figures, and notes that it publishes updated global preterm analyses only every three to five years.

**Where it starts.** Previous preterm birth is the strongest single predictor. Multiple pregnancy, a short cervix on ultrasound, cervical surgery and uterine anomaly all raise risk. So do infection — intrauterine infection, bacterial vaginosis, urinary tract infection, and periodontal disease, the last contested. Pre-eclampsia and other medical indications for **iatrogenic** preterm delivery are a large and growing share of the total in high-income countries and must be counted separately from spontaneous preterm labour. Short interpregnancy interval, maternal age at both extremes, low maternal body mass index, smoking, heavy physical work and psychosocial stress are established, as is assisted reproduction, largely through multiple pregnancy. No effect sizes were located.

The cause of spontaneous preterm labour is not known in most cases. It is a syndrome with several recognised pathways — infection and inflammation, uteroplacental ischaemia, cervical insufficiency, uterine overdistension, stress — and in the majority of individual cases no pathway is identified. There is no accurate predictive test: fetal fibronectin and cervical length have negative predictive value and poor positive predictive value. **Tocolytics delay delivery by days and do not improve neonatal outcomes**, which is itself the clearest evidence that the mechanism is not understood, because suppressing the contractions does not address whatever started them.

**Cure status.** RELIEF ONLY, for the labour itself. No treatment reliably stops preterm labour and returns the pregnancy to a normal course. Tocolysis buys 48 hours†. It does not cure. What those 48 hours buy† is the window for antenatal corticosteroids and for transfer to a facility, and those interventions do change the baby's survival substantially. So the condition is RELIEF ONLY and the intervention it permits is among the most effective in this book.

**Prevention.** - **Vaginal progesterone in women with a short cervix or prior preterm birth — MODERATE.** It reduces preterm birth before 34 weeks and reduces neonatal morbidity in meta-analyses, with the magnitude differing between the short-cervix and prior-preterm-birth populations; the large OPPTIMUM trial was null. Both the positive meta-analyses and the null trial are reported. - **Cervical cerclage in selected women — MODERATE.** The benefit is confined to specific indications, principally a short cervix with prior loss, and it is not beneficial unselected. - **Smoking cessation — STRONG.** One of the few preventive measures with a consistent effect across settings. - **Treating asymptomatic bacteriuria — STRONG**, for preterm birth and for pyelonephritis. A cheap antibiotic and a clear effect. - **Treating bacterial vaginosis — CONTESTED.** It does not consistently reduce preterm birth despite the epidemiological association. - **Avoiding non-medically-indicated early delivery, and reducing multiple embryo transfer in assisted reproduction — STRONG** for the iatrogenic share, which is the share most amenable to policy. - **Adequate interpregnancy interval, nutrition, and reducing heavy physical work — WEAK.** - **Antenatal care itself — STRONG**, as the delivery vehicle: it is where the short cervix is found, the bacteriuria treated, the corticosteroids given and the transfer arranged. WHO recommends a minimum of eight contacts, starting before 12 weeks. - **Low-dose aspirin — MODERATE**, through its pre-eclampsia effect, which removes an indication for iatrogenic preterm delivery.

**Treatment.** The highest-evidence treatments here treat the baby, not the labour.

**1. Antenatal corticosteroids**, the single highest-value intervention in this entry. The ACTION-I trial enrolled **2,852 women and their 3,070 babies** at 29 secondary and tertiary hospitals in Bangladesh, India, Kenya, Nigeria and Pakistan. Dexamethasone produced a **significantly lower risk of neonatal death and of stillbirth**, with **no increase in pos-**

**sible maternal bacterial infections**. WHO's own page does not publish the relative risk or its interval, and the trial's reported relative risk for neonatal death of approximately 0.84 could not be verified against the primary paper, so no relative risk is asserted here.

The significance of ACTION-I is specific. Antenatal corticosteroids had been standard in high-income settings since 1972, but a prior WHO cluster trial in 2015 found **harm** at population level when they were given in low-resource settings without accurate gestational age assessment and adequate newborn care. ACTION-I established benefit in hospitals that had both, and that condition is attached to the recommendation.

Dexamethasone is EML-listed in several sections, off-patent, and costs **under US$1 for a full course**; UNICEF indicative prices in October 2026 work out at about US$0.24 a 4 mg tablet. Betamethasone is the alternative: equivalent in effect, more expensive, and supply-constrained.

**2. Magnesium sulfate for fetal neuroprotection**, given before anticipated preterm birth, which reduces cerebral palsy in the surviving child. The same salt, EML-listed, off-patent, a few dollars.

**3. Tocolysis** with nifedipine or atosiban. Nifedipine is cheap, oral, EML-listed and off-patent. It **delays delivery by up to 48 hours† and does not improve neonatal mortality or morbidity.** Its value is entirely instrumental: it buys the corticosteroid window and the transfer.

**4. Antibiotics for preterm prelabour rupture of membranes**, which reduces neonatal infection. Erythromycin, EML-listed, off-patent, cheap. **Co-amoxiclav is specifically avoided** in this indication because of the increased necrotising enterocolitis signal in the ORACLE trial.

**5. Intrapartum antibiotic prophylaxis against group B streptococcus** where screening or risk-based protocols apply. Penicillin, EML-listed, off-patent, cents.

**6. In-utero transfer to a facility with newborn care.** Not a drug, and measured as one of the strongest determinants of preterm survival.

**7. Delayed cord clamping at the preterm birth.**

**Simple means.** - **Delayed cord clamping.** Waiting 60 seconds or more before cutting transfers placental blood to the preterm baby, reduces the need for transfusion, and reduces mortality in meta-analysis of preterm births. It costs nothing and requires only that the attendant wait. - **Skin-to-skin contact and kangaroo mother care immediately after a preterm birth.** The largest simple-means effect in this book: 28-day mortality relative risk 0.75†. - **Keeping the baby warm** — drying, a hat, a warm room, body contact. Neonatal hypothermia is a major preterm killer and the countermeasure is free. - **Immediate breastfeeding support and expressed milk**, which prevent necrotising enterocolitis and sepsis. No supply chain. - **Clean delivery practice.** - **Not sending the mother home.** Recognising threatened preterm labour and keeping her where corticosteroids and newborn care are is a decision rather than a resource. - **Accurate gestational age by last menstrual period or fundal height** where ultrasound is unavailable. This is the input the earlier cluster trial lacked and ACTION-I had, and it is the difference between the corticosteroid helping and harming.

The minimum chain: dexamethasone ampoules and a syringe for the corticosteroid. Everything else in the list requires nothing manufactured.

**Gaps.** WHO's own fact sheet gives two different global figures for preterm births, 13.4 million in the body text and 15 million in the metadata, and its 900,000 deaths for 2019 does not reconcile with GBD's 623,300 for 2023. All are printed. WHO publishes no numeric effect size for antenatal corticosteroids or for kangaroo mother care on that page, and the ACTION-I relative risk could not be verified against the primary paper. The earlier cluster trial and ACTION-I reached opposite conclusions on corticosteroids in low-resource settings; the reconciliation through gestational-age accuracy and level of newborn care is plausible and is WHO's position, and it is an interpretation of a discrepancy rather than a measured finding. Progesterone's positive meta-analyses and the null OPPTIMUM trial remain unresolved. The share of preterm birth that is iatrogenic rather than spontaneous is not globally reported, which makes the global rate hard to interpret and the trend harder. There is no accurate predictive test and no treatment that stops preterm labour, and both are absences

rather than thin evidence. Global preterm estimates are updated only every three to five years, so the rising trend rests on few data points.

---

## Ectopic pregnancy

**What it is.** A pregnancy that implants outside the womb, almost always in a fallopian tube. The tube cannot accommodate it. It ruptures and bleeds into the abdomen, which kills quickly.

**Measured.** Ectopic pregnancy deaths in 2023: **12,700 (8,500 to 17,800)**, **up 28.6 per cent** since 2000†. **This is one of only three causes in the entire maternal series that increased** — the others being other direct maternal disorders at plus 1.2 per cent and late maternal deaths at plus 10.8 per cent — and it is the largest proportional increase of any maternal cause.

Incidence is given as less than **2 per cent of pregnancies** worldwide, and as about **11 to 20 per 1,000 live births** in developed countries†; an infobox on the same source gives about 1.5 per cent of pregnancies†. It rises to as high as **4 per cent** with assisted reproductive technology†.

**The measured gradient is in case fatality.** Developed world figures are **0.1 to 0.3 per cent**†; a United Kingdom series for 2003 to 2005 gives 10 deaths among 32,100 cases, about **0.03 per cent**†; a UK Confidential Enquiry for 2006 to 2008 gives 6 deaths in 2.3 million pregnancies, 0.26 per 100,000†. The developing world figure is **1 to 3 per cent**† — a ten-fold or greater difference.

Ectopic pregnancy accounts for about **6 per cent of first-trimester maternal deaths** on one estimate and **6 to 13 per cent** on another. Both printed. A GBD-based analysis gives **3,478 ectopic pregnancy deaths in low-income countries in 2019** (2,849 to 4,187), 0.68 per 100,000 population and 37.69 DALYs per 100,000.

**Where it starts.** One figure is quantified: **endometriosis carries about 270 per cent higher risk, roughly an odds ratio of 2.7**, in a 30-year study of over 14,000 women†. Prior ectopic pregnancy carries a recurrence risk of about **10 per cent**†.

Risk tiers are given without odds ratios. High: tubal sterilisation, an intrauterine device in situ, prior ectopic, pelvic inflammatory disease, endometriosis, salpingitis isthmica nodosa. Moderate: smoking, more than one recent sexual partner, infertility, chlamydia. Low: douching, age over 35 or under 25, gamete intrafallopian transfer.

The dominant upstream exposure is tubal damage from chlamydia and gonorrhoea, which is why ectopic incidence tracks sexually transmitted infection prevalence.

What is genuinely not known is why the deaths are rising while every other major maternal cause falls. Candidate explanations — rising assisted reproduction, rising chlamydia prevalence, better ascertainment of a previously misclassified cause, and improved detection moving cases into the counted category — were not separated by any analysis located. This is the most important open question in the maternal data and no source reached offers an answer.

**Cure status.** CURABLE. Methotrexate resolves a selected subset medically and surgery resolves the rest definitively. Both cure the episode, and subsequent fertility is substantially preserved: a randomised study in 2013 found two-year intrauterine pregnancy rates of about **64 per cent after radical surgery, 67 per cent after medication and 70 per cent after conservative surgery**. Recurrence is about 5 per cent after salpingectomy and 8 per cent after salpingostomy, with intrauterine pregnancy rates of 56 and 61 per cent respectively. The condition kills only when not diagnosed before rupture. The entire clinical problem is detection in time.

**Prevention.** - **Preventing and treating chlamydia and gonorrhoea — STRONG** on mechanism, by preventing tubal damage. Chlamydia screening programmes have been associated with reduced pelvic inflammatory disease; the ectopic-specific effect size was not located. - **Early pregnancy ultrasound and β-hCG access — STRONG for death, not for incidence.** This is the decisive intervention and it is detection: finding the ectopic before it ruptures is what separates 0.03 per cent case fatality from 3 per cent. - **Not using an**

**intrauterine device in a woman at high ectopic risk — MODERATE**, with the framing stated correctly: an intrauterine device **reduces** absolute ectopic risk by preventing pregnancy overall, and raises the proportion of pregnancies that are ectopic among its rare failures. - **Reducing multiple embryo transfer and managing assisted reproduction — MODERATE**, for the 4 per cent figure above. - **Smoking cessation — MODERATE.** - There is **no primary prevention** for ectopic pregnancy in a woman with already-damaged tubes.

**Treatment. 1. Methotrexate**, for the selected subset: low β-hCG, a small mass, no rupture, haemodynamic stability and reliable follow-up. It works best when β-hCG is low and the mass small. Contraindications are a mass over 3.5 cm, a ruptured tube, and renal or hepatic dysfunction. **Regimens differ by country and so do their failure rates:** the United States uses up to four intramuscular doses, and France uses a single dose, which has a greater chance of failure. One source recommends giving methotrexate only when β-hCG rises by less than 35 per cent over 48 hours. **No success percentage is given on the sources consulted.** Published series commonly report 65 to 95 per cent† depending on selection and regimen, and no pooled figure is asserted here. Methotrexate is EML-listed as a cytotoxic medicine, off-patent, and costs a few US dollars a dose. The real supply-chain constraint is serial β-hCG measurement: the drug is cheap and the laboratory follow-up is unavailable in most places where women die of this.

**2. Surgery** — laparoscopy or laparotomy, with salpingostomy to open the tube and remove the pregnancy, or salpingectomy to remove the tube. It is recommended for rupture, a fetal heartbeat, or unstable vital signs. Surgery is needed for 0.5 to 11 per cent of pregnancies of unknown location. **Laparotomy requires no laparoscopic stack and is the operation that is actually available in low-resource settings.** It is one of the three Bellwether procedures, and this is exactly the indication for which it is included.

**3. Expectant management** for spontaneously resolving cases with falling β-hCG.

**4. Resuscitation and transfusion** for the ruptured, bleeding patient. This is the emergency, and blood availability is the determinant.

**5. Anti-D immunoglobulin** where indicated.

**Simple means.** The honest answer here is largely negative and that must be said plainly. - **A urine pregnancy test.** A cheap shelf-stable strip. In a woman of reproductive age with abdominal pain and a positive urine pregnancy test, ectopic is the working diagnosis until excluded. This single consumable is the highest-yield item in the entry: it converts abdominal pain into a surgical emergency. - **Clinical examination and the history** — amenorrhoea, abdominal pain, shoulder-tip pain, syncope, cervical excitation. No equipment. - **Recognition teaching and transport.** The determinant of death is the interval from rupture to laparotomy. - **Positioning and nothing by mouth during transfer**, with intravenous fluids where available.

A ruptured ectopic pregnancy requires a laparotomy and usually blood. **There is no simple means that substitutes for abdominal surgery.** Methotrexate requires a laboratory. The urine pregnancy test is the only genuine simple means in this entry, and its function is to send the woman to the surgery she needs. With obstructed labour, this is the clearest case in the chapter for the Lancet Commission's argument.

**Gaps.** The 28.6 per cent rise in deaths from 2000 to 2023 is unexplained in any source located, and whether it is a real increase, an ascertainment artefact, or a consequence of assisted reproduction and rising chlamydia is not established. Methotrexate success rates are not given on the sources reachable, and the United States four-dose and French single-dose regimens have acknowledged different failure rates with no head-to-head figure here. Risk factors are tiered and almost entirely unquantified: only endometriosis at an odds ratio of about 2.7 and prior ectopic at about 10 per cent recurrence carry numbers. Cost is not discussed in the sources consulted. Case-fatality sources give 0.1 to 0.3 per cent and 0.03 per cent for high-income settings, a ten-fold spread within one category, almost certainly from ascertainment of the denominator; both printed. GBD's low-income figure of 3,478 for 2019 and its global figure of 12,700 for 2023 come from different analyses and different years and cannot be compared.

## Miscarriage

**What it is.** A pregnancy that ends by itself before the fetus can survive outside the womb. Most happen in the first twelve weeks, and most are caused by a chromosomal error in the embryo that was present from conception.

**Measured.** GBD counts miscarriage inside maternal abortive outcome, at **19,600 deaths (12,200 to 30,800)** in 2023, down 54.8 per cent since 2000. That line also contains induced and unsafe abortion, so **no separate death figure for miscarriage exists in the GBD series.**

No WHO or GBD global incidence estimate was located. The clinically standard figures — roughly 10 to 15 per cent of recognised pregnancies ending in miscarriage, and a substantially higher proportion of all conceptions including those lost before recognition — come from cohort studies rather than a global estimation exercise, and are not asserted here as global figures. Recurrent miscarriage, meaning three or more consecutive losses, affects approximately 1 per cent of couples attempting pregnancy in the published cohorts†.

Incidence is not strongly patterned by income. **Death from miscarriage is**, because it is death from the haemorrhage or sepsis of an incomplete miscarriage without access to evacuation.

**Where it starts.** Fetal chromosomal abnormality is the cause in roughly half of first-trimester miscarriages in karyotyped series — most commonly autosomal trisomy, and most commonly arising de novo at meiosis. This is the dominant cause and it is not preventable.

Maternal age is the strongest risk factor, acting through oocyte aneuploidy, with risk rising steeply after 35 and sharply after 40. Antiphospholipid syndrome, uncontrolled thyroid disease, uncontrolled diabetes, uterine anomaly or fibroids distorting the cavity, and cervical insufficiency in the second trimester are established. Smoking, heavy alcohol use, high caffeine intake, obesity and underweight are associated with modest effect sizes. Infections include listeriosis, syphilis, malaria in pregnancy, rubella, cytomegalovirus and Zika.

**Not associated, despite persistent belief:** moderate exercise, sexual intercourse, air travel, previous induced abortion, and most occupational exposures. Reporting these negatives matters, because the dominant maternal experience of miscarriage is misplaced self-blame. No effect sizes were retrievable.

The cause is unknown in roughly half of cases and in the great majority of recurrent miscarriage. After full investigation most couples with recurrent miscarriage receive no explanation. The proposed mechanisms — immunological, thrombophilic, endometrial receptivity — have generated many treatments and almost no trial-proven ones, which is the signature of an unidentified mechanism.

**Cure status.** The loss itself: SELF-LIMITING. The pregnancy loss completes, and in the large majority the uterus empties without intervention; expectant management succeeds in most complete and incomplete miscarriages given time. Nothing prevents or reverses the loss once it has begun. The complications — retained tissue causing haemorrhage or sepsis: CURABLE. The deaths recorded above are entirely from these.

Recurrent miscarriage is not self-limiting in the sense that matters to the couple, and no treatment has been shown to cure it either.

**Prevention.** This section is mostly negative and must be reported that way. - **Nothing prevents chromosomally abnormal miscarriage**, which is the largest category. This is the central fact and the one most often obscured. - **Progesterone — CONTESTED, with one qualified positive.** The PROMISE trial was null for recurrent miscarriage. The PRISM trial was null overall and found benefit in the subgroup with bleeding **and** three or more previous miscarriages, and United Kingdom guidance now offers progesterone to that specific subgroup. Both results printed; this is a subgroup finding and should be read as one. - **Levothyroxine for overt hypothyroidism — STRONG.** For subclinical hypothyroidism or thyroid autoimmunity — **CONTESTED**, with the TABLET and T4LIFE trials null†. - **Aspirin plus heparin in antiphospholipid syndrome — STRONG** for that specific diagnosis, with **no benefit in unexplained recurrent miscarriage**, where the ALIFE and SPIN trials were null. - **Smoking and alcohol cessation, caffeine reduction, weight normalisation — MODERATE.** - **Folic acid does not prevent miscarriage.** It prevents neural tube defects. The distinction matters. - **Pre-pregnancy diabetes control — MODERATE.** - **Malaria**

**prevention in pregnancy — STRONG** in endemic areas, for the malaria-attributable share, by intermittent preventive treatment and insecticide-treated nets. - **Cervical cerclage — MODERATE**, in selected second-trimester cases only. - **Immunotherapy, intravenous immunoglobulin, paternal leucocyte immunisation — ineffective, and harmful in some trials.** A settled negative. - **Bed rest — no evidence of benefit.** A settled negative that continues to be prescribed.

**Treatment.** For the miscarriage itself, treatment means completing the uterine evacuation, and all three options are acceptable with differing profiles.

**1. Expectant management.** Waiting. It succeeds in the majority, and requires only that bleeding and infection be watched for. Free.

**2. Misoprostol**, 600 to 800 µg, with the regimen varying by whether the sac is retained. EML-listed, off-patent, cents a tablet. The MifeMiso trial showed that adding mifepristone to misoprostol for missed miscarriage increased the rate of complete miscarriage without surgery. Mifepristone is EML-listed as a co-package with misoprostol for induced abortion and for fetal death; availability is restricted by regulation rather than by patent, and cost is low. Oral and vaginal tablets, no cold chain, no theatre.

**3. Manual or electric vacuum aspiration.** A hand-powered syringe, no electricity, local anaesthesia, reusable. Preferred over sharp curettage, which has higher perforation and intrauterine adhesion rates and should be regarded as superseded.

**4. Antibiotics** for septic miscarriage — ampicillin, gentamicin, metronidazole. EML-listed, off-patent, a few dollars.

**5. Uterotonics and tranexamic acid** for the haemorrhage.

**6. Anti-D immunoglobulin** where the mother is RhD-negative and the gestation is beyond the local threshold. EML-listed, off-patent as a plasma-derived product, with supply rather than patent the constraint. This prevents haemolytic disease in a **later** baby: the intervention and its beneficiary are a pregnancy apart.

**7. Investigation after recurrent miscarriage** — karyotype, antiphospholipid antibodies, thyroid function, uterine imaging. It finds a cause in a minority.

**Simple means.** - **Expectant management.** Doing nothing, competently, with instructions on when to return. The majority of miscarriages need no intervention at all, and this is both the lowest-chain and an entirely evidence-based option. - **Misoprostol tablets.** Cents, shelf-stable, oral. - **Manual vacuum aspiration.** A plastic syringe. - **Oral analgesia** — paracetamol, ibuprofen. The pain of miscarriage is routinely undertreated. - **Oral rehydration**, and iron for the blood loss. - **Clear information on what to expect and when to come back** — how much bleeding is too much, and what fever means. This is the intervention that converts a self-limiting event into a safe one, and it costs a conversation. - **Being told it was not her fault.** The established epidemiology — a chromosomal error arising at meiosis, with no preventive action available — is the content of that statement, and stating it is free.

The minimum chain: nothing for the majority; one tablet or one plastic syringe for the rest; antibiotics if it becomes septic.

**Gaps.** GBD gives no separate figure for miscarriage, merging it with induced abortion inside maternal abortive outcome, so the miscarriage mortality burden is not separately published. No global incidence estimate exists from WHO or GBD: the familiar 10 to 15 per cent figure is from cohorts, and total conception loss including pre-recognition loss is not measurable at population scale. On progesterone, PROMISE was null and PRISM was null overall and positive in a subgroup, and guidelines differ internationally on the same data. Recurrent miscarriage has no established cause in most cases and almost no trial-proven treatment; the field has a long record of interventions adopted on mechanism and abandoned on trial. Effect sizes for risk factors were not retrievable. The psychological burden of miscarriage is substantial and almost entirely unmeasured in the global burden accounts, where it carries no disability weight.

## Postpartum depression

**What it is.** Depression beginning in the weeks or months after giving birth. Low mood, inability to feel pleasure, exhaustion beyond that of a new baby, and often intrusive fears about the baby. It is distinct from the brief low mood of the first days.

**Measured.** Global prevalence is given as roughly **10 to 20 per cent** of postpartum women; an infobox on the source consulted gives about **15 per cent of births**; and a review gives a mean of **10 to 15 per cent**, noting that cultural factors and stigma may hinder accurate reporting. All printed.

United States: **11.5 per cent overall, varying by state from 8 to 20.1 per cent**†. **About 60 per cent of United States women are not diagnosed, and about half of those diagnosed are not treated**; a second source gives up to 50 per cent of cases undiagnosed†.

Middle East: pooled prevalence **27 per cent**, with a country range of 10 to 40 per cent — Iran 40.2, Bahrain 37.1, Saudi Arabia about 10 — and 31 per cent in the first three months against 19 per cent in months 4 to 12†. Africa: **15 to 25 per cent**, with national figures from about 7 per cent in Morocco to 43 per cent in Uganda†.

South America: Brazil 42 per cent, Guyana and Colombia 57 per cent, Venezuela 22 per cent†. **The source is internally inconsistent here**, citing around 60 per cent for several South American countries while giving lower country-specific values for the same countries. Cross-country comparisons from it are not reliable.

Paternal postpartum depression: **8 to 10 per cent of fathers**†; a Japanese study found 13.6 per cent within four months of birth†. Postpartum psychosis: about **1 to 2 per 1,000 women**†, a separate and far more dangerous condition.

No GBD cause line exists for postpartum depression. Its burden sits inside depressive disorders. No trend was quantified in any source reached.

**Where it starts.** The quantified risks are social. - **Mother-in-law conflict: risk ratios of 1.8 and 2.7** across four studies†. - **Family violence: about 2.5 times higher risk** in Middle Eastern samples†. - **A female infant: 2 to 4 times higher risk** in Egyptian and Jordanian studies†. The risk factor is the social response to the baby's sex, not the baby. - **Absence of spousal support: 42.9 per cent of women without spousal support had postpartum depression against 14.7 per cent of those with it**†. - **A partner with postpartum depression:** fathers develop it about half the time when their partner has it. - **Race in the United States: African American mothers at the highest estimated risk, about 25 per cent, and Asian mothers the lowest at 11.5 per cent**†. - Lesbian and bisexual mothers had significantly higher screening scores than heterosexual mothers in one study. - Prenatal depression, prior postpartum depression, low income and low social support are all established associations with no effect sizes given.

The biology is not known. The hormonal-withdrawal hypothesis — the abrupt fall in oestrogen and progesterone after delivery — motivated the allopregnanolone analogues, and those drugs work, which is suggestive. Why only a minority of women are susceptible to the same hormonal change is not known, and no biomarker predicts it. The measured risk factors are overwhelmingly social and the effective new drugs are neurosteroidal, and nothing in the reachable literature reconciles those two facts.

**Cure status.** The episode: CURABLE. Most episodes remit, with treatment faster and more reliably than without, and the woman returns to her previous state. The susceptibility: CONTROLLABLE. A prior episode is the strongest predictor of another.

Not CONTROLLABLE for the episode, because the episode genuinely resolves. Not SELF-LIMITING, because untreated episodes can persist for a year or longer and some do not remit. An untreated episode also has consequences for the child's development that treating a later episode does not undo.

**Prevention.** - **Psychosocial and psychological interventions — MODERATE.** A 2013 Cochrane review found psychosocial interventions reduced the risk of postnatal depression — home visits, telephone peer support, and interpersonal psychotherapy — and no pooled effect size is given on the source consulted. - **Telephone peer support for high-risk women — MODERATE**. - **Counselling for women at high risk**, which the United States Preventive Services Task Force supports; that is the strongest formal endorsement available in this sec-

tion. - **Identifying and treating prenatal depression — MODERATE.** Prenatal depression is the strongest modifiable predictor. - **Spousal and family support — MODERATE**, with the largest observational effect size in the entry at 42.9 against 14.7 per cent. - **Addressing family violence — MODERATE** on mechanism, at a risk ratio of about 2.5. - **Screening alone — WEAK.** Screening without a treatment pathway does not change outcomes. The United States figures — 60 per cent undiagnosed, half of the diagnosed untreated — are a statement about pathways, not about instruments. - **Routine universal prophylactic antidepressants — not recommended, no evidence of benefit.**

**Treatment.** The proportion of episodes that remit with treatment, and without it, is not given here. **1. Psychological therapy** — cognitive behavioural therapy and interpersonal psychotherapy. Individual social and psychological interventions were found about equally effective. These are the first-line treatments with the best evidence and no pharmacological risk to a breastfed infant. **A 2021 meta-analysis found that non-specialist providers — lay counsellors and nurses — often deliver effective care**, which is the finding that makes treatment deliverable where there are no psychiatrists. Peer support is effective.

**2. Selective serotonin reuptake inhibitors, sertraline first. Low-certainty evidence supports their effectiveness**, which is a weaker statement than the prescribing volume implies and should be reported as it stands. Sertraline is first-line because little passes into breast milk. A recent study found **adding sertraline to psychotherapy gave no additional benefit**, and the source concludes it is unclear which antidepressants work best or for whom. Fluoxetine is the EML-listed SSRI and sertraline is also listed; both off-patent, cents a day, a month of generic treatment costing a few US dollars or less.

**3. Brexanolone**, an intravenous allopregnanolone analogue approved in the United States in 2019. Some trials showed effects within 48 hours. It requires a **60-hour infusion**, enrolment in a risk-management programme, and continuous monitoring; side effects include sedation and loss of consciousness. Not on the EML, not off-patent, and launched in the United States at approximately **US$34,000 per course** before administration costs. This is the price-per-effect outlier of the chapter and the opposite of the magnesium sulfate case.

**4. Zuranolone**, an oral allopregnanolone analogue approved in the United States in 2023, given as a 14-day course. Side effects are sedation, somnolence and dizziness, and long-term efficacy is uncertain. Not on the EML, not off-patent, launched at approximately **US$15,900 per 14-day course** in the United States.

**5. Electroconvulsive therapy**, effective for severe postpartum depression that fails medication, and the treatment of choice for postpartum psychosis with risk to life.

**6. Repetitive transcranial magnetic stimulation.** Tentative evidence.

**7. Light aerobic exercise**, useful for mild to moderate cases.

Reported as unclear: acupuncture, massage, bright light therapy, omega-3 supplementation†. Hormone therapy has some evidence and estradiol patches may help; oestrogen carries clot risk up to 12 weeks postpartum, and no studies included breastfeeding women†.

**Simple means.** This condition is unusually well served by them, which is the central practical finding. - **Non-specialist delivered talking therapy.** Lay counsellors and nurses often deliver effective care. The Thinking Healthy Programme in Pakistan and the Friendship Bench model in Zimbabwe are the worked examples: supervised lay workers delivering a structured brief psychological intervention. No drug, no clinician, no supply chain. **This is the single most important item in this section.** - **Telephone peer support** — a phone. - **Home visiting**. - **A ten-item self-report questionnaire on one sheet of paper.** The Edinburgh Postnatal Depression Scale. **A score of 13 or more suggests postpartum depression and warrants further assessment**. Free, translated into most languages, widely validated. Note an inconsistency in use: a neonatal intensive care protocol uses 12 as the threshold while the general cut-off is 13†, and a score above zero on the self-harm item triggers immediate referral. - **Practical help with the baby, and sleep.** Sleep deprivation is both a symptom and a driver, and arranging that someone else takes a night is an intervention. - **Breastfeeding support.** Difficulty with feeding is a common precipitant, and supporting it is free. - **Exercise** — walking. - **Asking the question at all.** With 50 to 60 per cent of cases undiagnosed, the single highest-yield act is a health worker asking two questions at a postnatal contact.

The minimum chain: a sheet of paper and a trained lay worker. Nothing manufactured.

**Gaps.** Prevalence estimates range from about 7 to 57 per cent† across countries, and the source consulted is internally inconsistent for South America; most estimates rely on Western-developed screening tools and self-report, which the source itself flags as a bias, so cross-country comparison is not currently reliable. No systematic comparison between low- and middle-income and high-income countries exists in the sources reached. SSRI evidence is low-certainty and adding sertraline to psychotherapy added nothing, so the prescribing base is wider than the evidence base. There is no GBD cause line, so the condition is absent from the global burden accounts despite affecting roughly one in seven births. Screening thresholds differ between protocols in use. The two new effective drugs cost tens of thousands of dollars a course and are unavailable in the settings with the highest measured prevalence; the treatment with the best evidence for scale and the treatment with the fastest effect sit at opposite ends of the cost range, and no located analysis compares them per outcome. Paternal postpartum depression is measured at 8 to 10 per cent and has essentially no intervention evidence base.

---

## Maternal anaemia

**What it is.** Too little haemoglobin in the blood during pregnancy. Most often from lack of iron, because the baby's demand exceeds the mother's supply. It leaves the mother tired and breathless, and leaves her with no reserve if she bleeds at delivery.

**Measured.** WHO's standing published estimate is that anaemia affects approximately **37 per cent of pregnant women worldwide**, on a 2019 base year, and the WHO diagnostic threshold in pregnancy is **haemoglobin below 110 g/L**†. Both are reported as the standing figures; neither was verified against a source fetched in the retrieval round.

GBD reports anaemia as an **impairment** rather than a cause, with large contributions to years lived with disability; dietary iron deficiency ranks 9th among causes of years lived with disability in 2023 at **39.3 million (24.8 to 63.5)**. Anaemia has no maternal deaths line. Its mortality contribution is indirect, counted within GBD's indirect maternal deaths — **23,000 (16,300 to 32,700)** in 2023, down 22.5 per cent — together with other conditions aggravated by pregnancy. It is the mechanism by which a survivable postpartum haemorrhage becomes a fatal one.

Prevalence is highest in South Asia and sub-Saharan Africa, where hookworm, malaria, schistosomiasis and dietary iron inadequacy act in combination.

The trend is the point. **Global anaemia prevalence in women of reproductive age has been close to flat for two decades**, against a maternal mortality ratio that fell about 40 per cent over the same period. It is one of the least-improved indicators in maternal health.

**Where it starts.** Iron deficiency is the dominant cause, from low dietary intake of bioavailable iron, from closely spaced pregnancies depleting stores, and from chronic blood loss.

Three infections make the regional pattern: **hookworm** through intestinal blood loss, **malaria in pregnancy** through haemolysis and placental sequestration, and **schistosomiasis**. Folate, vitamin B12 and vitamin A deficiency contribute. **Haemoglobinopathies** — sickle cell trait and disease, the thalassaemias — are a major non-nutritional contribution in high-prevalence populations, and iron will not correct them. Short interpregnancy interval, adolescent pregnancy, high parity, HIV and chronic inflammation all raise risk. No effect sizes were retrievable.

What is not known is how much of the flat global trend is dietary, how much infectious and how much haemoglobinopathy, because the population-level causal partition of anaemia is not established in most high-burden settings. Surveys measure haemoglobin, not its cause. Ferritin and inflammatory markers are rarely measured at scale. This matters directly: iron supplementation is the near-universal programmatic response and it will not correct the non-iron fraction, whose size is unknown. There is also an unresolved question about iron supplementation in malaria-endemic settings, where trials have raised safety concerns.

**Cure status.** Iron-deficiency anaemia, which is most cases: CURABLE. Iron replacement restores haemoglobin and the mother recovers completely. Thalassaemia and sickle cell disease: CONTROLLABLE. Other non-iron causes: CONTROLLABLE, by disorder.

Curing the episode without addressing the cause — hookworm, malaria, diet, closely spaced pregnancies — produces recurrence. Maternal anaemia as a measured prevalence figure is a mixture whose curable fraction is large and not total.

**Prevention.** - **Daily oral iron and folic acid supplementation in pregnancy — STRONG**, and WHO-recommended as routine antenatal care at 30 to 60 mg elemental iron plus 400 µg folic acid daily. This also delivers the folic acid that prevents neural tube defects, so one tablet carries two effects. - **Intermittent weekly iron and folic acid supplementation — MODERATE**, where daily is not tolerated or not feasible. - **Food fortification of staples with iron — MODERATE.** The evidence base is weaker than for folic acid fortification, because iron fortificants have bioavailability and taste problems that folic acid does not. - **Deworming with albendazole or mebendazole after the first trimester in hookworm-endemic areas — STRONG** for the hookworm fraction. A single tablet, cents, EML-listed. - **Intermittent preventive treatment of malaria in pregnancy with sulfadoxine-pyrimethamine, plus insecticide-treated nets — STRONG** in endemic areas, for both anaemia and low birth weight. - **Delayed cord clamping — STRONG for the baby's iron stores**, reducing infant anaemia at six months. It does not treat the mother. - **Birth spacing and contraception — MODERATE**, allowing iron stores to recover. - **Antenatal care with haemoglobin measurement — STRONG**, as the delivery vehicle.

**Treatment. 1. Oral iron salts** — ferrous sulfate, fumarate or gluconate, with folic acid. The fixed combination of iron 60 mg plus folic acid 400 µg is EML-listed and off-patent, and a UNICEF indicative price in October 2026 put a bottle of 100 tablets at US$1.24, or **about US$0.012 a tablet**. A full pregnancy's supplementation therefore costs well under one US dollar. The limitation is gastrointestinal side effects causing substantial non-adherence, which is the main reason programmatic coverage does not translate into haemoglobin change. Alternate-day dosing improves absorption and tolerability.

**2. Intravenous iron** — ferric carboxymaltose or iron sucrose — for severe anaemia, late pregnancy, oral intolerance, or where time to delivery is short. Iron sucrose is EML-listed on the complementary list and off-patent; the newer high-dose formulations are not. Iron sucrose is moderately cheap and ferric carboxymaltose substantially more expensive, and the latter allows a single large dose, which matters when a woman presents once at 34 weeks and will not return. Both need an infusion facility and resuscitation capacity. Trials in Africa and India have shown intravenous iron corrects severe late-pregnancy anaemia faster than oral; whether that translates into fewer deaths is being tested and is not established.

**3. Blood transfusion** for severe symptomatic anaemia or acute blood loss. It requires a blood bank, which is one of the measured gaps behind the obstetric haemorrhage deaths.

**4. Treating the cause** — albendazole or mebendazole for hookworm, antimalarials, and vitamin B12 or folate replacement where deficient.

**5. For haemoglobinopathy** — transfusion programmes, hydroxyurea in sickle cell disease, and specialist management. Hydroxyurea is EML-listed for other specified sickle cell disorders and other haemoglobinopathies. Iron is **contraindicated** in iron-loaded thalassaemia, which is why diagnosing the cause matters.

**Simple means.** - **Iron and folic acid tablets.** About a cent a tablet. The single highest-value-per-euro item in this entry and, alongside magnesium sulfate, in the chapter. - **Dietary change** — pulses, dark green leaves, offal where culturally acceptable; vitamin C-containing food eaten with the iron source to raise absorption; avoiding tea and coffee with meals, which inhibit it. All free. - **Cooking in iron pots.** Measured to raise dietary iron content and, in trials in some settings, haemoglobin. It requires an iron pot. - **Handwashing, footwear and sanitation.** The hookworm transmission route runs through bare feet and open defaecation, so shoes are a haematological intervention in hookworm-endemic areas. - **Insecticide-treated bed nets** for the malaria fraction. - **Delayed cord clamping** at the birth, for the baby's stores. Free. - **Clinical pallor assessment** of conjunctiva, palms and tongue where no haemoglobinometer exists. Insensitive for mild anaemia and usable for severe. A **haemoglobin colour scale** — a printed card compared against a blood drop — is the next step up and costs almost nothing.

The minimum chain: a tablet costing about a cent, taken daily. For the severe cases presenting late, intravenous iron or blood, and both need a facility.

**Gaps.** The 37 per cent prevalence figure could not be verified against a source fetched in the retrieval round and is reported as WHO's standing published estimate. The causal partition of anaemia is unknown in most high-burden settings: iron is given to everyone because the non-iron fraction cannot be identified without laboratory capacity that does not exist there, and the size of the fraction iron cannot fix is genuinely not known. Global anaemia prevalence has not fallen while maternal mortality fell about 40 per cent, and no located analysis explains the divergence. Iron supplementation safety in malaria-endemic settings is unresolved: trials in children raised concerns about increased malaria morbidity with iron in high-transmission areas, and whether that extends to pregnancy is contested. Whether intravenous iron reduces maternal deaths, as opposed to correcting haemoglobin, is under trial and not established. Adherence rather than supply is the binding constraint on oral iron programmes, and adherence is poorly measured. GBD treats anaemia as an impairment rather than a cause, so it has no deaths line and its contribution to the maternal deaths it enables is not separately quantified anywhere.

---

## ICD-11 Chapter 19 — Certain conditions originating in the perinatal period

Eight entries. The chapter-level denominators are these. Neonatal deaths in 2022: **2.3 million**, in the first 28 days of life, about 6,500 a day, and **47 per cent of all under-5 deaths**. The figure was 5.0 million in 1990 and has fallen **44 per cent since 2000**, with the decline slowing since 2010. **Seventy-five per cent of neonatal deaths occur in the first week and about 1 million in the first 24 hours**.

---

The highest regional neonatal mortality rates are sub-Saharan Africa at **27 per 1,000 live births** and central and southern Asia at **21**, with national rates in 2022 ranging from **0.7 to 39.4 per 1,000**. Sixty-four countries are projected to miss the 2030 target.

GBD 2023 gives **neonatal disorders 1,628,000 deaths (1,506,000 to 1,748,000)** in 2023, down 37.6 per cent since 2000 — a lower figure than the 2.3 million above, because GBD's neonatal disorders is a cause group rather than all deaths occurring in the neonatal period. Both are printed. GBD 2023 ranks neonatal disorders **2nd among all DALY causes at 170 million DALYs (159 to 183)** and 13th among causes of years lived

No global neonatal mortality rate is asserted here. The reachable WHO page reports 2022 and gives no global rate and no 2023 figure, and the interagency report carrying the 2024 rate was not reached. Deriving a rate by arithmetic from deaths and births would present an estimate as a measurement.

## Preterm birth complications

**What it is.** The problems a baby has because it was born too early. The lungs, gut, brain, immune system and skin are all unfinished. The baby cannot keep itself warm, cannot feed reliably, and cannot fight infection.

**Measured.** Preterm birth complications: **623,300 deaths (509,700 to 735,000)** in 2023, down 41.4 per cent since 2000. **The single largest cause of neonatal death in the GBD series.** WHO gives about **900,000 children died in 2019** from preterm birth complications and states that three-quarters of those deaths could be prevented with current, cost-effective interventions. Both figures printed; different years, different models.

**Prematurity is the leading cause of death in children under 5**. Births: 13.4 million preterm in 2020, more than 1 in 10 babies, with the same page's metadata giving 15 million†; the country rate ranges from 4 to 16 per cent.

**The survival gradient is the central measured fact.** In low-income settings, **half of babies born at or below 32 weeks die**, often from lack of warmth, breastfeeding support, and treatment for infections and breathing difficulties — WHO's own list, and every item on it is a simple means. In high-income countries almost all of these babies survive. For extremely preterm babies under 28 weeks, **more than 90 per cent die within the first few days in low-income countries against under 10 per cent in high-income settings**.

**Where it starts.** The cause of the complications is immaturity of every organ system, with gestational age at birth the dominant determinant. The causes of the preterm birth itself belong to the preterm labour entry.

Gestational age is the strongest predictor of every outcome, with risk rising steeply below 32 weeks and sharply below 28. Birth weight contributes independently of gestation. **Male sex carries higher mortality and morbidity at every gestational age**, consistently and unexplained. Absence of antenatal corticosteroids, absence of a skilled attendant, delivery outside a facility with newborn care, and multiple pregnancy all raise risk. No effect sizes beyond the survival gradients were located.

Two things are not known. Why the male disadvantage exists. And, more consequentially, the **viability threshold is not a biological constant but a function of available care** — the same 24-week baby survives in one country and does not in another, so statements about the limit of viability are statements about the health system. Which component of newborn care accounts for most of the gradient is not separated by any analysis located: WHO's list of warmth, feeding, infection treatment and breathing support is given without weights.

**Cure status.** CURABLE for the neonatal course: the condition is time-limited and the child recovers completely. Prematurity is not a disease that persists; it is a developmental deficit that closes. A baby that survives the neonatal period at an appropriate weight and without brain injury becomes a normal child. That is also why the intervention set is so cost-effective: the investment is weeks long and the benefit is lifelong.

Two qualifications. A share of survivors carry permanent sequelae — cerebral palsy, cognitive impairment, retinopathy of prematurity, chronic lung disease — and those are RELIEF ONLY or CONTROLLABLE in their own right. And the cure is delivered by supportive care over weeks, not by a treatment that removes anything.

**Prevention.** Prevention of the preterm birth belongs to the preterm labour entry. For the complications, given a preterm birth: - **Antenatal corticosteroids — STRONG.** - **Kangaroo mother care — STRONG**, and the largest simple-means effect in this book. - **Delayed cord clamping — STRONG.** It reduces mortality in preterm infants in meta-analysis, reduces the need for transfusion, and improves iron stores. - **Thermal care from the first minute — STRONG.** Drying, a hat, skin-to-skin, a warm room. Hypothermia is a leading preterm killer and a free intervention prevents it. - **Exclusive breastfeeding or expressed breast milk — STRONG.** It reduces necrotising enterocolitis and late-onset sepsis, and the effect size for necrotising enterocolitis with human milk against formula is large in meta-analysis. - **Clean delivery and hand hygiene in newborn care — STRONG.** - **In-utero transfer to a facility with newborn care — STRONG.** - **Caffeine citrate for apnoea of prematurity — STRONG.** - **Magnesium sulfate antenatally for fetal neuroprotection — STRONG**, for cerebral palsy reduction. - **Prophylactic probiotics for necrotising enterocolitis — MODERATE**, with the caveat that benefit was clearest in exclusively human-milk-fed very low birth weight infants. - **Vitamin K at birth — STRONG**, for haemorrhagic disease of the newborn. - **Avoiding unnecessary antibiotic exposure — MODERATE.**

**Treatment. 1. Kangaroo mother care**, the highest-evidence, lowest-cost treatment in this chapter. The iKMC trial randomised **2,944 mothers and 3,211 infants** at five tertiary hospitals in Ghana, India, Malawi, Nigeria and Tanzania, at birth weights of 1.0 to 1.799 kg.

**28-day mortality: 12.0 per cent on immediate kangaroo mother care against 15.7 per cent on conventional care. Relative risk 0.75 (95 per cent CI 0.64 to 0.89), p = 0.001.** An absolute reduction of 3.7 percentage points and a **number needed to treat of about 27**†. Mortality at 72 hours was 4.6 against 5.8 per cent, relative risk 0.77 (0.58

to 1.04), not statistically significant†. The trial was stopped early by its data monitoring committee for benefit.

A 25 per cent relative reduction in neonatal death, from holding the baby against the mother's skin. No drug, no device, no electricity, no supply chain. WHO's 2022 recommendations state that immediate kangaroo mother care after birth can substantially reduce mortality in preterm and low-birthweight babies, and WHO's preterm fact sheet gives no numeric effect size, so the figures above are the trial's.

The earlier evidence — the original Colombian work and the subsequent Cochrane reviews — established benefit for **stabilised** low-birth-weight infants. iKMC's contribution was to show benefit when started immediately, before stabilisation, which overturned the prior standard of stabilising in an incubator first.

**2. Antenatal corticosteroids**, given to the mother before the birth. The ACTION-I trial, 2,852 women and 3,070 babies at 29 hospitals in Bangladesh, India, Kenya, Nigeria and Pakistan, found a significantly lower risk of neonatal death and of stillbirth with no increase in possible maternal bacterial infections. WHO does not publish the relative risk and it could not be verified against the primary paper. Dexamethasone is EML-listed and off-patent at a few US dollars per full course. Conditional on accurate gestational age assessment and adequate newborn care.

**3. Thermal care and feeding support.** Not drugs. WHO names the absence of warmth and of breastfeeding support as direct causes of the deaths above.

**4. Caffeine citrate** for apnoea of prematurity. EML-listed under medicines administered to the neonate, for apnoea of the newborn. Off-patent, low cost. The CAP trial showed reduced bronchopulmonary dysplasia and improved neurodevelopmental outcome at 18 to 21 months†.

**5. Surfactant** for respiratory distress syndrome. Beractant is EML-listed under medicines administered to the neonate. Not off-patent for most products, and **of the order of several hundred US dollars a dose**. This is the expensive item in neonatal care and the one that does not reach low-resource settings.

**6. Continuous positive airway pressure.** Bubble CPAP is the low-cost form and belongs in simple means.

**7. Antibiotics** for suspected sepsis — ampicillin plus gentamicin.

**8. Human milk, and donor human milk where the mother's is unavailable**, which reduces necrotising enterocolitis.

**9. Vitamin K** at birth, and iron and vitamin supplementation from a few weeks.

**Simple means.** This entry is the richest in the book for simple means, and the evidence behind them is first-rate rather than second-best. - **Kangaroo mother care. Relative risk 0.75 for 28-day mortality, over 3,211 infants in five countries**†. Continuous skin-to-skin contact between the carer's chest and the naked baby, with a cloth wrap to hold it, plus exclusive breastfeeding. **Cost: a length of cloth.** It delivers thermal care, feeding, infection protection through colonisation with maternal flora, cardiorespiratory stabilisation and bonding at once. No other intervention in this book has this effect size at this cost. - **Skin-to-skin contact in the first minutes**, which is the mechanism of the above and standard immediately after any birth. - **Delayed cord clamping.** Waiting at least 60 seconds. It reduces preterm mortality in meta-analysis, reduces transfusion need, and raises iron stores at six months. It costs nothing and requires the attendant to wait. - **Early and exclusive breastfeeding, including expressed milk by cup or tube**, which prevents necrotising enterocolitis and sepsis. Cup feeding needs a cup. - **The thermal care bundle**: immediate drying, removing the wet cloth, a hat, skin-to-skin, delayed bathing, a warm room, and keeping mother and baby together. Free. - **Bubble CPAP.** Oxygen or air bubbled through a bottle of water to generate positive airway pressure, with nasal prongs. It needs a gas source, which is the limiting input, and no ventilator and no electricity for the pressure itself. Published series from low-resource units report substantial reductions in mortality from respiratory distress. - **Clean hands.** - **Chlorhexidine cord care** in high-mortality community settings. - **A clock and a counting finger.** Respiratory rate counted for one minute is the diagnostic test for respiratory distress and for pneumonia. - **Cup feeding and nasogastric tube feeding** by a trained family member.

The minimum chain: a cloth, a cup, clean hands and someone willing to hold the baby continuously. Everything that produces the iKMC effect size is in that list.

**Gaps.** WHO's 900,000 deaths for 2019 and GBD's 623,300 for 2023 do not reconcile beyond the year difference; both printed. WHO publishes no numeric effect size for kangaroo mother care or antenatal corticosteroids on its own fact sheet, and the ACTION-I relative risk could not be verified against the primary paper. The components of the survival gradient are not weighted: WHO lists warmth, feeding, infection treatment and breathing support without saying how much of the 90-against-10 per cent mortality difference under 28 weeks each accounts for, and that is the most consequential analytic gap in the chapter — the intervention set is known and the priority ordering within it is not. iKMC was conducted in tertiary hospitals, so its applicability to home and primary-level births, where most of the deaths are, is an extrapolation. Surfactant and mechanical ventilation are effective and unaffordable at scale where the mortality is, and no located analysis addresses what the optimal package is at a given budget. Global preterm estimates are updated only every three to five years. Long-term neurodevelopmental follow-up of survivors in low-income settings is almost absent, so the sequelae burden is unmeasured where it is largest.

---

## Birth asphyxia and neonatal encephalopathy

**What it is.** The baby does not get enough oxygen around the time of birth. The brain is injured by the lack of oxygen and blood flow. The baby may not breathe at birth, may have seizures, and may be left with permanent brain damage.

**Measured.** Neonatal encephalopathy due to birth asphyxia and trauma: **562,100 deaths (471,400 to 678,700)** in 2023, down **31.9 per cent** since 2000†. The second-largest neonatal cause, and a notably slower decline than preterm birth complications at 41.4 per cent†.

WHO names birth complications among the leading causes of neonatal death; together with prematurity, infections and congenital anomalies these account for **almost 4 in 10 under-5 deaths**, a proportion that was the same in 2000 and in 2022.

No global incidence figure for neonatal encephalopathy was located from WHO or GBD. The commonly cited literature figure is of the order of 1 to 3 per 1,000 live births in high-income settings and several times that in low-income settings; it is not asserted here as a global estimate.

Neonatal encephalopathy is the leading cause of cerebral palsy attributable to perinatal events, and a leading cause of epilepsy and of cognitive impairment originating at birth. The surviving-disability burden is not separately quantified in the GBD cause structure reached. The deaths are concentrated where labour is not monitored and where no one at the birth can resuscitate a newborn.

**Where it starts.** Intrapartum events: obstructed labour, uterine rupture, cord prolapse, placental abruption, shoulder dystocia, and uterine hyperstimulation including from inappropriate oxytocin augmentation. Antepartum factors: pre-eclampsia, fetal growth restriction, maternal infection and chorioamnionitis, maternal diabetes, post-term pregnancy, multiple pregnancy. And the absence of a skilled attendant able to recognise fetal distress and to resuscitate. No effect sizes were located.

Two things are not known, and one of them is in the condition's name. **What share of neonatal encephalopathy is actually caused by intrapartum asphyxia is not established.** A significant proportion of cases have antenatal origins — infection, inflammation, thrombophilia, genetic and metabolic conditions, congenital brain malformation — and present as encephalopathy at birth without an intrapartum hypoxic event. The term birth asphyxia therefore attributes a cause that is not established in the individual case, and the GBD cause label embeds that attribution.

The second is the hypothermia contradiction, which has its own paragraph below.

**Cure status.** The established brain injury: RELIEF ONLY. Once hypoxic-ischaemic injury has occurred, nothing removes it. Therapeutic hypothermia reduces the extent of injury if started within six hours, in settings where it has been shown to work, and that is mitigation. Cerebral palsy, epilepsy and cognitive impairment resulting from it are permanent. The acute asphyxia, in the minute before: essentially preventable, and reversible. A baby that does not

breathe at birth and is successfully resuscitated within the first minute has, in the large majority of cases, **no injury at all.**

Everything in prevention and simple means is about that minute.

**Prevention.** - **Newborn resuscitation capability at every birth — STRONG.** This is the decisive intervention. Helping Babies Breathe and similar structured programmes teach bag-and-mask ventilation of the non-breathing newborn to birth attendants including non-clinicians. Published evaluations in Tanzania and elsewhere reported reductions in early neonatal mortality and in fresh stillbirth of the order of **25 to 50 per cent** after implementation†. **The implementation evidence is pre-post and programme evaluation rather than randomised**, and a large cluster-randomised trial of the package in India and other settings did not reproduce the effect. Both results belong in the record. - **Skilled attendance and intrapartum fetal monitoring — STRONG** for the outcome, with the qualification that continuous electronic fetal monitoring against intermittent auscultation has not shown a mortality benefit in high-income trials and increases caesarean rates. **Intermittent auscultation with a Pinard stethoscope or a Doppler is the evidence-supported standard**, not continuous electronic monitoring. - **Timely caesarean section for fetal distress and for obstructed labour — STRONG.** - **Avoiding uterine hyperstimulation from oxytocin augmentation — STRONG** on mechanism. This is an iatrogenic cause and avoiding it is free. - **Managing pre-eclampsia and growth restriction — MODERATE.** - **Antenatal corticosteroids** where preterm delivery is anticipated, which reduces the overlapping preterm burden. - **Delayed cord clamping and immediate thermal care** are supportive and do not prevent asphyxia. - **Partograph — CONTESTED** on outcome evidence.

**Treatment. 1. Newborn resuscitation with bag-and-mask ventilation, using air.** This is the treatment, and it is delivered in the first minute by whoever is present. **Air, not 100 per cent oxygen**, for term newborn resuscitation: meta-analysis of trials found lower mortality with room air than with 100 per cent oxygen†. This is a rare instance where the correct treatment is the one requiring no supply at all. The sequence is dry, stimulate, clear the airway if needed, position, and ventilate at about 40 breaths a minute; chest compressions and adrenaline are needed in a very small minority. The equipment is a self-inflating bag, a mask and a suction device, reusable, no power, **tens of US dollars a set**.

**2. Therapeutic hypothermia.** Cooling to 33 to 34 °C for 72 hours, started within six hours. This is the clearest case in the book of a guideline that does not travel between contexts, and it needs its own statement.

**In high-income settings, meta-analysis of the major trials — CoolCap, TOBY, NICHD, ICE and neo.nEURO — found reduced death or major disability, with a number needed to treat of approximately 7 for the composite outcome**†. On that evidence cooling became standard care for moderate and severe neonatal encephalopathy across high-income neonatal units.

**The HELIX trial, conducted in India, Sri Lanka and Bangladesh in 2021, found no reduction in death or disability and an increase in mortality with cooling**. That is a direct contradiction of the high-income result, in a population carrying the same nominal diagnosis, from the same intervention delivered to protocol.

The contradiction is not resolved. The candidate explanations — different injury timing, antenatal rather than intrapartum origin, co-existing infection, the absence of intensive care to support a cooled baby — have not been separated by any analysis located. What follows for practice is unambiguous even though the mechanism is not: WHO does not recommend therapeutic hypothermia outside settings with intensive care and the capacity to deliver it to protocol, and the low-cost adaptations — phase-change material, water bottles — are **unsupported rather than merely unproven**, because the trial conducted in the settings they were designed for found harm.

**3. Anticonvulsants for neonatal seizures.** Phenobarbital first line, EML-listed for epilepsy or seizures and for status epilepticus, off-patent; a UNICEF indicative price in October 2026 works out at about US$0.017 a 30 mg tablet. Levetiracetam is increasingly used, and trial evidence favours phenobarbital for initial seizure control.

**4. Supportive intensive care** — ventilation, blood pressure support, glucose and electrolyte management, treatment of coagulopathy and renal failure.

**5. For survivors with impairment:** physiotherapy, occupational therapy, feeding support, spasticity management, epilepsy treatment. All relief.

**Simple means.** - **Bag-and-mask ventilation with room air.** A self-inflating bag and a mask, reusable, costing a few tens of dollars, used by a trained birth attendant who need not be a doctor. **This is the single highest-value simple means in this chapter alongside kangaroo mother care**, because the window is one minute and the alternative is death or permanent brain injury. - **Drying and stimulation.** A substantial share of newborns who do not breathe immediately will breathe after being dried and rubbed. A cloth and two hands. - **Clearing the airway** — positioning, and suction with a bulb or a mucus extractor. - **Thermal care during and after resuscitation.** Hypothermia worsens the outcome and warming is free. - **Delayed cord clamping in the baby who is breathing**, with immediate clamping only where resuscitation at the mother's side is impossible. Resuscitation with the cord intact is increasingly supported and requires only that the resuscitation happen beside the mother. - **A Pinard stethoscope.** A wooden or plastic cone for intermittent auscultation of the fetal heart in labour. It costs almost nothing, is the evidence-supported monitoring standard, and needs no battery. - **Counting the fetal heart rate for a full minute** after a contraction. - **Not augmenting labour against an obstruction.** A decision, not a resource. - **Structured training.** Helping Babies Breathe uses a doll, a bag and mask, and a laminated flipchart. The entire intervention is a teaching package.

The minimum chain: a bag, a mask and a trained pair of hands. There is **no simple means for the established brain injury**, and the HELIX result means the improvised cooling approaches are not supported.

**Gaps.** The causal attribution in the condition's name is not established: an unknown but substantial share of neonatal encephalopathy is not caused by intrapartum asphyxia, and GBD's cause label embeds the attribution. No global incidence estimate was located. HELIX contradicts the high-income hypothermia trials and the contradiction is unresolved; it is the most important open question in the entry. Helping Babies Breathe has positive pre-post evaluations and a null cluster-randomised trial, and the programme is widely implemented on the pre-post evidence; both printed. Continuous electronic fetal monitoring does not reduce mortality and raises caesarean rates, and it remains standard in high-income practice, so the sources and the practice disagree. The disability burden among survivors is not separately quantified in the global accounts, and long-term follow-up in low-income settings is almost absent. The 31.9 per cent decline is the slowest of the major neonatal causes and no analysis located explains why.

---

## Neonatal sepsis

**What it is.** Bacterial infection in the bloodstream of a newborn. It can be acquired from the mother during birth, which is early-onset, or from the environment afterwards, which is late-onset. Newborns have little immune defence, so it progresses within hours.

**Measured.** Neonatal sepsis and other neonatal infections: **223,200 deaths (155,600 to 315,200)** in 2023, down 31.3 per cent since 2000†. The third-largest neonatal cause. It is described in the clinical literature as the single most common cause of in-hospital and community neonatal death in developing countries, with no figure or year attached to that statement on the source consulted.

**A unit error in the source must be carried as a correction.** United States early-onset sepsis incidence is **about 0.77 to 1 per 1,000 live births**†. **The source as fetched renders this as "0.77 to 1 per 100,000", which is inconsistent by two orders of magnitude with the low-birth-weight figures printed beside it on the same page.** The figure is reported here as per 1,000, which is the standard unit in that literature, and the discrepancy is stated rather than silently corrected. The original sources could not be checked directly.

Low birth weight raises early-onset sepsis incidence to roughly **26 per 1,000 and 8 per 1,000 live births** in two cited groups, and the source does not specify which group corresponds to which figure. African American preterm infants in the United States: **5.14 per 1,000 live births with a 24.4 per cent case fatality ratio**†.

**Culture yield is the central diagnostic problem: only 3 to 8 per cent of infants who receive a sepsis workup have positive cultures**. So the measured incidence is partly a measure of clinical suspicion.

Early-onset sepsis declined after the 1990s with group B streptococcus screening, and intrapartum antibiotics reduced its incidence between 2000 and 2020. No global incidence estimate per 1,000 live births was located from WHO or GBD.

**Where it starts.** Early-onset: maternal group B streptococcus colonisation, prolonged rupture of membranes, chorioamnionitis, maternal fever in labour, preterm birth, unclean delivery. Late-onset: the hospital environment, intravascular catheters, mechanical ventilation, prolonged hospitalisation, formula rather than breast milk feeding, unclean cord care, unwashed hands.

Prematurity and low birth weight raise risk steeply — the low-birth-weight incidence figures above are an order of magnitude above the general population. Mothers with poor healthcare access, low socioeconomic status or substance use have higher rates, and African American preterm infants have the highest infection and mortality rates in the United States data.

Organisms: **group B Streptococcus, *E. coli* and *Listeria monocytogenes*** are the empirically targeted maternal-tract organisms, with *Streptococcus pneumoniae* and *Neisseria meningitidis* also causing meningitis and bacteraemia, and anaerobes suspected in necrotising enterocolitis or intestinal perforation. **In low- and middle-income settings the organism mix differs substantially — Klebsiella, Staphylococcus aureus and Acinetobacter are prominent — and the empirical regimens designed around group B Streptococcus and *E. coli* are not matched to it**.

Three things are not known. The organism distribution where the deaths occur: blood culture capacity is absent in most high-mortality settings, so the pathogen mix is substantially unknown exactly where it determines whether the recommended antibiotics work. Which antibiotics are superior: the source states this plainly, citing Cochrane reviews on early-onset and late-onset regimens that could not resolve it. And, with only 3 to 8 per cent of workups culture-positive, how much of the measured incidence is disease.

**Cure status.** CURABLE. Antibiotics given early cure neonatal sepsis and the baby recovers completely. The determinants of survival are the interval to the first dose and whether the organism is susceptible. Where antibiotics are given promptly and the organism is susceptible, case fatality is low; where either fails, it is very high — the 24.4 per cent figure above is from a high-risk group in a high-income country. Meningitic sepsis leaves sequelae — hearing loss, hydrocephalus, cognitive impairment — in a share of survivors, and those are separate and permanent.

**Antimicrobial resistance is the live threat to this classification.** Where the prevalent organisms are resistant to ampicillin and gentamicin, the condition is not reliably curable with the drugs that are available, and that situation already exists in parts of South Asia and sub-Saharan Africa.

**Prevention.** - **Clean delivery and hand hygiene — STRONG.** The highest-yield preventive act, and nearly free. - **Chlorhexidine 7.1 per cent cord cleansing in high-mortality community settings — STRONG.** Trials in Nepal, Bangladesh and Pakistan found reductions in neonatal mortality of the order of **20 to 38 per cent** and in omphalitis of the order of 50 to 75 per cent, in community settings where unclean substances were traditionally applied to the cord. **WHO recommends it specifically for home births where neonatal mortality exceeds 30 per 1,000, and specifically recommends dry cord care elsewhere** — a trial in a hospital setting in Africa showed no benefit. The effect is conditional on the baseline practice, and both results belong in the record. The pooled relative risk could not be verified. - **Intrapartum antibiotic prophylaxis against group B streptococcus — STRONG** for early-onset group B disease. The measured consequence is the decline in early-onset sepsis after the 1990s. Penicillin is EML-listed, off-patent, cents. - **Exclusive breastfeeding — STRONG**, reducing late-onset sepsis and necrotising enterocolitis. - **Kangaroo mother care — STRONG**, partly through colonisation with maternal rather than hospital flora. - **Probiotics — MODERATE, and conditional.** A 2017 meta-analysis of 37 studies found **reduced late-onset sepsis risk only in exclusively human-milk-fed very low birth weight infants**, with no safety problems reported. An Indian randomised trial of **4,556 neonates** using *Lactobacillus plantarum* reported reduced sepsis risk, cited via news coverage on the

source consulted rather than the primary publication. - **Maternal tetanus immunisation**, for the tetanus fraction. - **Avoiding unnecessary antibiotic exposure — MODERATE.** Antibiotic overuse in infants is linked to microbiome changes associated with asthma, food allergies and childhood obesity, and promotes resistance. - **Infection control in neonatal units — STRONG.** Hand hygiene, catheter care bundles, cohorting.

**Treatment. 1. Empirical antibiotics, immediately on clinical suspicion.** WHO's recommended first line is **ampicillin, or benzylpenicillin, plus gentamicin**. Amoxicillin is EML-listed as an Access group antibiotic with neonatal sepsis among its first-choice indications; a UNICEF indicative price in October 2026 puts 250 mg dispersible tablets at **about US$0.054 each**. A full parenteral course costs a few US dollars.

The common alternative regimen is a third-generation cephalosporin, usually cefotaxime. **Ceftriaxone is specifically avoided in neonates because of kernicterus risk** — it displaces bilirubin from albumin. The antibiotic choice is constrained by the jaundice entry.

**Which antibiotics are superior is unknown.** The regimens are standard on pharmacological reasoning and susceptibility patterns, not on comparative trial superiority. Clindamycin is often added where necrotising enterocolitis or intestinal perforation is suspected.

**2. Source control** — removal of an infected catheter, and surgery for necrotising enterocolitis with perforation.

**3. Supportive care** — fluids, oxygen, thermal control, glucose, and inotropes where available.

**4. Adjuncts, with their results reported honestly.** - **GM-CSF: a 2009 randomised trial found it corrects neutropenia and does not reduce sepsis or improve survival**. A clear negative. - **Intravenous immunoglobulin: the INIS trial found no benefit**. A clear negative. - **Heart rate characteristics monitoring:** a randomised trial of **3,003 very low birth weight infants** found a **22 per cent reduction in all-cause mortality**, and a later report gave a **40 per cent reduction in mortality after infection**†. A positive result for a monitoring rather than a therapeutic intervention. - **The Sepsis Risk Calculator:** an independent Greek cohort of **2,084 infants** found it would significantly reduce antibiotic use **and would have missed a significant portion of clinical early-onset sepsis cases**. A systematic review linked its use to reduced antibiotic therapy. The trade-off is explicit and unresolved.

**Simple means.** - **Handwashing with soap.** The highest-yield act in the entry, for both prevention and interruption of unit outbreaks. - **Chlorhexidine cord cleansing** in the specific setting where it works. A small bottle of antiseptic, with a 20 to 38 per cent mortality reduction in community settings that traditionally apply harmful substances to the cord. - **Dry cord care** — nothing applied at all — in settings where that is already the practice. Here the simple means is the absence of an intervention. - **A clean delivery kit** — soap, a clean sheet, a sterile blade, clean string. - **Exclusive breastfeeding from the first hour.** Colostrum is an immune intervention. Free. - **Kangaroo mother care**, which substitutes maternal skin flora for hospital flora. - **Counting the respiratory rate and taking the temperature.** The clinical signs — poor feeding, lethargy, temperature instability, fast breathing — are detectable by a trained family member or community health worker with no equipment. **WHO's integrated management algorithms for possible serious bacterial infection are built to be used by non-clinicians precisely because the cure depends on the interval.** - **Oral or intramuscular antibiotics at community level** where referral is impossible. WHO's simplified regimens for young infants with possible serious bacterial infection when referral is not feasible — oral amoxicillin plus injectable gentamicin, in reduced-duration schedules — were established by the AFRINEST and SATT trial programmes to be non-inferior to full hospital regimens for defined clinical syndromes. **This is the finding that puts cure within reach of a community health worker.**

The minimum chain: soap for prevention, manufactured antibiotics for cure. There is no simple-means substitute for the antibiotic. Prevention is nearly free and cure is not improvisable.

**Gaps. The source as fetched reports United States early-onset sepsis incidence as 0.77 to 1 per 100,000 live births, which is inconsistent by two orders of magnitude with the low-birth-weight and African-American-preterm figures given beside it. It is reported here as per 1,000, the standard unit in that literature, and flagged; the**

**original papers could not be checked directly.** No global incidence estimate exists in the sources reached. The organism mix where the deaths occur is unknown for want of blood culture capacity. Which antibiotic regimen is best is unknown, and two Cochrane reviews could not settle it. Only 3 to 8 per cent of sepsis workups are culture-positive, so incidence figures largely measure clinical suspicion. No antimicrobial resistance statistics were available on the source consulted, and resistance is the principal threat to curability; this is the most serious data gap in the entry. Chlorhexidine cord care works in community settings and not in hospital settings, so the effect depends on what it replaces, and the pooled figure could not be verified. The Sepsis Risk Calculator reduces antibiotic use and misses cases, and that trade-off is unresolved. The low-birth-weight incidence figures of 26 and 8 per 1,000 are reported without which group each belongs to.

---

## Neonatal jaundice and kernicterus

**What it is.** Yellow staining of a newborn's skin and eyes from bilirubin, the breakdown product of red blood cells. Most of it is normal and passes. If the level climbs high enough the bilirubin enters the brain and causes permanent injury, which is kernicterus.

**Measured.** Haemolytic disease and other neonatal jaundice: **30,300 deaths (16,700 to 47,800)** in 2023, down **69.4 per cent** since 2000†. **This is the largest proportional decline of any cause in this chapter** and one of the largest in the book.

**The two best available death estimates differ threefold.** GBD 2023 gives 30,300. A 2018 analysis based on the GBD 2016 study gives **over 100,000 late-preterm and term babies dying each year from jaundice, mostly in low- and middle-income countries**. The years and the methods differ. Neither source explains the gap, and both are printed; it is the largest unresolved quantitative disagreement in this chapter.

Jaundice itself affects about **60 per cent of term and 80 per cent of preterm newborns** in the first week of life†; an infobox on the same source gives a broader more than 50 per cent of babies†. Both printed.

**Kernicterus incidence: no numeric global or regional figure was located.** The source states that screening, phototherapy and exchange transfusion have dramatically reduced severe complications. Kernicterus is rare in term infants even at 25 mg/dL and substantially more likely in preterm infants†.

Deaths and kernicterus are overwhelmingly in low- and middle-income settings. In high-income countries kernicterus is a reportable near-elimination event. G6PD deficiency prevalence is high across sub-Saharan Africa, the Mediterranean, the Middle East and Southeast Asia, which patterns the severe cases.

**Where it starts.** Physiological immaturity of hepatic bilirubin conjugation in the first week is the cause of the normal 60 to 80 per cent. Haemolysis from rhesus or ABO blood group incompatibility, G6PD deficiency and hereditary spherocytosis produce the dangerous levels. Prematurity raises vulnerability at any given bilirubin level, through lower albumin binding and an immature blood-brain barrier. Sepsis, cephalohaematoma and bruising from instrumental delivery, and inadequate feeding and dehydration — which concentrate bilirubin and reduce its excretion — all contribute. **Ceftriaxone and certain other drugs displace bilirubin from albumin**, which is an iatrogenic route and the reason ceftriaxone is avoided in neonates. Breastfeeding jaundice from insufficient intake in the first days and breast milk jaundice, a later benign prolonged form, are distinct entities, and the first is a feeding problem rather than a reason to stop breastfeeding. No effect sizes were located.

What is not known is **the bilirubin level at which an individual baby will be injured.** The treatment thresholds are population conventions rather than individual tolerances. The source notes kernicterus is rare in term infants even at 25 mg/dL, which means many babies tolerate levels at which others are injured, and no test identifies which. Albumin binding capacity, the bilirubin-to-albumin ratio and individual blood-brain barrier variation have all been proposed and none is established as a clinical discriminator. Also unknown: how many kernicterus cases occur, because in the settings where they occur they are not registered.

**Cure status.** The jaundice, before the brain is stained: CURABLE. Blue light converts bilirubin in the skin to water-soluble isomers that the baby excretes. **Phototherapy removes the**

**cause of injury using light.** Exchange transfusion removes it mechanically where light is insufficient. A baby treated in time has no sequelae whatever and needs no follow-up. Kernicterus, once established: RELIEF ONLY. It is permanent — choreoathetoid cerebral palsy, sensorineural hearing loss, upward gaze palsy, dental enamel dysplasia, cognitive impairment. Nothing reverses it.

The two strata are divided by a window of hours to days. The 69.4 per cent death decline is what happens when the light arrives in time, and the over-100,000 estimate is what happens when it does not.

**Prevention.** - **Anti-D immunoglobulin to RhD-negative mothers — STRONG.** Prophylaxis in pregnancy and after delivery, and after any sensitising event including miscarriage, prevents rhesus haemolytic disease in subsequent babies. This came close to eliminating the single most dangerous cause of neonatal jaundice in countries that implemented it, and the 69.4 per cent death decline substantially reflects it. EML-listed, off-patent as a plasma-derived product with supply rather than patent the constraint, moderate cost. **Its absence is why severe haemolytic disease persists where antenatal care does not include blood grouping.** - **Early and effective feeding — STRONG.** Adequate milk intake drives bilirubin excretion. Free. - **Universal pre-discharge bilirubin screening with a nomogram — MODERATE.** It reduces severe hyperbilirubinaemia and readmission, and has been adopted as standard in several high-income systems. - **G6PD screening in high-prevalence populations — MODERATE.** It identifies the babies who need closer watching and whose families need to avoid known triggers. - **A postnatal follow-up contact in the first three to five days — STRONG.** Bilirubin peaks after most babies have gone home, and the babies who develop kernicterus are very often babies who were discharged well. - **Not using ceftriaxone in neonates — STRONG**, for the iatrogenic route. - **Avoiding naphthalene mothballs, menthol-containing products and known oxidant triggers in G6PD-deficient infants — MODERATE.** - **Parent education on recognising deepening jaundice** — including that jaundice progressing to the palms and soles, poor feeding or lethargy means return immediately. Free, and it addresses the dominant delay.

**Treatment. 1. Phototherapy.** Blue light at 460 to 490 nm, applied to the maximum skin area. The landmark randomised trial establishing it was published in 1968, and the original observation was made in 1958; the source gives no effect size from that trial. With intensive phototherapy, total serum bilirubin should fall by 1 to 2 mg/dL within 4 to 6 hours, and the source attaches no citation to that figure. The 2022 American Academy of Pediatrics threshold is that any newborn above **359 µmol/L, or 21 mg/dL**, should receive phototherapy, with lower thresholds for preterm babies and those with risk factors, on gestational-age and hour-specific nomograms.

Not a drug. The equipment is an LED or fluorescent blue light unit. **LED units cost of the order of hundreds of US dollars are low-power, long-lived, and can run from solar or battery supply**. This is the pivotal fact about the condition: the cure is a lamp.

**2. Exchange transfusion**, for bilirubin above the exchange threshold or for rapidly rising levels despite intensive phototherapy. The 2004 American Academy of Pediatrics guidance is that any newborn above **428 µmol/L, or 25 mg/dL**, should undergo exchange transfusion. It lowers bilirubin by roughly 50 per cent. It requires cross-matched blood, umbilical venous access and a trained operator, and it carries real procedural mortality and morbidity. **This is the procedure that phototherapy exists to avoid, and the procedure that is unavailable in most places where it is needed.**

**3. Intravenous immunoglobulin** in haemolytic disease, to reduce the need for exchange transfusion. The evidence is moderate and has weakened in later trials.

**4. Adequate hydration and feeding support.** Not fluids for their own sake — intravenous fluid supplementation does not reduce bilirubin in the well-hydrated — but effective feeding does.

**5. Treating the underlying cause** — sepsis, and for haemolytic disease the antenatal management of rhesus disease including intrauterine transfusion.

Phenobarbital, agar, charcoal and metalloporphyrins have all been proposed; none is standard, and tin-mesoporphyrin remains investigational.

**Simple means.** This is the entry where the simple-means question has the most interesting answer in the book. - **Filtered sunlight phototherapy.** Sunlight contains the therapeutic wavelengths. The problem is that it also contains ultraviolet and infrared, which burn and overheat. Randomised trials in Nigeria used canopies of commercially available window-tinting film that filter out ultraviolet and most infrared while transmitting the blue therapeutic band. They were designed as **non-inferiority comparisons against conventional electric phototherapy**, with the primary outcome the proportion of treatment days on which the method achieved an adequate rate of bilirubin decline, and they reported filtered sunlight **non-inferior**, with monitored safety outcomes — sunburn, hyperthermia, dehydration — remaining acceptable under supervision. The primary papers could not be retrieved, so the sample sizes, percentages and confidence intervals are not asserted. What can be stated without them: filtered sunlight phototherapy has been tested in randomised non-inferiority trials in a high-burden setting and found non-inferior, and it requires a canopy, tinting film and supervision. - **Unfiltered sunlight exposure is not recommended.** The burn, hyperthermia and dehydration risks are real and WHO has not endorsed it. The distinction between filtered and unfiltered is the whole of the evidence, and conflating them is dangerous. - **Solar-powered and battery LED phototherapy units.** Low-power LED arrays running from a small photovoltaic panel and battery. This is the engineering answer where mains electricity is absent, and it keeps the intervention inside the trialled modality rather than substituting an untested one. - **Effective breastfeeding, frequently.** Bilirubin leaves in the stool and feeding drives it. Free, and it is the single most common deficiency in the babies who become severely jaundiced. - **Looking at the baby in daylight, pressing the skin, and checking the palms and soles.** Clinical assessment by cephalocaudal progression is insensitive, free, and detects the severe cases. **An icterometer** — a strip of calibrated yellow glass or plastic pressed against the nose — costs almost nothing. - **Postnatal home visits on days 2 to 4.** The intervention is a visit. - **Anti-D immunoglobulin** is not a simple means, being plasma-derived and cold-chain dependent, and it is named here because its absence creates the cases.

The minimum chain: a lamp, or a canopy of tinting film and the sun. For the cases beyond light, cross-matched blood and an operator, and there is no simple-means substitute for exchange transfusion.

**Gaps. The two best available death estimates differ threefold: 30,300 from GBD 2023 against over 100,000 from the 2018 analysis based on GBD 2016.** Both printed; the discrepancy is not explained in either source. No kernicterus incidence figure exists at global or regional level: the condition that matters most is the one least counted, because it occurs where vital registration does not. The filtered sunlight trial figures could not be verified, so the non-inferiority conclusion is reported and the numbers are not. The injury threshold is a convention rather than a measurement, and no test identifies the individual baby's tolerance; the 2004 and 2022 guidance thresholds differ, and the 2022 revision raised phototherapy thresholds in some categories, so guidance has moved in both directions. The 1 to 2 mg/dL per 4 to 6 hours figure for intensive phototherapy carries no citation on the source consulted. The 1968 trial established phototherapy without a reported effect size in the source reached, and the modern evidence base is nomogram-driven observational practice rather than contemporary randomised comparison, because withholding phototherapy is no longer ethical. G6PD deficiency patterns the severe cases and G6PD screening coverage is not reported anywhere located.

---

## Low birth weight and small for gestational age

**What it is.** A baby born weighing less than 2,500 grams. Either because it was born early, or because it grew poorly in the womb, or both. Small for gestational age means below the tenth weight centile for its gestation — a baby that did not grow as it should have.

**Measured.** WHO names low birth weight as a cause of hearing loss and other sequelae and publishes no global count on the fact sheets reachable.

GBD does not carry low birth weight as a **cause**. It is a **risk factor** in the GBD risk architecture, as low birthweight and short gestation, which ranks fifth among the top ten risks by health loss in 2023. That is why it has no deaths line of its own in this chapter. As a risk

factor it attributes a very large share of neonatal death to itself, overlapping almost entirely with preterm birth complications, asphyxia and sepsis, and the figures cannot be added.

The standing published estimates, reported as such: approximately **14.7 per cent of live births, about 19.8 million babies, were low birth weight in 2020**, with the large majority in South Asia and sub-Saharan Africa and the global trend close to flat since 2000†. Neither was verified against a source fetched in the retrieval round.

Small for gestational age and preterm overlap partially, and the three groups — preterm appropriately grown, term small for gestational age, and preterm and small — carry different risks. **Term small-for-gestational-age babies are the largest group in South Asia, and preterm is the dominant route in sub-Saharan Africa**.

Like anaemia, low birth weight prevalence is among the least-improved maternal and newborn indicators.

**Where it starts.** Maternal undernutrition before and during pregnancy — short stature, low pre-pregnancy body mass index, inadequate gestational weight gain — is the dominant driver of term small-for-gestational-age in South Asia. Maternal anaemia contributes. **Malaria in pregnancy**, through placental sequestration, is a major driver in sub-Saharan Africa. Pre-eclampsia and placental insufficiency, smoking including second-hand smoke, and household air pollution from solid cooking fuels all restrict growth; smoking's effect on birth weight is one of the best-quantified exposures in perinatal epidemiology. Adolescent pregnancy, short interpregnancy interval, high parity, maternal infections including HIV and syphilis, multiple pregnancy, congenital anomalies and congenital infections all raise risk. Female sex carries a lower mean birth weight and is not pathological. **The mother's own birth weight** matters: the intergenerational transmission of growth restriction is established and is why the condition does not respond quickly to intervention. No effect sizes were retrievable.

Three things are not known. How to distinguish, at birth and without serial antenatal measurement, a baby that is **constitutionally small** from one that is **growth-restricted** — a crucial difference, because the first is well and the second is at risk; customised growth standards partly address this and are contested. How much of the flat global trend is nutritional, infectious or intergenerational, because the causal partition has not been established at population level. And whether antenatal detection of growth restriction improves outcomes, which is not settled, because detection leads to earlier delivery, which trades growth restriction for prematurity.

**Cure status.** The weight deficit itself: CURABLE. A low birth weight baby that survives and is fed catches up, and most reach a normal weight in infancy or childhood. The developmental-origins metabolic consequence, in a share: RELIEF ONLY. The established association with adult cardiovascular disease, type 2 diabetes and hypertension is strong and observational, and nothing reverses it.

The stunting that follows in a proportion of these children is only partly reversible and only if addressed early. Rapid catch-up growth itself carries metabolic risk, so the cure is not simply to feed more.

**Prevention.** - **Balanced energy-protein supplementation for undernourished pregnant women — STRONG.** Meta-analyses show reduced small-for-gestational-age and low birth weight, with an effect modest in grams and meaningful at the threshold. - **Multiple micronutrient supplementation in pregnancy rather than iron-folic acid alone — STRONG.** Meta-analysis shows reductions in low birth weight and small-for-gestational-age of the order of **10 to 15 per cent relative** for low birth weight†. WHO's recommendation has moved toward it in the context of rigorous research and implementation. Cost is a few US dollars per pregnancy for the UNIMMAP formulation — slightly more than iron-folic acid, which is the barrier. - **Intermittent preventive treatment of malaria in pregnancy plus insecticide-treated nets — STRONG** in endemic areas, with measured increases in mean birth weight. - **Smoking cessation in pregnancy — STRONG.** One of the largest single modifiable effects on birth weight. - **Clean cooking fuel and reducing household air pollution — MODERATE.** - **Treating maternal anaemia — MODERATE.** - **Preventing adolescent pregnancy, and birth spacing — MODERATE.** - **Syphilis screening and treatment in pregnancy — STRONG** for the syphilis-attributable fraction. A single dose of benzathine benzylpenicillin, EML-listed with syphilis as its first-choice indication; a UNICEF indicative price in October 2026 works out at **about US$0.59 a 2.4 MIU vial** in the fifty-vial

pack, against US$3.01 for the single-vial pack with solvent. - **Low-dose aspirin for women at risk of pre-eclampsia — MODERATE**, via the placental pathway. - **Deworming in hookworm-endemic areas — MODERATE**, via anaemia. - **Antenatal care with fundal height or ultrasound growth monitoring — MODERATE**, with the caveat that the benefit of detection is itself uncertain. - **Improving girls' nutrition and preventing stunting — STRONG and generation-long.** The most important and the slowest.

**Treatment.** For the baby after birth. **1. Kangaroo mother care.** The iKMC trial population **was** low birth weight babies, at 1.0 to 1.799 kg: **28-day mortality 12.0 against 15.7 per cent, relative risk 0.75 (0.64 to 0.89), p = 0.001**, over 3,211 infants in five countries†. **This is the primary treatment for low birth weight and it is free.**

**2. Exclusive breastfeeding, with expressed milk by cup or tube where suck is immature**, and donor human milk where the mother's is unavailable. It reduces necrotising enterocolitis and sepsis.

**3. Thermal care** — drying, a hat, skin-to-skin, a warm room, delayed bathing.

**4. Delayed cord clamping at birth.** It raises haemoglobin and iron stores, reduces infant anaemia at six months, reduces transfusion need in preterm infants, and reduces mortality in preterm infants in meta-analysis. **Free.**

**5. Vitamin K at birth, iron supplementation from two to six weeks, and vitamin D.** All EML-listed, off-patent, cents.

**6. Monitoring and treating hypoglycaemia.** Low birth weight babies have minimal glycogen reserve. Early and frequent feeding is the prevention; measured glucose and oral or intravenous dextrose the treatment.

**7. Treating infection promptly.** These babies carry an order-of-magnitude higher sepsis incidence.

**8. Growth monitoring and nutritional support through infancy**, with attention to the catch-up growth trade-off above.

**Simple means.** - **Kangaroo mother care.** A cloth. **Relative risk 0.75 for 28-day mortality**†. - **Skin-to-skin contact from the first minute.** - **Delayed cord clamping.** Waiting 60 seconds. Free, and one of the few interventions whose benefit extends to the infant's haemoglobin at six months. - **Breastfeeding initiation within the first hour.** Free, and the strongest determinant of whether a low birth weight baby feeds successfully at all. - **Cup feeding and expressed milk** — a cup and a clean container. - **Weighing the baby.** A spring scale or a beam scale. **Knowing the birth weight is what triggers everything else in this list**, and an unweighed baby is an unidentified one. A colour-coded weighing sling costs a few dollars. - **A hat.** The head is the largest surface area for heat loss in a small baby. - **The thermal care bundle.** - **Hand hygiene.** - **Community-based follow-up with weighing.**

The minimum chain: a cloth, a cup, a scale and a hat. The entire effective treatment package for low birth weight in the setting where most of it occurs is in that list, and the iKMC effect size attaches to the first item.

**Gaps.** The prevalence figures could not be verified against a source fetched in the retrieval round and are reported as the standing interagency estimates. GBD treats low birth weight as a risk factor rather than a cause, so it has no deaths line and its burden overlaps irreducibly with preterm birth, asphyxia and sepsis; the figures cannot be summed with those entries. Constitutional smallness cannot be distinguished from growth restriction without serial measurement, and customised growth standards are contested. Whether antenatal detection of growth restriction improves outcomes is unsettled, because the response to detection is earlier delivery, which substitutes prematurity for restriction. The causal partition of low birth weight is not established at population level. Global prevalence has not fallen while neonatal mortality fell 44 per cent†, and no located analysis explains the divergence. The developmental-origins literature is observational, large, consistent, and unable to exclude confounding by the socioeconomic conditions that produce both the low birth weight and the adult disease. The catch-up growth trade-off is unresolved: the nutritional intervention that corrects the deficit may carry the metabolic risk, and no trial has settled the optimal trajectory.

## Respiratory distress syndrome of the newborn

**What it is.** A preterm baby's lungs lack surfactant, the substance that keeps the air sacs from collapsing at the end of each breath. The baby works harder and harder to reinflate collapsed lungs and tires. Also called hyaline membrane disease.

**Measured.** GBD **includes neonatal respiratory distress syndrome inside preterm birth complications** and does not report it as a separate cause, so **there is no separate deaths figure**.

Incidence is a steep function of gestational age: in the published literature it affects the large majority of babies born before 28 weeks, declining to a small minority at 34 to 36 weeks and rarely occurring at term†. No global incidence estimate was located.

The relevant measured quantity is the survival gradient. In low-income settings **half of babies born at or below 32 weeks die**, often from untreated breathing difficulties among other causes, and **more than 90 per cent of babies under 28 weeks die within the first few days in low-income countries against under 10 per cent in high-income settings**.

In high-income settings, mortality from respiratory distress syndrome fell steeply from the late 1980s with surfactant and from the 1970s with antenatal corticosteroids. In low-income settings the fall has been much smaller, because the two effective interventions have very different prices.

**Where it starts.** Gestational age is the dominant determinant: surfactant production rises sharply after about 34 weeks, so risk is essentially a function of how early the birth is. Absence of antenatal corticosteroids raises it, because the drug accelerates surfactant production. **Male sex** carries higher incidence and severity at the same gestation, consistently and unexplained. **Maternal diabetes** delays surfactant maturation independently of gestation, so a diabetic mother's baby may have respiratory distress syndrome at a gestation where it would be unexpected. **Caesarean section without labour** raises risk, because labour itself promotes lung fluid clearance. Perinatal asphyxia, hypothermia, multiple pregnancy, being the second twin, and family history all contribute. No effect sizes were located.

Two things are not known. The male disadvantage. And, more practically, **how much of the respiratory mortality in low-resource settings is respiratory distress syndrome and how much is pneumonia, sepsis, transient tachypnoea or meconium aspiration**, because the diagnosis requires chest radiography and blood gases that are not available. The conditions are treated as one clinical syndrome of respiratory distress, and the component proportions are unknown exactly where the deaths are.

**Cure status.** The syndrome itself: SELF-LIMITING. It is self-resolving within days to a week as the baby's own surfactant production begins, and the entire clinical task is to keep the baby alive and the lungs open until that happens. Surfactant replacement and positive airway pressure do that, and a baby that survives it has normal lungs. Nothing persists. Bronchopulmonary dysplasia in a share of survivors: CONTROLLABLE at best. It affects particularly the most immature and those ventilated longest, and carries years of increased respiratory morbidity. Aggressive mechanical ventilation is itself a cause of it, which is why the shift toward CPAP and less invasive surfactant administration has been the main advance of the last two decades.

**Prevention.** - **Antenatal corticosteroids — STRONG, and this is the prevention. Dexamethasone, a few US dollars a course, EML-listed, off-patent**. The ACTION-I trial, 2,852 women and 3,070 babies in five countries, found significantly lower neonatal death and stillbirth in low-resource hospitals, and WHO publishes no relative risk on that page. The original high-income evidence is the Liggins and Howie trial of 1972 and the subsequent Cochrane review, which established reductions in respiratory distress syndrome, neonatal death and intraventricular haemorrhage. - **Preventing preterm birth — STRONG** where possible. - **Avoiding non-medically-indicated caesarean before 39 weeks — STRONG.** An iatrogenic cause, and avoiding it is free. - **Maternal glycaemic control — MODERATE.** - **Thermal care from the first minute — STRONG.** Hypothermia worsens surfactant function and increases oxygen consumption. Free. - **Delayed cord clamping — MODERATE**, for reduced need for respiratory support in preterm infants. - **Antenatal thyrotropin-**

**releasing hormone — ineffective and harmful.** A settled negative, reported because it was once standard.

**Treatment. 1. Antenatal corticosteroids**, given before birth to the mother. **The highest effect-per-euro intervention in this entry by a wide margin.**

**2. Continuous positive airway pressure, started early.** Trials comparing early CPAP against routine intubation and ventilation — COIN, SUPPORT, CURPAP and the subsequent meta-analyses — found **CPAP non-inferior or superior for death or bronchopulmonary dysplasia**, with less intubation. Early CPAP is now the first-line respiratory support for spontaneously breathing preterm infants. **Bubble CPAP** is the low-cost implementation; published series from low-resource neonatal units report substantial mortality reductions after introduction, on pre-post rather than randomised evidence. The equipment is a gas source, tubing, nasal prongs and a water column, and **the gas source is the binding constraint** — oxygen concentrators running on mains or solar power have changed that in some settings.

**3. Exogenous surfactant replacement.** The single most effective specific treatment: the original randomised trials and meta-analyses established **reductions in mortality of the order of 30 to 40 per cent relative** and reductions in pneumothorax in treated preterm infants. Animal-derived preparations — poractant alfa, beractant, calfactant — outperform the early synthetic ones. Beractant is EML-listed under medicines administered to the neonate for respiratory distress syndrome of the newborn. Not off-patent for the current animal-derived products in most markets, and the manufacturing — porcine or bovine lung extraction and purification — is itself a barrier independent of patent. **Cost: hundreds to thousands of US dollars a dose**, with some babies needing more than one. **This is the most expensive single item in the chapter's treatment set and the clearest case in it of an effective treatment that does not reach the patients who need it.** Administration has moved from intubation-surfactant-extubation toward **less invasive surfactant administration** via a thin catheter in a baby on CPAP, which avoids intubation altogether.

**4. Supplemental oxygen, with targeted saturation.** Both too little and too much oxygen cause harm: too much causes retinopathy of prematurity and oxidative lung injury. The target saturation trials — SUPPORT, BOOST-II and COT — found **lower targets reduced retinopathy and increased mortality**, and the current consensus target of 90 to 95 per cent is a compromise with acknowledged uncertainty†. **A pulse oximeter is therefore essential equipment**, and it is cheap at tens of dollars and low-power.

**5. Mechanical ventilation** where CPAP fails. Effective and expensive, and itself a cause of bronchopulmonary dysplasia.

**6. Caffeine citrate**, which reduces apnoea, facilitates extubation and reduces bronchopulmonary dysplasia. EML-listed, off-patent, low cost.

**7. Thermal care, fluid and glucose management, and treatment of concurrent sepsis.**

**Simple means.** - **Bubble CPAP.** Blended air or oxygen delivered through nasal prongs, with the expiratory limb submerged in a column of water to a depth of 5 to 8 cm, which sets the pressure. **Assemblable from tubing, a bottle, water and a measuring scale.** It needs a gas source and a flow meter, which are manufactured, and no ventilator, no electricity for the pressure generation, and no electronics. **The most important intermediate technology in neonatal care**, and the reason respiratory distress syndrome is survivable in units with no ventilator. - **Oxygen from a concentrator** running on mains or solar, which removes the cylinder supply chain. - **A pulse oximeter.** Tens of dollars, battery or solar powered, and it is what prevents both hypoxia and oxygen toxicity. Close to a simple means in cost and entirely essential. - **Thermal care:** drying, a hat, skin-to-skin, a warm room, delayed bathing. Hypothermia directly worsens surfactant function. Free. - **Kangaroo mother care** once the baby is stable enough — and iKMC established benefit when begun before stabilisation. - **Positioning.** Prone positioning improves oxygenation in the preterm infant. Free. - **Counting the respiratory rate and observing grunting, recession and nasal flaring.** The clinical diagnosis requires no equipment, and the Silverman-Andersen score is a laminated card. - **Feeding by cup or tube** rather than withholding feeds unnecessarily. - **Antenatal dexamethasone.** Not quite a simple means — ampoules and a syringe — and close to one, and its effect is the largest here.

The minimum chain: a gas source and a bottle of water. Below that, thermal care, positioning and kangaroo care remain. **There is no simple-means substitute for surfactant**, and that is the honest limit of this entry.

**Gaps.** There is no separate GBD cause line and no global incidence estimate; the condition sits inside preterm birth complications. The component diagnoses within neonatal respiratory distress are not separated in low-resource settings for want of radiography and blood gases, so what proportion of those deaths surfactant would prevent is unknown. Surfactant costs hundreds of dollars a dose and is EML-listed, and the gap between listing and availability is the central practical fact, which no located analysis quantifies. The ACTION-I relative risk could not be verified against the primary paper and WHO does not publish it. Bubble CPAP's mortality evidence in low-resource settings is pre-post rather than randomised. Optimal oxygen saturation targets are unresolved, with lower targets reducing retinopathy and increasing mortality across three trials, and the current compromise target acknowledged as such. The male disadvantage is unexplained. Long-term pulmonary outcomes of survivors in low-resource settings are essentially unmeasured.

---

## Neonatal hypothermia

**What it is.** A newborn's body temperature falling below normal. Babies are born wet, have a large surface area for their weight, little fat, and cannot shiver effectively. In a cool room a naked wet newborn loses heat fast enough to become hypothermic within minutes.

**Measured.** GBD does not carry neonatal hypothermia as a cause. **It has no deaths line.** Its mortality contribution is counted within preterm birth complications, sepsis and other neonatal disorders, because it kills by worsening those conditions rather than as a recorded cause of death.

WHO names the absence of **warmth** first in its list of what the babies in low-income settings die from: often from lack of basic care such as warmth, breastfeeding support, and treatment for infections and breathing difficulties.

WHO's classification thresholds: normal axillary temperature **36.5 to 37.5 °C**; **mild hypothermia, or cold stress, 36.0 to 36.4 °C; moderate 32.0 to 35.9 °C; severe below 32.0 °C**†.

Facility-based studies across South Asia and sub-Saharan Africa have repeatedly measured hypothermia in a large fraction — in many series a majority — of newborns in the first hours, including in warm climates and including inside hospitals. **No global estimate exists**, and the facility series are not comparable: different thresholds, different timing of measurement, different ambient conditions. No figure is asserted here.

**It is not a cold-climate condition.** It is measured in tropical settings, because the relevant comparison is the newborn's thermoneutral requirement — an ambient temperature of around 28 to 30 °C for a naked term baby, and higher for a preterm one — rather than the outdoor climate. The trend is unknown, because it is not tracked.

**Where it starts.** The mechanism is simple physics. **Evaporation** from wet skin is the largest early loss, which is why immediate drying matters most. Convection, conduction and radiation to cool air, cool surfaces and cool walls follow.

Low birth weight and prematurity raise risk steeply, through a higher surface-area-to-mass ratio, less subcutaneous fat, less brown adipose tissue and immature thermoregulation; risk rises steeply below 2,000 g. Delayed drying, early bathing, separation from the mother, cool delivery rooms, transport without thermal protection and resuscitation under a cool open warmer all contribute. Asphyxia impairs thermoregulation. **Sepsis can cause hypothermia rather than fever in a newborn, which makes hypothermia a sign as well as a cause.** No effect sizes were located.

What is not known is how much neonatal mortality is attributable to hypothermia, because it is not recorded as a cause and because it is almost always present alongside the condition that is recorded. Observational studies consistently find hypothermia at admission strongly associated with death, commonly with mortality odds rising substantially per degree below normal, and **the direction is not establishable from those data**: a sick, septic, asphyxiated or very preterm baby becomes cold *because* it is dying, as well as dying because it is

cold. The attributable fraction is therefore genuinely unknown, and that is the single reason a condition prevented by a free intervention has no burden figure.

**Cure status.** CURABLE. Rewarming corrects hypothermia and the baby recovers completely, provided rewarming is achieved before the metabolic consequences — hypoglycaemia, acidosis, coagulopathy, pulmonary hypertension, increased oxygen consumption — have caused secondary injury. The intervention is heat. There is no residual condition.

The rate of rewarming matters and is debated. Rapid rewarming has been associated with apnoea and instability in very preterm infants, and slow rewarming prolongs the metabolic stress. Current guidance favours rewarming at approximately 0.5 °C an hour for severe hypothermia in a very preterm baby and more rapid rewarming in a term baby, with monitoring.

**Prevention.** This entry is almost entirely prevention, and the prevention is free. - **The WHO warm chain — STRONG.** Ten steps, essentially all costless: a warm delivery room at at least 25 °C and ideally higher for preterm births; **immediate drying**; **immediate skin-to-skin contact**; **breastfeeding within the first hour**; **delayed bathing and weighing**, with bathing postponed at least 24 hours and ideally longer for small babies; appropriate clothing and bedding including a hat; keeping mother and baby together; warm transport; warm resuscitation; and training and awareness. - **Immediate drying and removal of the wet cloth — STRONG.** The single highest-yield act, because evaporation is the largest loss. It takes seconds and a dry cloth. - **Skin-to-skin contact and kangaroo mother care — STRONG.** The mother's chest is a thermostatically regulated heat source, and the iKMC mortality effect of relative risk 0.75 operates partly through this mechanism. - **A hat — STRONG.** The head is the largest exposed surface in a newborn. - **Delayed bathing — STRONG.** Bathing a newborn in the first hours is a measurable cause of hypothermia and has no benefit. **Stopping doing something is the intervention.** - **Plastic wrap or a food-grade polyethylene bag for very preterm babies immediately at birth — STRONG.** Randomised trials and the subsequent Cochrane review found occlusive plastic wrapping of preterm infants at birth significantly reduces hypothermia on admission. **Cost: a plastic bag.** - **Raising the delivery room temperature — STRONG**, and free where climate permits, which is most of the high-burden world. - **Warm transport — STRONG.**

**Treatment.** Every effective treatment here is also a simple means. No drug treats hypothermia.

**1. Skin-to-skin rewarming on the mother's chest.** First line for mild and moderate hypothermia. The physiological evidence is direct and the iKMC trial carries the mortality outcome. **Free.**

**2. A radiant warmer or incubator** for severe hypothermia or where the mother is unavailable. Effective, and it requires electricity.

**3. A warm room, warm blankets, a hat, and a dry covered head.**

**4. Thermal mattresses and phase-change material warming mattresses.** Chemically activated or warm-water-filled, used for transport and for delivery-room stabilisation. Low cost, no electricity, and trials in low-resource settings support their use for transport.

**5. Treating the consequences:** blood glucose measurement and correction — hypothermia and hypoglycaemia travel together, both are fatal and both are cheap to fix — oxygen for the increased consumption, and **treating sepsis**, because hypothermia may be its presenting sign.

**6. Monitoring temperature.** A low-reading thermometer is required: standard clinical thermometers do not read below 35 °C, so severe hypothermia is systematically missed by the wrong instrument. **A thermometer that reads to 25 °C costs a few dollars and is the single most-overlooked item in this entry.**

**Simple means.** This entry is **entirely** simple means. It is the clearest case in the book of a condition that kills at scale and is prevented by acts requiring nothing manufactured. - **Drying the baby immediately with a cloth, and discarding the wet cloth.** Seconds. Largest single effect. - **Skin-to-skin contact on the mother's chest, immediately and continuously.** Free, and it is simultaneously the prevention, the treatment, and the delivery mechanism for the iKMC mortality benefit at relative risk 0.75†. - **Kangaroo mother care with a cloth wrap.** A length of cloth. - **A hat.** A knitted or cloth cap. - **Not bathing the baby.** Delaying the bath 24 hours or more. The intervention is omission. - **Closing the**

**windows and doors of the delivery room.** Free. - **A plastic bag for the very preterm baby at birth.** Food-grade polyethylene, Cochrane-supported. - **Warm transport:** the baby carried skin-to-skin against the carrier's chest under their clothing, with a hat and a blanket. This is both the warmest and the cheapest transport incubator available, and it works on a motorcycle. - **A low-reading thermometer.** A few dollars. Without it, severe hypothermia is invisible. - **Warm water bottles or warmed cloth**, with care against burns. - **Teaching the family.** The warm chain is a list of behaviours, and the whole intervention is knowing it.

The minimum chain: a dry cloth, a hat, and the mother. Nothing else is strictly necessary for the majority of cases, and a low-reading thermometer and a plastic bag complete the set for a few dollars.

**Gaps. There is no burden figure at all** — no GBD cause line, no global prevalence estimate, no deaths attributed. A condition prevented by a dry cloth has no number against its name, and that absence is itself the finding. The attributable fraction of neonatal mortality is unknown because of the reverse-causation problem above: the observational associations are strong and uninterpretable as causal. Facility prevalence studies are not comparable, with different thresholds, timings and ambient conditions, and no pooled estimate exists. No effect sizes for the warm-chain components, individually or as a bundle, were retrievable; the bundle is recommended on physiological grounds and observational data rather than randomised evidence of mortality benefit, with two exceptions — plastic wrapping for preterm infants, which is randomised and Cochrane-supported, and kangaroo mother care, which is randomised. The optimal rewarming rate is debated and the guidance differs by maturity. Hypothermia is both a cause and a sign of sepsis, and no clinical rule distinguishes them at the bedside. It is not tracked as an indicator, so there is no trend.

---

## Neonatal tetanus

**What it is.** Tetanus in a newborn, from spores entering through the cut umbilical cord. The toxin causes rigid spasms: the baby stops feeding, arches backward, and convulses at any touch or sound. It begins in the first days of life.

**Measured.** Neonatal tetanus deaths: **just over 7,700 in 2021**, from an estimated **46,898 in 2000** — a fall of **84 per cent**. WHO attributes the decline largely to scaled-up tetanus toxoid-containing vaccine immunisation, and the fact sheet gives only these two data points.

**As of July 2026, 8 countries have yet to achieve maternal and neonatal tetanus elimination**. Elimination is defined as **fewer than one neonatal tetanus case per 1,000 live births in every district** — a district-level rather than national threshold. WHO does not state how many countries have achieved it.

The global elimination goal was launched at the World Health Assembly in 1989, and the elimination initiative in 1999. In 2025, **85 per cent of infants worldwide received 3 doses of DTP-containing vaccine**.

**Case fatality with and without treatment is not reported on the WHO fact sheet.** The published clinical literature gives neonatal tetanus case fatality approaching 100 per cent without treatment and, with intensive care including ventilation, of the order of 10 to 30 per cent; without ventilation it remains very high†. Those are reported as the standing clinical literature position and were not verified.

The remaining cases are concentrated in the eight countries without elimination, and in conflict-affected and inaccessible districts within countries that have achieved it nationally.

**Where it starts.** This is a condition whose causation is fully understood. ***Clostridium tetani* spores**, ubiquitous in soil, dust and animal faeces, enter the umbilical stump. WHO names three risk practices: **non-sterile instruments for cutting the umbilical cord; contaminated cord coverings; and deliveries by people with unclean hands or on contaminated surfaces**. Traditional cord applications — ash, dung, oil, mud, clarified butter — are the classic route. **Absence of maternal immunisation** removes the baby's only protection, because maternal antibody crosses the placenta. Home birth without a skilled attendant and without a clean delivery kit raises exposure. **WHO gives no figures** for the contribution of any of these practices.

Very little about the mechanism is unknown. This is the most completely understood condition in the chapter: a known organism, a known toxin, a known portal of entry, a vaccine with a known mechanism, and a prevention understood in full. **What is not known is where the remaining cases are.** In the districts that still have them, surveillance is weakest, so the 7,700 figure is a model output and the true distribution within the remaining eight countries is poorly characterised. Also not well characterised: how much of the residual is immunisation failure, how much unclean delivery, and how much both.

**Cure status.** RELIEF ONLY, and this must be stated plainly because it is the exception in this chapter.

Once the toxin has bound to nerve terminals, nothing removes it. Antitoxin neutralises only circulating toxin. Recovery depends on the regeneration of new nerve terminals over weeks, during which the baby must be kept alive through spasms that prevent breathing. With ventilation and intensive care a share survive; without ventilation most die. Treatment is entirely supportive: control the spasms, protect the airway, feed, and wait.

**This is the striking asymmetry of the entry: the condition is almost perfectly preventable at a cost of cents, and almost untreatable at a cost of weeks of intensive care.** A two-dose course of a vaccine costing a fraction of a dollar prevents what a fully equipped intensive care unit often cannot cure.

**Prevention.** - **Maternal tetanus toxoid immunisation — STRONG, and it is effectively complete protection.** WHO recommends **6 doses over a lifetime**, three primary and three booster. Maternal immunisation with an adequate course confers passive protection on the newborn through transplacental antibody. **The measured consequence is the 84 per cent fall in deaths from 2000 to 2021**, which WHO attributes largely to immunisation scale-up. The vaccine is EML-listed, off-patent, and of the order of a few US cents to a few tens of cents a dose at supply-division prices. **No efficacy figure is given** on the WHO fact sheet: the 84 per cent decline is an attribution rather than a measurement of vaccine efficacy. The historical trial and field evidence for maternal immunisation is of the order of 80 to 100 per cent protection with two or more doses†. - **Clean delivery and clean cord care — STRONG.** WHO lists it as prevention and gives no figures. The three named risk practices are the targets: a sterile blade, clean hands, a clean surface, and nothing applied to the cord. - **Skilled birth attendance — STRONG**, as the delivery vehicle for both. - **Chlorhexidine cord cleansing — MODERATE** for the omphalitis and sepsis route; its specific effect on tetanus is not separated in the trials. - **The combination is what achieves elimination.** The elimination strategy is explicitly both: immunise women of reproductive age in high-risk districts, and promote clean delivery. Neither alone reaches the district threshold.

**Treatment.** All of it supportive. **1. Tetanus antitoxin** — human tetanus immunoglobulin, or equine antitoxin where the human product is unavailable. It neutralises circulating unbound toxin and does nothing for bound toxin, so it limits progression rather than reversing disease. Intrathecal administration has been studied with some benefit reported and is not universal practice. EML-listed under sera and immunoglobulins, off-patent as a plasma- or serum-derived product with supply the constraint. Cost is moderate and supply in high-burden settings is unreliable.

**2. Spasm control** — benzodiazepines, principally **diazepam**, in high and sustained doses, with **magnesium sulfate** as an adjunct. Trials in adults found magnesium reduced the requirement for other drugs without reducing the need for ventilation. Both are EML-listed and off-patent; diazepam costs cents and magnesium sulfate about US$0.33 an ampoule on October 2026 indicative prices. The limit is that the doses required to control spasms suppress breathing, which is why ventilation determines survival.

**3. Airway protection and mechanical ventilation, with neuromuscular blockade where needed. This is the intervention that separates survival from death, and it is the one unavailable in the settings where the cases are.**

**4. Antibiotics** — metronidazole, preferred over penicillin, which is a GABA antagonist and may worsen spasms — to eliminate the organism at the wound. EML-listed, off-patent, cents.

**5. Wound and cord care** — cleaning and debridement of the umbilical stump.

**6. Nutrition by nasogastric tube; a dark, quiet environment to reduce spasm triggers; and management of autonomic instability.**

**7. Immunisation of the surviving baby and of the mother.** Surviving the disease confers no immunity, because the toxin dose required to cause disease is below that required to immunise.

**Simple means.** For **prevention**, this entry is almost entirely simple means. - **A sterile razor blade or a boiled instrument for cutting the cord.** One of the cheapest life-saving items that exists. - **The clean delivery kit** — soap, a clean plastic sheet, clean string, a sterile blade, clean gloves. Designed to be distributable at near-zero unit cost. - **Handwashing with soap.** - **Dry cord care — applying nothing at all.** The intervention is the removal of a practice. Free, and it addresses one of WHO's three named risk factors directly. - **Boiling instruments** where no sterile blade exists. - **Teaching the traditional birth attendant and the family.** The entire preventive package is a set of behaviours plus one blade.

For **treatment**, the honest answer is largely negative and must be stated. - **A dark, quiet room, and minimal handling.** This reduces spasm frequency, and it is real: spasms are triggered by light, sound and touch. - **Nasogastric feeding** by a trained family member. - **Positioning and airway suction.** - **Diazepam**, a cheap manufactured drug that can be given rectally where no intravenous access exists. - **Magnesium sulfate** intramuscularly. - **What cannot be improvised is ventilation**, and ventilation is what determines whether the baby lives. Hand-bagging a baby for the two to three weeks the toxin takes to clear is not a sustainable intervention, and attempts at it are the historical practice this condition's mortality reflects.

The minimum chain: for prevention, a blade and a vaccine vial. For cure, an intensive care unit. The ratio between those two is the entire argument of this entry.

**Gaps.** WHO gives no case fatality figures, with or without treatment; the figures above are from the standing clinical literature and were not verified. WHO gives no vaccine efficacy figure, and the 84 per cent decline is an attribution across a period in which clean delivery also improved, so the immunisation and clean-delivery contributions are not separated. WHO does not state how many countries have achieved elimination, only that 8 have not as of July 2026. The latest death figure on the fact sheet is for 2021, no 2023 figure was available, and GBD does not report neonatal tetanus as a separate cause in the series consulted. The residual case distribution within the remaining countries is poorly characterised because surveillance is weakest where the cases are, so the 7,700 figure is a model output. No effect sizes are given for clean delivery practices, individually or as a bundle. Elimination is defined at district level and countries are validated nationally, so a validated country can retain districts above the threshold: the indicator and the achievement are not the same thing. Intrathecal antitoxin and magnesium sulfate as an adjunct both have supportive and not definitive trial evidence, largely from adult tetanus.

---

## ICD-11 Chapter 20 — Developmental anomalies

---

Eleven entries. The chapter-level denominators are these. Congenital anomalies accounted for **54.8 million DALYs** in 2023, the 13th leading DALY cause; GBD 2021 gave **52.3 million** for congenital birth defects, a different cause label between rounds, and both are printed.

**About 240,000 new-borns die within 28 days of birth each year from con-geni-tal dis-or-ders**, and a fur-ther **about 170,000 chil-dren aged 1 month to 5 years**. The total num-ber of ba-bies born with a con-geni-tal disor-der is not given any-where on the WHO page.

**WHO's own page contradicts itself on where they occur.** Its key facts state that **nine of ten** children born with a serious congenital disorder live in low- and middle-income countries; its body text states that about **94 per cent** of severe congenital disorders occur there. Two different shares for the same statistic on one page, with no explanation. Both are printed.

The most common severe types are named as heart defects, neural tube defects and Down syndrome, with **no prevalence figures given for any of them**. Parents related by blood is described as **nearly doubling** the risk of neonatal and childhood death, intellectual disability and other anomalies, qualitatively and without a figure.

WHO lists the preventive measures — folic acid, avoiding alcohol and tobacco, rubella vaccination, iodine, diabetes control, reducing heavy-metal and pesticide exposure, justified medication and radiation use, screening for rubella, varicella and syphilis, and preconception care — **without quantifying any of them**. Where an effect size appears below it comes from elsewhere and is

## Neural tube defects

**What it is.** The tube that becomes the brain and spinal cord fails to close in the first four weeks after conception, before most women know they are pregnant. If the lower end stays open it is spina bifida: the spinal cord is exposed and the legs, bladder and bowel are affected. If the upper end stays open it is anencephaly: the brain does not form and the baby dies.

**Measured. Over 300,000 births affected each year worldwide**, and about **71,000 deaths in 2010**. Both figures are old and no current cause-specific GBD figure was retrievable.

Spina bifida in the United States: about **3.5 per 10,000 births, roughly 1,500 cases a year**, down from about **5 per 10,000** before folic acid fortification†. United States annual deaths from neural tube defects fell from about **1,200 to 840**†, with the year of the decline not given.

**No anencephaly prevalence figure** is given on the source consulted. Affected infants are usually stillborn or die within hours or days, and **no treatment exists**.

WHO names neural tube defects among the three most common severe congenital disorders, without a prevalence figure.

**A measurement caveat that matters: birth-based prevalence undercounts neural tube defects**, because prenatal diagnosis and termination remove affected pregnancies from the denominator. One study found the share of affected pregnancies ending in abortion **roughly doubled between 1986 and 1999**†. Comparisons of birth prevalence across countries and across time are therefore partly measuring termination rates rather than occurrence.

**Where it starts. Maternal folate status at conception is the dominant modifiable cause. Folic acid supplementation reduces neural tube defect prevalence by about 70 per cent**, on a randomised controlled trial in women with a previous affected pregnancy published in 1991†. **The remaining roughly 30 per cent are not folate-dependent**†.

Also established: a previous affected pregnancy, with a substantially elevated recurrence risk, which is why the trial used that population; maternal diabetes; maternal obesity; maternal hyperthermia in early pregnancy. **Antiepileptic drugs, valproate in particular and also carbamazepine**, are a major iatrogenic cause and the reason valproate prescribing in women of childbearing potential is now restricted in many jurisdictions. Folate antagonists — methotrexate, trimethoprim, some antimalarials — contribute. Consanguinity raises risk, as it does for anomalies generally. Genetic factors are real and incompletely mapped, with MTHFR variants among others. Fumonisin exposure from mould-contaminated maize has been implicated in some high-prevalence populations. No effect sizes beyond the 70 per cent figure were located.

**The mechanism by which folic acid prevents the defect is not known.** The effect is one of the best-established in all of preventive medicine and the pathway is not identified. It is not simply correction of deficiency, because the effect occurs in women who are not folate-deficient, and the dose-response is not fully characterised. What causes the folate-unresponsive 30 per cent is also not known. The result is a measurement without a mechanism, and the residual is a cause without a name.

**Cure status.** Anencephaly: RELIEF ONLY. In practice no treatment exists. Infants are stillborn or die within hours or days, and nothing is attempted beyond comfort care. Spina bifida: CONTROLLABLE. Surgical closure of the defect prevents infection and further damage and does not restore the nerve function already lost. The paralysis, bladder and bowel denervation, and hydrocephalus requiring shunting are permanent and lifelong. Management — shunt revision, bladder catheterisation, bowel programmes, orthoses, pressure-area care, scoliosis surgery, latex avoidance — holds the state and does not remove it.

Prenatal in-utero repair changes this a little. The MOMS trial in 2011 found prenatal repair of myelomeningocele **reduced the need for shunting and improved motor outcomes at 30 months**, at the cost of increased preterm birth and uterine dehiscence. That is improved control, not cure.

Neither stratum is CURABLE, which is exactly why the prevention below carries the weight it does. This is the clearest case in the book where the intervention that matters is one taken before the woman knows she is pregnant.

**Prevention. Folic acid — STRONG, and this is the single best-documented population prevention in the chapter.**

The trial evidence: folic acid supplementation reduces neural tube defect prevalence by **about 70 per cent**†.

The country before-and-after data from mandatory flour fortification:

| Country | Before | After | Change |
|---|---|---|---|
| United States | 10.8 per 10,000, 1995–1996 | 6.9, end of 2006 | **−36 per cent**† |
| United States, affected pregnancies | about 4,000, 1995–1996 | about 3,000, 1999–2000 | roughly 1,000 fewer a year† |
| Chile | 17.1 per 10,000, 1999–2000 | 9.7, 2001–2002 | **−43 per cent**† |
| Canada | — | — | **−46 per cent** in incidence after mandatory fortification† |
| Costa Rica, South Africa, Canada | — | — | **25 to 50 per cent** declines in affected pregnancies; no country-specific figures, years or counts are given for these three |
| United States spina bifida | about 5 per 10,000 | 3.5 per 10,000, 2017 | — |
| United States deaths | about 1,200 a year | 840 a year | **−30 per cent**† |

The United States required folic acid in enriched grain products in 1996, with mandatory compliance from January 1998; Canada made grain fortification mandatory by 1998†.

A projection, reported as a projection and not a result: **150,000 to 210,000 neural tube defects preventable per year globally**†, derived from the 50 to 70 per cent preventable share rather than observed in any country.

**The gap that defines the field:** the source consulted does not state how many countries have mandatory fortification, and the standing reference dataset was not reachable. **The measured effect is 25 to 50 per cent in every country that has done it, and most countries have not.**

Other prevention: - **Periconceptional folic acid supplementation — STRONG**, at 400 µg daily for all women who may become pregnant and 4 to 5 mg for women with a previous affected pregnancy. The limitation is timing: the neural tube closes by day 28, so supplementation must precede the recognised pregnancy. **This is why fortification outperforms supplementation as a population strategy** — it does not depend on the woman knowing she is pregnant or planning to be. - **Avoiding valproate in women of childbearing potential — STRONG.** Iatrogenic prevention. - **Pre-pregnancy diabetes control and weight management — MODERATE.** - **Avoiding hyperthermia in early pregnancy — WEAK.** - **Prenatal screening — this is detection, not prevention.** Maternal serum alpha-fetoprotein and second-trimester ultrasound reduce birth prevalence by enabling termination, which is why the measurement caveat above matters. It is not a reduction in occurrence. - **Folic acid does not prevent miscarriage.** The distinction is often blurred.

Folic acid is EML-listed, off-patent, and costs **a fraction of a cent a tablet**: a UNICEF indicative price in October 2026 works out at about **US$0.0054 per 5 mg tablet**. Fortification of flour costs of the order of **US$0.01 to 0.10 per person per year**†. Published cost-effectiveness analyses of mandatory fortification repeatedly find it among the most cost-effective public health interventions available, with benefit-cost ratios reported in the tens. **This is the leading candidate for the highest life-saving effect per euro in this chapter.**

**Treatment.** For anencephaly: **none.** Comfort care only.

For spina bifida, no drug treats it. **1. Postnatal surgical closure of the defect**, within the first days. It prevents infection and further cord damage and does not restore lost function. It requires a paediatric neurosurgical service.

**2. Ventriculoperitoneal shunting** for the hydrocephalus that accompanies most myelomeningocele. Lifelong, with repeated revisions for blockage and infection. **Endoscopic third ventriculostomy with choroid plexus cauterisation** is the shunt-free alternative developed substantially in East Africa, and a significant advance for settings where shunt revision is not accessible.

**3. Prenatal in-utero repair**, with the MOMS results above. Available in very few centres.

**4. Bladder management** — clean intermittent catheterisation, anticholinergics, and surveillance for renal damage. **Renal failure, not the paralysis, is the historical cause of death in spina bifida**, and catheterisation is what prevents it.

**5. Bowel management** — programmes, laxatives, enemas.

**6. Orthoses, wheelchairs, physiotherapy, and orthopaedic surgery** for hip, knee and foot deformity and for scoliosis.

**7. Pressure-area care.** Insensate skin ulcerates; prevention is positioning and inspection.

**8. Latex avoidance.** Latex allergy prevalence is high in this population from repeated surgical and catheter exposure.

**9. Treatment of tethered cord and syringomyelia** as they present.

**Simple means.** For prevention, this is the entry where the simple means is also the best intervention available. - **A folic acid tablet costing a fraction of a cent**, taken before conception. Nothing in this book has a better ratio of cost to prevented disability. - **Fortified flour.** Once the mill adds it, the woman need do nothing and need know nothing. **Of the order of US$0.01 to 0.10 per person per year.** The intervention is a decision taken at a mill. - **Dietary folate** — dark green leafy vegetables, pulses, liver. Free, and insufficient on its own to reach the protective intake in most diets, which is why fortification exists.

For care of the affected child: - **Clean intermittent catheterisation taught to the parent and later the child.** Reusable catheters, clean water and soap. **This is the intervention that prevents renal failure**, and it is teachable to a family. - **Pressure-area inspection and repositioning.** A mirror and a routine. - **A bowel programme** — timing, diet and manual techniques. - **Keeping the back lesion clean and covered before surgery** — a sterile or clean moist dressing, which prevents the meningitis that kills unoperated babies. - **Positioning the newborn prone** to avoid pressure on the sac. - **Physiotherapy and range-of-movement exercises** taught to the family. - **Locally made orthoses and adapted seating.** - **Parent-to-parent teaching.**

The minimum chain: for prevention, one tablet. For the affected child, neurosurgery, and there is no simple means that substitutes for closing the defect or draining the hydrocephalus. The asymmetry between a fraction of a cent and a neurosurgical service is the whole of the entry.

**Gaps.** The folic acid fortification systematic review could not be read, so the country table is built from the 2010 public health review and secondary sources and is less complete than that review would allow; Costa Rica and South Africa are reported only inside the 25 to 50 per cent band without country-specific figures. The number of countries with mandatory fortification is not stated in any source reached. Birth prevalence undercounts occurrence because of termination, and the termination share roughly doubled between 1986 and 1999, so cross-country and cross-time comparisons are partly comparisons of termination rates. The mechanism of the folic acid effect is unknown, and the cause of the folate-unresponsive 30 per cent is unknown. The global burden figures are old — 300,000 affected births from a 2012 report and 71,000 deaths from the 2010 burden study — and no current cause-specific figure was retrievable. The 150,000 to 210,000 preventable per year is a projection, not an observation. No anencephaly prevalence figure was located. The MOMS benefit is measured at 30 months, with limited longer-term outcomes and limited applicability outside specialist centres. Fortification's safety debate — the possibility of masking vitamin B12 deficiency, and a contested association with certain cancers — is live in the literature and no source reached resolves it.

## Congenital heart defects

**What it is.** The heart forms wrongly in the first weeks of pregnancy. A hole between chambers, a narrowed or missing valve, a great vessel in the wrong place, or a chamber that never developed. Some cause no symptoms; some kill within days unless operated on.

**Measured.** Birth prevalence is given as **about 4 to 75 per 1,000 live births**, depending on how it is diagnosed; **moderate-to-severe cases at 6 to 19 per 1,000**; and heart defects occurring in **about 1 per cent of live births**, or 2 to 3 per cent including bicuspid aortic valve†. The nearly twenty-fold range is a statement about ascertainment, not about populations.

People living with it: **48.9 million in 2015** on one round of the burden study, **34.3 million in 2013** on another†. Both printed.

**The death figures disagree substantially across rounds and all are printed.** 2017: **261,247 (216,567 to 308,159)**, including 180,624 among infants under 1 year†. 2015: **303,300**†. 2010: **223,000**†. The derived trends disagree too: 366,000 in 1990 falling to 303,300 in 2015 on one round; 278,000 falling to 223,000 in 2010 on another; and a 34.5 per cent decline from 1990 to 2017 on a third†. The rounds are not consistent with each other and none is a count.

Congenital heart defects are the leading cause of birth-defect-related deaths, and WHO names heart defects first among the three most common severe congenital disorders.

Ventricular septal defects are collectively the most common type; about 30 per cent of adults have a probe-patent foramen ovale; and the source gives no shares for other types.

About **94 per cent of severe congenital disorders occur in low- and middle-income countries**, where paediatric cardiac surgery is largely unavailable. So the prevalence is roughly uniform and the mortality is not.

**Where it starts.** The identified genetic contributions, as attributable shares: **aneuploidies 5 to 8 per cent; copy number variants 10 to 12 per cent; inherited protein-coding variants 3 to 5 per cent; de novo protein-coding variants about 10 per cent**†. Together these account for under 40 per cent of cases.

**Monochorionic twins carry about 9 times the risk** of singletons, on a meta-analysis of four studies†. De novo defects carry a recurrence risk in offspring of **3 to 5 per cent**, higher for left ventricular outflow tract obstruction, heterotaxy and atrioventricular septal defects. **Down syndrome carries congenital heart disease in about 40 per cent of newborns**†.

Maternal obesity raises risk as obesity increases, with no effect size given. Maternal diabetes, phenylketonuria, lupus, rubella, consanguinity, and having a parent with congenital heart disease are all established without effect sizes. Drug exposures named are alcohol, hydantoin, lithium and thalidomide, and paternal alcohol use is listed as a risk factor.

The cause is unidentified in the majority. **Identified genetic mechanisms account for under 40 per cent of cases and the remainder have no identified cause.** The identified environmental exposures account for a small share of the total. Also not known: why measured birth prevalence ranges nearly twenty-fold across studies, which the source attributes to diagnostic method rather than real variation — meaning the true occurrence is not established even approximately.

**Cure status.** The split is by lesion, and the entry contains three. Small ventricular septal defects that close spontaneously in infancy: SELF-LIMITING. Anatomically correctable lesions: CURABLE. Secundum atrial septal defect, most ventricular septal defects, patent ductus arteriosus, coarctation, and simple pulmonary or aortic valve stenosis are corrected with a single operation after which the child is normal and needs no further treatment. **A substantial fraction of congenital heart disease is a one-operation cure in childhood followed by a normal life.** Complex lesions — single-ventricle physiology, transposition, tetralogy, hypoplastic left heart: CONTROLLABLE. These are palliated rather than cured. Staged operations and arterial switch produce survival into adulthood with a circulation that is not normal, requiring lifelong cardiology, anticoagulation, arrhythmia management, and in some cases transplantation. The deviation remains.

The source gives no numeric survival rates, which is a real gap for an entry whose cure status depends on them.

**Prevention.** - **Rubella vaccination — STRONG** for the congenital rubella fraction. WHO names rubella vaccination for children and women, and screening for rubella, varicella and syphilis, without effect sizes. Rubella-containing vaccine is EML-listed, off-patent and costs cents a dose. Congenital rubella syndrome is eliminable, and has been eliminated in the Americas. - **Pre-pregnancy diabetes control — MODERATE.** WHO names controlling diabetes before and during pregnancy. - **Avoiding alcohol in pregnancy — MODERATE.** - **Avoiding valproate and hydantoin, lithium and thalidomide in pregnancy — STRONG** for those specific iatrogenic routes. - **Maternal weight management — MODERATE.** - **Maternal phenylketonuria control — STRONG** for that rare specific cause. - **Folic acid — CONTESTED** for congenital heart defects specifically. The evidence is much weaker than for neural tube defects; some fortification studies report reductions and the finding is not secure. - **Reducing the alternatives to single-embryo transfer in assisted reproduction — MODERATE**, via the nine-fold monochorionic twin risk. - **There is no prevention for the majority of cases**, because the majority have no identified cause.

Detection, which is not prevention and determines survival: - **Pulse oximetry screening of newborns — STRONG for mortality.** Performed at or after 24 hours of life, or earlier if the newborn is discharged or oxygen is stopped. **Pass: saturation of 95 per cent or more in the right hand and foot with a difference of 3 points or less. Fail: below 90 per cent in the right hand or foot**, which triggers further workup including echocardiography. Retest an hour later if 90 to 94 per cent or the difference exceeds 4 points. State-level implementation in the United States has been associated with fewer emergency hospitalisations for critical congenital heart disease, lower infant mortality and fewer early cardiac deaths, and was **not shown to significantly increase resource use or cost**. False positives occur, not all congenital heart disease is detected, and it should be used alongside prenatal ultrasound and physical examination. **A pulse oximeter costs tens of dollars, runs on batteries, and the test takes minutes.** This is one of the highest-value screening interventions in the chapter. - **Prenatal ultrasound**, which detects a share of major defects and allows delivery at a centre with cardiac surgery.

**Treatment.** The source gives no numeric survival rates, so the ordering below is by established practice rather than by reported effect size.

**1. Surgical repair.** Open cardiac surgery with cardiopulmonary bypass for most significant lesions, and staged palliation for single-ventricle physiology. The inputs are a surgeon, a cardiac anaesthetist, a perfusionist, a bypass circuit, paediatric intensive care, blood products and echocardiography. **This is the most infrastructure-dependent treatment in the whole of this chapter** and it exists in a small minority of countries.

**2. Catheter-based intervention** — device closure of atrial septal defect and patent ductus arteriosus, balloon valvuloplasty, balloon atrial septostomy, stenting. It avoids bypass and requires a catheterisation laboratory and fluoroscopy.

**3. Prostaglandin E1 infusion** to keep the ductus arteriosus open in duct-dependent lesions. **This is the drug that keeps a newborn with critical congenital heart disease alive long enough to reach surgery.** Its EML status could not be confirmed against the sections reachable. Off-patent, moderate cost, and it requires refrigeration and a syringe pump.

**4. Diuretics, ACE inhibitors, beta blockers and digoxin** for heart failure from a shunt lesion pending repair. Spironolactone is EML-listed for heart failure; all of these are off-patent and cost cents a day.

**5. Ibuprofen or paracetamol for closure of patent ductus arteriosus in preterm infants**, as an oral or intravenous alternative to surgical ligation. Both EML-listed, off-patent and cheap; indomethacin is the traditional agent.

**6. Oxygen, careful fluid management and nutritional support.** Growth failure is a major problem in unrepaired shunt lesions, and feeding support is part of treatment.

**7. Antibiotic prophylaxis against infective endocarditis** in defined high-risk lesions; the indications have narrowed considerably.

**8. Arrhythmia management, anticoagulation and transplantation** for the palliated circulations.

**Simple means.** This entry has the least favourable simple-means profile in the chapter, and that should be stated first. - **A pulse oximeter.** Tens of dollars, battery-powered, no

consumables. It converts an undetected lethal lesion into a diagnosed one. **It is the single most valuable low-cost item in the entry**, and its value is entirely in triggering a referral that must then exist. - **A stethoscope and clinical examination** — murmur, femoral pulses, cyanosis, hepatomegaly, respiratory rate, feeding history and growth. It detects a large share of significant lesions and costs nothing beyond the stethoscope. - **Counting the respiratory rate and weighing the baby.** Failure to thrive and tachypnoea are the presentation of a large shunt, and both are measurable with a scale and a clock. - **Nutritional support** — high-energy feeding, including fortified expressed breast milk, for the infant with a large shunt. Free or nearly so, and it determines operability. - **Diuretics** — furosemide tablets, cents a day, which hold a child with heart failure for months. - **Treating anaemia and intercurrent infection** promptly. Both decompensate an unrepaired lesion. - **Keeping the child warm and avoiding dehydration.** - **Teaching the family the warning signs** — poor feeding, sweating with feeds, blue spells, fast breathing.

**What the chain minimally requires, stated plainly: cardiac surgery with cardiopulmonary bypass.** There is no simple means, no improvisation and no drug that substitutes for it. For the lethal lesions this is the clearest example in the book of a condition that is curable in principle and untreated in practice.

**Gaps.** The rounds of the burden study disagree substantially on deaths — 223,000 for 2010, 303,300 for 2015, 261,247 for 2017 — and the trend statements derived from them differ; all printed, none a count. Birth prevalence ranges nearly twenty-fold by diagnostic method, so the true occurrence is not established. No numeric surgical survival rates are given on the source consulted, which is a substantial gap for an entry whose cure status depends on them. The cause is unidentified in the majority, with identified genetic mechanisms accounting for under 40 per cent. No current cause-specific figure was retrievable; GBD 2023 reports only the aggregate congenital anomalies DALY figure. Prostaglandin E1's EML status could not be confirmed. Folic acid's effect on congenital heart defects is contested, unlike its effect on neural tube defects. Pulse oximetry screening's evidence is state-level association rather than randomised, and "not shown to significantly increase cost" is a weaker statement than a cost-effectiveness figure. Coverage of paediatric cardiac surgery globally is not quantified in any source reached, so the size of the treatment gap is unknown.

---

## Cleft lip and palate

**What it is.** The lip, the roof of the mouth, or both fail to fuse in early pregnancy, leaving a gap. The baby cannot generate suction to feed. Speech, hearing and teeth are affected later. Surgery closes it.

**Measured.** Prevalence: **about 1 in 1,000 to 1 in 1,500 births**. No global annual count, no deaths figure and no cleft-specific DALY figure was located; GBD reports only the aggregate congenital anomalies figure.

The burden is overwhelmingly morbidity rather than mortality. Feeding failure in infancy can be fatal in settings without feeding support, and the long-term burden is speech, hearing, dental, nutritional and social.

Occurrence is roughly uniform with some population variation, higher in parts of Asia and among Indigenous American populations and lower in populations of African descent. **The untreated prevalence is not uniform.** In high-income countries essentially every cleft is repaired in infancy, and in low-income settings a large number of adults live with unrepaired clefts, which is why surgical missions find them. No trend was quantified in any source reached.

**Where it starts.** Maternal smoking in pregnancy is one of the better-established environmental associations, with a modest relative risk. Maternal alcohol use contributes. Antiepileptic drugs, particularly valproate and topiramate, are established; corticosteroids carry a weak signal; and **ondansetron carries a contested cleft palate signal**. Folate status has a weaker and less consistent effect on clefts than on neural tube defects. Maternal diabetes and obesity raise risk. Genetic factors are real: cleft lip with or without cleft palate and isolated cleft palate have partly distinct genetics, multiple susceptibility loci including IRF6 are identified, and about 30 per cent of cases are syndromic†. Consanguinity and family history raise risk, with sibling recurrence elevated several-fold. No effect sizes were located.

The cause is unknown in most non-syndromic cases. Cleft is the standard textbook example of a multifactorial threshold trait, and multifactorial is a description of ignorance about the specific combination. Whether cleft lip with cleft palate and isolated cleft palate are one condition or two remains partly unresolved. The ondansetron signal is unresolved.

**Cure status.** CURABLE, and this is one of the clearest surgical cures in the chapter. Primary closure of the lip at a few months and of the palate at around a year produces a child who eats, speaks and grows normally. The operation is anatomically definitive.

Two qualifications. The full course is not one operation: speech therapy, grommets for middle ear effusion, orthodontics, alveolar bone grafting, and in some cases revision surgery or pharyngoplasty for velopharyngeal insufficiency extend over years. And residual scarring, mild speech difference and dental problems persist in a share. The condition is nonetheless removed — a repaired cleft is not a lifelong disease — which places it in CURABLE rather than CONTROLLABLE.

The repair is among the cheapest high-impact operations in surgery. Published cost-effectiveness analyses in low-income settings report costs per DALY averted tens of US dollars, comparable to the clubfoot figures below. An exact figure could not be verified.

**Prevention.** - **Maternal smoking cessation — MODERATE.** The best-established modifiable exposure. - **Avoiding alcohol in pregnancy — MODERATE.** - **Avoiding valproate and topiramate in women of childbearing potential — STRONG** for those routes. - **Folic acid — CONTESTED** for clefts specifically. Weaker and less consistent than its neural tube defect effect, though some fortification studies report reductions. - **Pre-pregnancy diabetes control and weight management — MODERATE.** - **Genetic counselling** for families with an affected child, which informs and does not prevent. - WHO lists the general congenital-disorder prevention measures without quantifying any of them. - **There is no prevention for the majority of cases.**

**Treatment.** No drug treats cleft lip or palate. **1. Surgical repair.** Lip closure typically at **3 to 6 months**; palate closure typically at **9 to 18 months**, timed to precede speech development. The rule of tens — 10 weeks, 10 pounds, haemoglobin 10 — is the classic operability threshold. Millard rotation-advancement and its variants for the lip; various palatoplasty techniques. It requires a surgeon and paediatric anaesthesia, and **safe anaesthesia for an infant is the binding constraint in low-resource settings, not the surgical technique.**

**2. Feeding support, immediately from birth.** This comes before surgery in importance and is the difference between life and death in the first months. A baby with a cleft palate cannot generate negative pressure and will not feed from breast or standard teat. Specialised cleft teats, squeezable bottles and the Haberman feeder solve it, and so do far cheaper means.

**3. Speech and language therapy.** Essential after palate repair, and the functional outcome depends on it at least as much as on the surgery.

**4. Middle ear management.** Otitis media with effusion is near-universal in cleft palate because of eustachian tube dysfunction. Grommets and hearing surveillance prevent the hearing loss and the consequent speech and educational delay.

**5. Orthodontics and alveolar bone grafting** in childhood and adolescence, and orthognathic surgery in a minority.

**6. Secondary surgery** for velopharyngeal insufficiency, fistula closure, and lip or nose revision.

**7. Dental care.** Caries risk is high.

**8. Nutritional support and growth monitoring** throughout infancy.

**Simple means.** - **Feeding technique. This is the central simple means and it saves lives in the first months.** Upright positioning, a squeezed soft bottle, a cup and spoon, expressed breast milk delivered by cup or spoon, slower paced feeding with frequent burping, and a finger supporting the cleft to help a seal. **A modified ordinary teat with an enlarged or cross-cut hole** works where a cleft teat is unavailable. All of it is teachable to a mother in one session and costs nothing beyond a cup. - **Expressed breast milk by cup**, which keeps the baby on breast milk when direct breastfeeding fails, preserving the immune and nutritional benefits. - **Weighing the baby.** Growth faltering is the sign that feeding is failing, and the scale is what detects it. - **Teaching the mother to support the**

**lip cleft with a finger or thumb** to allow a seal. A proportion of isolated cleft lip babies breastfeed successfully this way. - **Speech stimulation and play by the parent**, where no therapist exists. Structured parent-delivered speech programmes have been used in low-resource settings; the evidence base is thin and the alternative is nothing. - **Hearing checks by observation** — response to sound, speech development milestones. - **Dental hygiene** — a brush. - **Nasoalveolar moulding with strapping and simple appliances** before surgery, in some protocols, to narrow the gap. - **Case-finding.** As with fistula, families often do not know repair exists. Announcing a surgical mission is close to free and is the throughput constraint.

The minimum chain: a cup and a taught technique will keep the baby alive and growing. **The repair itself requires an operating theatre and safe infant anaesthesia, and there is no substitute for that.**

**Gaps.** No global count, no deaths figure and no cleft-specific DALY figure: WHO gives only a prevalence range and GBD reports only the aggregate congenital anomalies figure, which is thin accounting for a condition this common and this treatable. The untreated prevalence — how many people are living with unrepaired clefts — is not quantified anywhere located, and that is the number that would size the surgical need. No effect sizes for any risk factor or preventive measure were retrievable, and the cost per DALY averted could not be verified. Folic acid's effect on clefts is contested. The ondansetron cleft palate signal is unresolved and matters because ondansetron is widely used for nausea in early pregnancy. Long-term functional outcomes after repair in low-resource settings — speech, hearing, education, employment, psychosocial — are almost unmeasured, and the surgical mission model generates little follow-up data. Whether cleft lip with palate and isolated cleft palate are one condition is partly unresolved.

---

## Down syndrome and other trisomies

**What it is.** An extra copy of a chromosome. In Down syndrome it is chromosome 21. The extra chromosome affects every tissue: intellectual development, the heart, the gut, hearing, vision and the immune system. It arises at conception and is present in every cell.

**Measured.** Global incidence: **about 1 per 1,000 births**†. United States: **about 1 in 700 births** and **1.4 per 1,000 live births** on two sources†; in the 1950s it was **2 per 1,000 live births**†, and the fall reflects prenatal screening and termination rather than a change in occurrence. Norway: **1.1 per 1,000**†. All printed.

People affected: **5.4 million globally in 2015**†. **Deaths: 27,000 in 2015, down from 43,000 in 1990, on one source; about 17,000 globally as of 2010 on another**†. Both printed; they do not reconcile.

Life expectancy, as a measured trend: **about 12 years in 1912; about 25 years in the 1980s; 50 to 60 years in the developed world in the 2000s; about 10 per cent reaching age 70 in the early 2000s**†. Infant mortality in the first year was 4 to 12 per cent in data from 1985 to 2003†. **A four- to five-fold increase in life expectancy within a century, achieved almost entirely by treating the heart defects and infections rather than by anything addressing the chromosome.**

WHO names Down syndrome among the three most common severe congenital disorders, without a prevalence figure.

Other trisomies: trisomy 18 and trisomy 13 occur at roughly 1 in 5,000 and 1 in 10,000 to 16,000 live births respectively in the published literature, with very high early mortality; no figure from a source fetched in the retrieval round is available and none is asserted. Sex chromosome aneuploidies are recorded with no global figure retrieved.

**Where it starts.** This is one of the best-quantified risk gradients in medicine. **Maternal age, risk of Down syndrome at delivery: age 20, 1 in 1,441; age 30, 1 in 959; age 40, 1 in 84; age 50, 1 in 44**†.

**But mothers aged 35 and younger account for about 70 per cent of cases**, because they have far more children overall†. This is the single most important and most misunderstood fact in the entry: the risk is concentrated in older mothers and the cases are concentrated in younger ones, which is why age-based screening offers alone miss most cases.

Advanced paternal age is a risk factor for women over 35, and about 10 per cent of cases are linked to it†. The mechanism is meiotic non-disjunction, overwhelmingly maternal in origin, arising in the oocyte. About 95 per cent of cases are full trisomy 21 from non-disjunction; the remainder are translocation forms, some inherited and therefore carrying a recurrence risk, and mosaic forms.

Why oocyte non-disjunction increases with maternal age is not known. The candidate mechanisms — cohesin degradation over decades of meiotic arrest, spindle checkpoint weakening, reduced recombination — are plausible and none is established as the determinant. **Nothing modifiable has been identified.** There is no exposure to avoid, no supplement to take, and no intervention that reduces the chance of the event. This is the clearest case in the chapter of a condition with a precisely measured risk and no preventable cause.

**Cure status.** CONTROLLABLE. Nothing removes the extra chromosome and nothing is in prospect that would. Every treatment addresses an associated condition, and the four- to five-fold life expectancy increase above was achieved entirely that way: cardiac surgery, antibiotics, thyroid replacement, leukaemia treatment, and the end of institutionalisation.

The state is held well and increasingly long. **Intellectual disability is present in nearly all cases** and is permanent, and Down syndrome accounts for about a third of all intellectual disability. The associated conditions are individually treatable, several of them curable, and the total burden is substantially a function of whether they are treated.

The associated conditions and their measured frequencies: - **Congenital heart disease: about 40 per cent of newborns.** - **Hearing problems: 50 to 90 per cent of children**; otitis media with effusion 50 to 70 per cent; chronic ear infections 40 to 60 per cent. - **Vision problems: 38 to 80 per cent**; strabismus 20 to 50 per cent; **cataracts 15 per cent**; keratoconus 21 to 30 per cent. - **Thyroid problems with hypothyroidism: 20 to 50 per cent; congenital hypothyroidism 1 per cent.** - **Sleep apnoea: about half to 60 per cent.** - **Constipation: nearly half**; Hirschsprung's disease 2 to 15 per cent. - **Coeliac disease 7 to 20 per cent**; type 1 diabetes more common. - **Epilepsy: 5 to 10 per cent of children and up to 50 per cent of adults.** - **Alzheimer's disease: about 15 per cent of those living to 40 and over, and 50 to 70 per cent of those reaching 60.** This is the dominant determinant of late-life outcome and it is RELIEF ONLY. - **Autism 5 to 10 per cent of children; mental illness in nearly 30 per cent of children.** - **Atlantoaxial instability 1 to 2 per cent.** - **Leukaemia: 10 to 15 times more common in children; acute lymphoblastic leukaemia 20 times; acute megakaryoblastic leukaemia 500 times. Transient myeloproliferative disease in 3 to 10 per cent of newborns, of whom about 10 per cent progress to acute megakaryoblastic leukaemia.** Solid cancers of lung, breast and cervix are less common; testicular germ cell cancer more common.

**Prevention. There is no prevention.** No exposure, supplement, behaviour or treatment reduces the chance of trisomy 21 occurring. The only modifiable factor is maternal age at childbearing, and the risk gradient above is not a basis for a preventive recommendation.

What exists is prenatal screening, which detects rather than prevents, and whose consequence is overwhelmingly termination. That must be reported as what it is.

Prenatal screening detection rates:

| Screen | Timing | Detection rate | False positive rate |
|---|---|---|---|
| Combined test | 10–13.5 weeks | **82–87 per cent** | 5 per cent |
| Quad screen | 15–20 weeks | **81 per cent** | 5 per cent |
| Integrated test | 15–20 weeks | **94–96 per cent** | 5 per cent |
| Cell-free fetal DNA | from 10 weeks | **96–100 per cent** | **0.3 per cent** |

Common screening overall gives 90 to 95 per cent detection with 2 to 5 per cent false positives; nuchal translucency alone 75 to 80 per cent with 6 per cent false positives; second-trimester blood markers about 60 to 70 per cent; and cell-free DNA first-trimester accuracy 98.6 per cent.

**The outcome of diagnosis: about 92 per cent of diagnosed European pregnancies are terminated, and about 75 per cent in the United States, with a range of 61 to 93 per cent**†. These are the measured consequences of the screening programme and the

reason the United States birth prevalence fell from 2 per 1,000 in the 1950s to about 1.4 per 1,000.

Prevention of the associated conditions, where the real preventive gains are: - **Newborn pulse oximetry and echocardiography — STRONG** for the 40 per cent with heart defects. - **Newborn and annual thyroid screening — STRONG** for the 20 to 50 per cent with thyroid disease. - **Hearing screening at birth and annually — STRONG** for the 50 to 90 per cent with hearing problems. Untreated hearing loss compounds the intellectual disability and is largely preventable. - **Vision screening including for cataract — STRONG.** - **Coeliac screening; a sleep study for apnoea; cervical spine assessment before anaesthesia or sport.** - **Early intervention, education and inclusion — STRONG** for functional outcome. The life expectancy and functional gains of the last fifty years are substantially attributable to deinstitutionalisation and education rather than to medicine.

**Treatment.** There is no treatment for the trisomy. Treatment is of the associated conditions. **1. Cardiac surgery** for the 40 per cent with congenital heart disease. **This is the single largest contributor to the life expectancy increase above.** Atrioventricular septal defect, the characteristic lesion, requires bypass surgery in infancy.

**2. Levothyroxine** for hypothyroidism. EML-listed for hypothyroidism, oral solid 25, 50 and 100 µg, first added 1977; off-patent, **cents a day**. It treats a condition affecting up to half of this population, cheaply and completely.

**3. Hearing management** — grommets, hearing aids, and treatment of recurrent otitis media. The commonest treatable contributor to apparent cognitive limitation.

**4. Vision management** — spectacles, strabismus surgery, cataract surgery.

**5. Leukaemia treatment.** Children with Down syndrome and acute lymphoblastic or myeloid leukaemia have better response rates to standard chemotherapy for myeloid leukaemia and greater treatment toxicity, requiring dose modification. Transient myeloproliferative disease of the newborn usually resolves spontaneously and requires surveillance rather than treatment.

**6. Surgical treatment of duodenal atresia and Hirschsprung's disease** in the newborn period.

**7. Treatment of sleep apnoea** — adenotonsillectomy, and continuous positive airway pressure.

**8. Early intervention, physiotherapy, speech and language therapy, occupational therapy, and educational support.** The strongest determinants of functional outcome, and none is a drug.

**9. Epilepsy treatment**, for the 5 to 10 per cent of children and up to 50 per cent of adults.

**10. Coeliac management** — a gluten-free diet for the 7 to 20 per cent.

**11. Dementia care** from the fifth decade. RELIEF ONLY, and the dominant late-life issue.

**Nothing targeting the trisomy itself exists.** Trials of cholinesterase inhibitors, memantine, antioxidants and GABA-A antagonists for cognition in Down syndrome have been negative.

**Simple means.** - **Breastfeeding support.** Hypotonia makes latching and sustained sucking difficult, and most babies with Down syndrome can breastfeed with positioning support, patience and expressed-milk supplementation. Free, and it matters because of the infection burden. - **Feeding and growth monitoring** with a scale and the Down-syndrome-specific growth charts. - **Physiotherapy and positioning taught to the parent.** Hypotonia responds to handling; the gross motor milestones come later and they come. Parent-delivered programmes are the standard where no therapist exists. - **Speech and language stimulation by the family**, with sign and gesture as a bridge, because expressive speech lags comprehension substantially. - **Looking in the eyes for a white pupil**, and **observing response to sound** — two examinations requiring nothing. - **Checking for constipation and managing it** with diet and fluid. It affects nearly half. - **Dental hygiene.** Periodontal disease is common. - **Education and inclusion.** The largest measured functional gains of the past half-century came from schooling and from not institutionalising children, and neither is a medical technology. - **Parent-to-parent support and accurate information at diagnosis.** What parents are told at birth shapes the child's life course, and in many

settings it is still inaccurate and pessimistic. - **A thyroid blood spot** — a heel prick and a card. Low chain, very high value here given the 20 to 50 per cent frequency.

The minimum chain: for the conditions that determine survival, cardiac surgery, with no substitute. For the conditions that determine function, levothyroxine tablets, grommets, spectacles and education. **Most of what improves life with Down syndrome is not pharmaceutical.**

**Gaps.** The death figures do not reconcile: 27,000 in 2015 against about 17,000 in 2010; both printed. Birth prevalence figures measure occurrence minus termination, and the United States fall from 2 per 1,000 in the 1950s to 1.4 per 1,000 is a screening effect rather than a biological one, so **any trend statement about Down syndrome prevalence is a statement about screening policy.** The 70 per cent figure — that mothers aged 35 and younger account for most cases — is routinely omitted from accounts of maternal-age risk, and it determines screening policy. No figure from a source fetched in the retrieval round is available for trisomy 18 or 13, or for Klinefelter and Turner syndromes. Life expectancy figures are all from high-income settings; life expectancy with Down syndrome in low-income countries, where the 40 per cent with heart defects are largely unoperated, is not reported anywhere located, and the gap is likely very large. Several associated-condition frequencies are given as very wide ranges reflecting differing ascertainment. No current cause-specific burden figure was retrievable. No cognition-targeted treatment works, and the trial record is uniformly negative. Termination rates are from 1999 and 2012 sources and will have moved with cell-free DNA screening; no current figure was located.

---

## Clubfoot

**What it is.** The foot is turned inward and downward at birth, with the sole facing inward. The bones, ligaments and tendons are all shortened on the inner side. Untreated, the child walks on the outside or top of the foot, which ulcerates and disables.

**Measured.** Birth prevalence: **about 1 in 800 live births**†, and **0.5 to 2.0 per 1,000 live births in low- and middle-income countries**†. Annual burden: **150,000 to 200,000 children every year**†.

**Treatment coverage is the central measured fact: less than 15 per cent of children born with clubfoot in low- and middle-income countries start treatment**. A survey of 2015 data found **11 per cent coverage across all such countries and 14 per cent in respondent countries**, for children under age 1†.

Service availability: treatment is offered in **113 of 193 UN member states**, **80 countries showed no evidence of such activity**, and in most countries programmes do not cover all new patients.

No deaths figure and no clubfoot-specific DALY figure exists; the condition does not kill. Occurrence is roughly uniform, and **untreated prevalence is concentrated entirely in low- and middle-income countries**, because in high-income countries essentially every case is treated in infancy.

**Where it starts.** Male sex, at roughly twice the rate in boys. Strong familial clustering, with sibling recurrence elevated several-fold. Bilateral in about half of cases. Breech presentation, oligohydramnios and first pregnancy raise risk, as does maternal smoking in pregnancy, with a reported interaction with family history. It is associated with spina bifida, arthrogryposis and some syndromes, and **syndromic clubfoot is stiffer, more resistant to casting and has worse outcomes**, so distinguishing it from idiopathic clubfoot at presentation matters for the prognosis. No effect sizes were located.

The cause of idiopathic clubfoot, which is the large majority, is not known. A primary germ plasm defect in the talus, abnormal muscle fibre composition, a neurogenic abnormality, intrauterine constraint and a vascular abnormality have all been proposed, and none is established. The genetics are clearly contributory and incompletely mapped. **There is no preventive intervention because there is no identified modifiable cause.**

**Cure status.** CURABLE — and with the Ponseti method it is among the clearest curable-with-simple- means cases in all of surgery. A deformity that permanently disables is corrected with

plaster casts applied weekly over about six weeks, by a trained non-surgeon, followed in most cases by a tendon release under local anaesthesia and a bracing period.

Success rates: **four of five systematic reviews reported initial correction rates around or above 90 per cent**†; one series reported **96.4 per cent, 661 of 686 feet**†; the method is described as effective in more than 90 per cent of patients, and the cost-effectiveness model assumes 90 per cent success†. A programme funder's own model assumes **80 per cent**, which it describes as a subjective guess lower than the published rates, and that is printed because it is the most conservative figure available and it comes with its reasoning.

**The relapse qualification must be stated.** A 2021 review found **47 per cent relapse across studies averaging 14.5 years of follow-up, and 79 per cent of relapsed patients needed further surgery**. The 2020 Cochrane review found only low-certainty evidence for some comparisons; it included 21 trials with 905 participants, the largest at 100. So initial correction is achieved in about 90 per cent and is well documented, long-term durability is substantially less certain, and relapse — usually managed by repeat casting rather than major surgery if caught early — is common. Bracing adherence is the main determinant and the main failure mode.

Cost figures disagree, and all are printed. **US$167 per patient** for average treatment on the abstract of one paper, against **US$140** in the results section of the same paper, which is internally inconsistent. **US$170 per patient in Pakistan**†. **About US$652 total per child — US$543 from non-governmental organisations at 2022 prices, plus US$109 from governments**†. An estimated average of **US$317 per child in 2017, falling to US$82 by 2030**†. Against those: over **US$30,000 for recurrent bilateral cases in the United States**†.

Cost-effectiveness: **US$22.46 per DALY averted, sensitivity range US$5.28 to 29.75**. **This is among the lowest cost-per-DALY figures for any surgical or orthopaedic intervention in the literature.** A funder's model estimates about 6 DALYs averted per child treated and publishes no cost per DALY; dividing its US$652 by 6 gives roughly **US$109 per DALY**, which that source notes is arithmetic rather than its own figure. **The two cost-per-DALY figures differ roughly five-fold, at about US$22 and about US$109**, and both are printed; the difference is driven by the cost per child and by the included cost perspective. The arithmetic is internally consistent: US$22.46 × 6 = US$134.76, which sits just below the US$140 to 167 range, and US$652 ÷ 6 = US$108.67, matching the printed figure.

**Prevention.** - **There is no prevention.** No modifiable cause is identified. - **Maternal smoking cessation — WEAK**, the only modifiable association, with a reported family-history interaction. - **Folic acid — no established effect** on clubfoot.

What substitutes for prevention is early detection, because the method works best in the first weeks of life and becomes harder with age. - **Newborn examination of the feet — STRONG.** It costs nothing and requires looking. - **Prenatal ultrasound**, which detects a share from the second trimester and allows the family to be prepared and referred. - **Community case-finding and referral — STRONG** for coverage, which is the binding constraint at 11 to 15 per cent.

**Treatment.** No drug treats clubfoot. **1. The Ponseti method.** First line, and it displaced primary surgery entirely. - **Weekly manipulation and above-knee plaster casting**, typically **5 to 7 casts over about 6 weeks**, correcting the deformity components in a specific sequence: cavus, adductus, varus, then equinus. - **Percutaneous Achilles tenotomy** under local anaesthesia in about 80 to 90 per cent of cases†, to correct the residual equinus. **A scalpel, local anaesthetic, and no operating theatre.** - **Foot abduction bracing** — full-time for about 3 months, then at night and during naps until age 4 or 5. **Bracing adherence is the single determinant of relapse** and the main reason for the 47 per cent long-term figure. - **Deliverable by trained non-physician health workers** — physiotherapists, orthopaedic officers, clinical officers. This is what makes it scalable.

**2. Repeat Ponseti casting for relapse.** First line for relapse detected early, and it avoids surgery.

**3. Tibialis anterior tendon transfer** for dynamic supination relapse in the walking child.

**4. Extensive soft-tissue release surgery**, now a salvage option rather than a primary treatment. It produces a stiff, painful, scarred foot in the long term, which is why Ponseti replaced it. Osteotomy and arthrodesis in the neglected adolescent or adult foot.

**5. The French functional physiotherapy method** — daily manipulation and taping, an alternative with comparable short-term results in trained hands and far more labour-intensive.

**Simple means.** This is one of the strongest entries in the book for simple means, because the standard best treatment **is** the simple means. - **Plaster of Paris.** Rolls of plaster bandage and water. The correction of a permanently disabling deformity is achieved with plaster, hands and a weekly appointment. **The casting materials for a full course cost a few US dollars**. - **Trained hands rather than a surgeon.** The method is explicitly designed to be taught to non-physicians, and the training package is a course plus supervision. - **A scalpel and local anaesthetic** for the percutaneous tenotomy. No theatre, no general anaesthesia. - **Locally manufactured foot abduction braces.** Steenbeek braces, made from leather, plywood and a steel bar by a local workshop, cost a few US dollars against hundreds for imported designs and are the standard in African clubfoot programmes. **This is the clearest example in this chapter of a device whose supply chain was deliberately shortened to the point of local manufacture.** - **Parent-delivered bracing.** The parent applies the brace, checks the skin, and brings the child back. Adherence is the outcome determinant and the parent is the intervention. - **Looking at the newborn's feet.** Free. - **Community case-finding.** At 11 to 15 per cent coverage the overwhelming constraint is not the treatment but finding the children. - **A follow-up card and a walk to a clinic.**

The minimum chain: plaster, water, a scalpel, local anaesthetic, a locally made brace and a trained non-surgeon. Everything needed to cure a disabling congenital deformity in about 90 per cent of cases is in that list, for a few dollars in materials and a cost in the low hundreds of dollars at most.

**Gaps.** The cost figures disagree by more than four-fold — US$140 to 167 per patient from a paper internally inconsistent between abstract and results, US$317 from a 2017 estimate, US$652 from a 2022 funder model — and the cost-per-DALY figures differ roughly five-fold in consequence; all printed. The 2020 Cochrane review found only low-certainty evidence for some comparisons, with 21 trials, 905 participants and the largest at 100, so the best-documented success rate in this entry rests on systematic reviews of small studies and on programme series rather than large trials. The 47 per cent relapse figure at 14.5 years' mean follow-up, with 79 per cent of relapsed patients needing further surgery, sits uneasily beside the 90 per cent initial correction rate; both are true of different time horizons and the long-term figure is less often quoted. Many cost and coverage sources are authored by people affiliated with clubfoot programmes, and the funder rates its own uncertainty as high, particularly on disability weights, relapse, economic effects and marginal impact; its shallow review did not assess the systematic reviews' quality in depth. Its 80 per cent assumed success rate is lower than every published rate and is described as a subjective guess. No deaths figure and no clubfoot-specific DALY figure exist, the burden is entirely disability, and the disability weight is contested. The number of untreated children alive today is not quantified: the 11 to 15 per cent coverage figure implies a very large accumulated untreated population and no source located sizes it. There are no effect sizes for risk factors and no identified preventable cause. Syndromic and idiopathic clubfoot have different outcomes and are not separated in most of the coverage and success data.

---

## Developmental dysplasia of the hip

**What it is.** The ball of the hip joint does not sit properly in the socket. The socket may be too shallow, or the hip may slip in and out, or be dislocated outright. Caught in the first months it is corrected by a harness; caught late it needs surgery and often leaves a damaged joint.

**Measured.** Birth prevalence: **about 1 in 1,000 babies have hip dysplasia**†. **Meaningful hip instability: 1 to 2 per cent of term births**†. The two figures measure different things — frank dysplasia against detectable instability — and the ten-fold difference is the reason screening is contested.

Early newborn instability may affect as many as **1 in 60 newborns, falling to about 1 in 240 by one week**†, with no publication year given. Most neonatal instability resolves spontaneously within days.

Females are affected **about eight times more often than males**. Native Americans have the highest reported risk at **about 25 to 50 per 1,000**†, with no year given. The left hip is more often affected, and in most unilateral cases it is the left.

About **7.5 per cent of hip replacements address problems arising from hip dysplasia**. There is no deaths figure and no DALY figure.

**Where it starts. Breech presentation** is described as probably the most important single risk factor, whether delivered vaginally or by caesarean, with **no effect size given**; the mechanism is intrauterine hip position, not the delivery. **If one identical twin is affected, the other has about a 40 per cent risk**†. Female sex carries eight-fold risk, and the source states that female sex alone, without other known risk factors, accounts for **75 per cent of cases**, while **noting itself that this statement is ambiguous and should be read cautiously**.

**Swaddling and restrictive carriers** — tight swaddling and cradle boards that hold the hips adducted and extended — are linked to the condition, with no effect size given. **This is the one genuinely modifiable cause**, and the historical evidence is the high rates in populations using cradle boards and the fall following swaddling-education campaigns in Japan and elsewhere.

Firstborn status, a locus on chromosome 13, the hormone relaxin as a proposed contributor, and oligohydramnios are also named.

Almost all of the effect sizes are missing. The source gives numbers only for the twin concordance at 40 per cent and the sex ratio at eight-fold, and flags the 75 per cent figure as ambiguous. And one thing is genuinely unresolved: **whether dysplasia reliably causes early osteoarthritis.** It is often cited as doing so, **some studies contradict it**, and **no study has yet found a reliable method for predicting outcomes**. That matters, because the justification for universal screening rests on preventing a late consequence whose inevitability is contested.

**Cure status.** Mild neonatal instability, which is most of it: SELF-LIMITING. Many mild cases resolve without specific treatment, and most neonatal instability resolves within days. Caught early: CURABLE. The source states that the Pavlik harness or Frejka pillow usually gives normal results when used in the first year, and **gives no success rate and no source for that statement**. The published literature reports harness success in the region of 85 to 95 per cent for reducible hips treated in the first months†; no figure is asserted here, because the source consulted does not supply one. Caught late: CONTROLLABLE. Surgery and casting may be needed, and the result is a joint that has been reduced rather than a normal joint. Untreated cases can lead to arthritis, limping and low back pain.

Harness complications bear on the risk-benefit of screening and belong in the record: **femoral nerve palsy and avascular necrosis have been reported**, and **whether these result from improper application or from the disease itself is unresolved**.

**Prevention.** - **Avoiding tight swaddling that holds the hips adducted and extended — MODERATE, and this is the only real prevention.** Hip-healthy swaddling allows the legs to flex and abduct. The evidence is the historical rates in cradle-board populations and the declines following education campaigns, and **no effect size was located.** Cost: zero. It is a change in technique, and the baby can still be swaddled. - **Baby-carrying positions that abduct the hips**, with the legs astride the carrier’s body, are protective; the historically low rates in populations carrying babies this way are the supporting observation. - **There is no other prevention.** Breech position, sex and genetics are not modifiable.

Screening is detection rather than prevention, and it is genuinely contested. - **Clinical examination of all newborns — recommended**. **A 2024 systematic review found clinical tests are not sufficiently reliable for diagnosis**. - **Ultrasound**, generally preferred up to about 4 months, and **it should usually not be performed before 3 to 4 weeks of age** because of normal physiological laxity, which would otherwise generate large numbers of false positives. - **Universal ultrasound screening against targeted screening produced an insignificant reduction in late diagnoses, and is therefore not recommended**. This

is the key finding and it is a negative one. - **Isolated hip clicks are no longer clinically significant** on 2021 guidance† — a sign that was screened on for decades and has been discarded. - Newborn hip examinations may be painful; oral glucose has been suggested for pain relief and is not widely accepted.

**Treatment.** No drug treats hip dysplasia. **1. Observation** for mild instability in the first weeks, since most resolves.

**2. The Pavlik harness, or Frejka pillow.** Worn for weeks to months, holding the hips flexed and abducted so the femoral head seats in the socket and the socket deepens in response. First line under about 6 months. **A cloth-and-strap device.** The source states it usually gives normal results in the first year and supplies no success rate. Complications are femoral nerve palsy and avascular necrosis. It requires serial clinical and ultrasound monitoring, which is the real resource requirement.

**3. Closed reduction under anaesthesia with hip spica casting**, where the harness fails or the child presents after about 6 months, with an arthrogram to confirm reduction.

**4. Open reduction**, with or without femoral or pelvic osteotomy, for later presentation or failed closed reduction.

**5. Pelvic and femoral osteotomy** in the older child, and periacetabular osteotomy in the adolescent and young adult with residual dysplasia.

**6. Total hip replacement** in adulthood for the degenerate joint — about 7.5 per cent of hip replacements address dysplasia-related problems.

**7. Abduction bracing and physiotherapy** as adjuncts.

**Simple means.** - **Hip-healthy swaddling and carrying. The prevention is a technique, taught in one demonstration, costing nothing.** Allow the hips to flex and spread; carry the baby with the legs astride. This is the only genuinely preventive simple means in the entry and it works on the only modifiable cause. - **Clinical examination — the Ortolani and Barlow manoeuvres.** Two hands, no equipment, performed at every newborn check and at subsequent visits. Imperfect, as the 2024 review found, and free, and in settings with no ultrasound it is the entire screening programme. - **Looking for asymmetry** — unequal thigh skin creases, limited abduction, apparent leg-length difference, and in the walking child a limp or waddling gait. Free, and limited abduction in the older infant is the most useful single sign. - **The Pavlik harness is itself close to a simple means** — cloth straps and buckles. Locally manufactured harnesses are used in some programmes, as with the Steenbeek brace. - **Parent-applied harness care and skin checks.** - **A hip spica cast** is plaster, a materials cost of a few dollars, though it requires anaesthesia for the reduction. - **Return appointments.** The outcome depends almost entirely on the age at detection, so a follow-up card is an intervention.

The minimum chain: two hands for the examination and a change in swaddling technique for the prevention. For the dysplastic hip that needs reduction, anaesthesia and plaster; for the late presentation, major orthopaedic surgery, with no substitute.

**Gaps.** The source gives no harness success rate despite describing its results as usually normal, which is a significant absence for the entry's central treatment, and the figure could not be verified elsewhere. Almost no effect sizes exist: only twin concordance at 40 per cent and the sex ratio at eight-fold are quantified, and breech presentation is called the most important single risk factor with no number attached. The "female sex accounts for 75 per cent of cases" statement is flagged as ambiguous by the source itself. **Both the recommended and the unrecommended screening strategies have negative evidence against them:** universal ultrasound screening produced an insignificant reduction in late diagnoses and is not recommended, and clinical examination, which is recommended, was found insufficiently reliable by a 2024 review. Whether dysplasia reliably causes early osteoarthritis is contested, and no reliable method for predicting outcomes exists, so the late consequence that justifies screening is not established as inevitable. Whether harness complications are iatrogenic or disease-related is unresolved, which prevents a clean risk-benefit calculation for early treatment. The early instability figures have no publication year. There is no deaths or DALY figure, no global incidence estimate, and no cost or cost-effectiveness figure. The high-prevalence population figures are reported without a year or a method.

## Congenital hypothyroidism

**What it is.** A baby is born without enough thyroid hormone, because the gland did not form properly or because the mother and baby lacked iodine. Thyroid hormone is required for brain development. Untreated, the child is permanently intellectually disabled; treated within the first weeks, the child develops normally.

**Measured.** Primary congenital hypothyroidism: **about 1 in 2,000 to 1 in 3,000 births worldwide**†. Central congenital hypothyroidism: **about 1 in 16,000 to 1 in 30,000 births**†. Severe deficiency: **about 1 in 4,000 newborns**, with more having mild or moderate deficiency†.

Global prevalence across 1969 to 2020: **4.23 to 4.28 per 10,000 newborns**, varying by region and income level, most prevalent in the Eastern Mediterranean and in upper-middle-income countries, and least prevalent in Europe and high-income countries.

**The incidence has risen, mainly from wider newborn screening and lower TSH thresholds**, with preterm survival, older maternal age and environmental toxin exposure named as possible contributors. The rise is substantially a detection effect.

Risk factors named are female sex and gestational age over 40 weeks†. In Down syndrome, congenital hypothyroidism affects about 1 per cent and thyroid problems with hypothyroidism 20 to 50 per cent†.

No deaths figure and no DALY figure specific to congenital hypothyroidism were located. **The burden is intellectual disability, and it is entirely preventable.** It is described as the most common preventable cause of intellectual disability.

**Where it starts. Worldwide, iodine deficiency is the most common cause.** In the developed world, developmental thyroid defects rather than iodine deficiency dominate, with the dysgenesis breakdown given as **agenesis 22 to 42 per cent, ectopy 35 to 42 per cent, and gland-in-place defects 24 to 36 per cent**; recent studies report more cases from in-place glands with hormone production defects.

Also established: genetic defects in thyroid development and in hormone synthesis; in-utero lithium exposure; **topical iodine in preterm neonates under 32 weeks**, which can cause transient dysfunction and is an iatrogenic route; maternal antibodies, which can cause temporary hypothyroidism; and organochlorine and dioxin-like chemicals, associated in one study. No effect sizes beyond the dysgenesis shares were located.

The cause of thyroid dysgenesis, which dominates where iodine is sufficient, is not known. Most cases are sporadic, the monogenic causes explain a minority, and why a gland fails to descend or to form is not established. The rising incidence is also not explained: lower thresholds and wider screening account for much of it, and whether any real increase is occurring, and whether the additional mild cases detected at lower thresholds actually benefit from treatment, is unresolved and consequential.

**Cure status.** CURABLE. A **heel-prick blood spot** costing a few cents detects it. A **levothyroxine tablet costing cents a day**, started in the first one to two weeks of life, prevents the intellectual disability entirely. The treatment is lifelong and it is replacement of a missing hormone rather than management of a disease process, and the child's development is normal.

The evidence: screening substantially reduces the risk of irreversible neurodevelopmental harm, and the goal is to start treatment within the first 1 to 2 weeks of life†. **Developmental outcomes at 24 months for treatment started within the first 3 weeks: developmental quotients of about 89 to 92 in severe cases, 96 to 98 in moderate and 99 to 100 in mild, across domains**† — essentially normal development in moderate and mild cases and near-normal in severe. Most promptly treated children grow and develop normally, including bone growth, puberty, fertility and cardiac health. Even treated infants with no thyroid gland at all may have normal cognition, though mild learning problems and lower academic performance are possible.

Against that, the cost of missing it: **severe untreated congenital hypothyroidism causes growth failure and permanent intellectual disability**, and **before screening, fewer than half of severe cases were recognised in the first month, and most untreated severe cases had an IQ below 80**†.

The ratio is a few cents of test and cents a day of tablet against permanent intellectual disability.

**Prevention.** Two distinct things, which must not be conflated.

**Preventing the condition.** - **Iodine fortification or supplementation — STRONG** for the iodine-deficiency fraction, which is the most common cause worldwide. WHO lists iodine fortification or supplementation among its congenital-disorder prevention measures **without quantifying it**, and the source consulted for this entry reports no data on iodisation programmes. Universal salt iodisation is among the cheapest population interventions in existence, of the order of a few US cents per person per year, and the global decline in iodine deficiency disorders since the 1990s is attributed to it. **The exact effect on congenital hypothyroidism incidence could not be sourced**, and no figure is asserted. - **Avoiding topical iodine in very preterm neonates — STRONG** for that iatrogenic route. - **Avoiding in-utero lithium exposure where alternatives exist — MODERATE.** - **There is no prevention for thyroid dysgenesis**, the dominant cause where iodine is sufficient.

**Preventing the harm — newborn screening, which is where the measured benefit is.** - **Heel-prick dried blood spot TSH testing, ideally at least 48 hours after birth — STRONG**. - **Adding free T4 improves detection of central congenital hypothyroidism**†. - **Preterm or ill infants: a repeat test at 10 to 14 days is advised**, because delayed TSH rise causes false negatives. - **Follow-up at 4 to 6 weeks**, because maternal antibodies can cause transient hypothyroidism. - In central congenital hypothyroidism, screening may reveal combined pituitary hormone deficiencies, which changes long-term management. - **Coverage is the gap.** Newborn screening is universal in high-income countries and absent or partial across much of South Asia and sub-Saharan Africa, which is where the higher prevalence is. **No coverage figure was located.**

**Treatment. 1. Levothyroxine. One drug, and it is sufficient.** Dose 10 to 15 µg/kg daily, typically 12.5 to 37.5 or 44 µg. **Start within the first 1 to 2 weeks of life**: the interval to the first dose is the determinant of the outcome. EML-listed for hypothyroidism, oral solid 25, 50 and 100 µg, first added 1977. Off-patent. **Cost: cents a day**, with a year of treatment for an infant costing a few US dollars; the source describes treatment as simple, effective and inexpensive and gives no cost figures. It is lifelong, with dose adjustment by weight and by TSH and free T4 monitoring. Practical caveats: the tablet must be crushed and given in water or milk; soy, iron and calcium interfere with absorption; and the preparation's potency must be reliable, which makes product quality a real issue in markets with poor regulation.

**2. In central congenital hypothyroidism, hydrocortisone must be started before levothyroxine when ACTH deficiency is present, to avoid adrenal crisis**. This is a safety rule with a fatal failure mode and it belongs in the treatment order.

**3. Monitoring** — TSH and free T4 at intervals through infancy and childhood, with dose adjustment. **This is the resource requirement that limits the intervention more than the drug does.**

**4. Re-evaluation at age 2 to 3** to distinguish permanent from transient congenital hypothyroidism, so that children with transient disease can stop treatment.

**5. Iodine supplementation** where deficiency is the cause.

**Simple means.** - **The heel-prick blood spot on a filter paper card.** A lancet, a card, and a postal route to a laboratory. **The consumable cost is a few cents.** This is the screening technology for the condition and it is among the shortest supply chains of any diagnostic in the book — the card can be posted. - **Levothyroxine tablets, crushed in water.** Cents a day, no cold chain, oral, once daily. - **Clinical examination for the untreated case**, where no screening exists: prolonged jaundice, a large fontanelle, umbilical hernia, macroglossia, hypotonia, hoarse cry, constipation, poor feeding, cold mottled skin, delayed milestones, and a goitre in dyshormonogenesis. **These signs appear after the window for preventing brain injury has largely closed**, which is exactly why screening exists — and in its absence they are what can be done. - **Iodised salt.** A few cents per person per year, delivered through the existing salt trade, and requiring nothing of the individual. - **Growth monitoring** — length and weight plotted. Growth failure is the visible sign. - **Teaching the parent to give the tablet daily and consistently**, away from soy, iron and calcium. Adherence over years is the long-run determinant. - **A treatment card** recording the dose and the next review.

The minimum chain: a lancet, a filter paper card, a laboratory and a tablet. The laboratory is the only part that is not improvisable, and a single central laboratory can serve a very large population by post.

**Gaps.** No cost figures appear in the source consulted, which calls treatment inexpensive without quantifying it; the figures given here are order-of-magnitude from the generic market. No data on iodisation programme effects on congenital hypothyroidism incidence appear in the source consulted, despite iodine deficiency being named the most common cause worldwide, and **this is the largest gap in the entry: the leading cause globally has the least-quantified prevention.** No newborn screening coverage figure was located, so the size of the preventable burden is unknown, and the prevalence is highest where screening is least available. There is no deaths or DALY figure. The rising incidence is largely a detection effect of lower thresholds, and whether the additional mild cases detected benefit from treatment is unresolved — a live question about over-treatment that no source reached settles. Dysgenesis shares vary widely between studies and the more recent data shift toward gland-in-place defects, suggesting the classification itself is moving. Long-term academic outcomes in treated athyreosis rest on a 1994 source, with no modern cohort figure located. Levothyroxine product quality in poorly regulated markets is a real risk to the CURABLE classification and is unquantified.

---

## Hypospadias

**What it is.** In a baby boy the opening of the urethra is not at the tip of the penis but somewhere along its underside. The penis may also curve downward. It affects urination standing and, in severe cases, later sexual function.

**Measured.** Birth prevalence: **about 1 in 250 males, roughly 4 per 1,000 male births**†. The same source also states it may affect as many as **1 per cent of males** at birth, which is 10 per 1,000†. Both printed. Including milder cases, prevalence reaches up to **4 per cent, or 40 per 1,000**, in one Danish cohort of 1,072 boys†. **A ten-fold range across definitions.**

Prevalence varies by country, and **the source states that national registries cannot reliably determine incidence or geographic variation because their reporting requirements differ**.

**No trend is reported.** The source cites a 1999 paper on international trends without stating its findings†. A widely discussed reported doubling in some registries in the late twentieth century is contested and partly ascertainment, and no trend is asserted here.

Severity distribution: about **90 per cent of male cases are distal**, and the rest proximal†. **No studies have estimated prevalence in newborn females**.

There is no deaths figure and no DALY figure. The condition does not kill; the burden is functional, surgical and psychological.

**Where it starts.** The quantified figures available: **chordee, or downward curvature, in about 10 per cent of distal and 50 per cent of proximal cases at surgery**†; **undescended testicle in about 3 per cent of distal and 10 per cent of proximal cases**†; and **disorders of sex development or syndromes in about 10 per cent of cases**†, with proximal hypospadias and undescended testes requiring investigation for a disorder of sex development.

**Identical twins: when one is affected, the other is affected only 25 per cent of the time**†. **This is the strongest single piece of evidence against a predominantly genetic cause** — a 25 per cent concordance in genetically identical individuals.

Genetic, environmental and prenatal hormonal factors have been studied and **the source gives no effect sizes for any of them**. The epigenetic model is **explicitly described as unproven**, and a 2023 study reported altered foreskin DNA methylation in patients. The standing hypotheses in the wider literature involve androgen action during the critical window of urethral closure — placental insufficiency, low birth weight, and endocrine-disrupting chemical exposure — and none is established.

The cause is not known in almost all cases. **This is one of the least-explained conditions in this chapter:** the twin concordance rules out simple genetics, the environmental

hypotheses are unproven, the epigenetic model is described by its own proponents as unproven, and the registries cannot even establish geographic variation reliably. The reported secular trend, which drives much of the endocrine-disruptor hypothesis, is itself contested.

**Cure status.** Minor cases with a well-formed forward-directed opening: no intervention is required. Distal hypospadias, 90 per cent of cases: CURABLE. Tubularised incised plate repair is used for all distal cases, with **complications in under 10 per cent**. Proximal hypospadias, repair successful: CURABLE in 55 to 85 per cent depending on technique. Proximal, often needing more than one operation: CURABLE. Most are anatomically corrected in the end. The same repair for proximal cases with a straight or mildly curved penis gives **about 85 per cent success**; foreskin-based repair for proximal cases gives **55 to 75 per cent**.

Urethroplasty failure rates by graft type are given as **about 5 per cent for simple repairs, 15 to 20 per cent with buccal grafts, and nearly 50 per cent with grafts from other skin**†. **The source itself flags this figure as failing verification**, and it is printed with that caveat. Fistulas in severe cases are below 5 per cent for third-degree repairs at high-volume centres†. Common complications are fistula, glans dehiscence, meatal stenosis, stricture and diverticulum, and most appear within six months.

Functional and satisfaction outcomes qualify the surgical success figures. Erectile problems are more common with chordee, and ejaculation problems occur at similar rates whether or not the hypospadias was repaired. **Patients were less satisfied than surgeons**. That is a measured discrepancy and it belongs in the record.

**Prevention.** - **There is no established prevention**, because there is no established cause. That must be stated plainly. - **Avoiding endocrine-disrupting chemical exposure in pregnancy — CONTESTED.** Mechanistically plausible, epidemiologically inconsistent, and the reported secular trend that motivates it is itself contested. - **Avoiding exogenous progestins and certain hormonal exposures in early pregnancy — WEAK.** - **Folic acid — no established effect** on hypospadias. - **Managing placental insufficiency and preventing fetal growth restriction — WEAK**, via the low-birth-weight association. - WHO's general measures, including reducing exposure to hazardous substances such as heavy metals or pesticides, are listed **without quantification**. - **What exists instead of prevention is examination of the newborn genitalia**, which is detection, and it matters because **circumcision must be avoided in a boy with hypospadias**: the foreskin is the graft material for the repair. **Not circumcising is a free and consequential intervention**, and failing to examine before a routine circumcision removes the repair material.

**Treatment.** No drug repairs hypospadias. **1. Surgical repair.** Single-stage tubularised incised plate repair is the standard for distal cases, with under 10 per cent complications†. Proximal cases use the same technique where the penis is straight or mildly curved, at about 85 per cent success; foreskin-based repairs at 55 to 75 per cent; or **staged repair** — severe cases with a scrotal opening and significant curvature are often corrected in two stages. It requires paediatric urological surgery, magnification, fine suture, paediatric anaesthesia, and a urinary stent or catheter postoperatively.

**2. Timing. The WHO standard is to delay surgery until the child can consent, unless emergency repair is needed**, and the source gives no specific age for this. That position sits against the long-standing paediatric urological convention of operating at 6 to 18 months. **Results are probably not affected by age at repair: adults and children had similar outcomes in a direct comparison**. That finding is what makes the deferred-consent position tenable, and it should be reported alongside it.

**3. Pre-operative hormone treatment** — testosterone or human chorionic gonadotropin to enlarge a small penis before surgery. **The evidence on whether this improves repair success is conflicting**. Testosterone is EML-listed, off-patent, low cost.

**4. Repair of complications** — fistula closure, meatotomy or dilation for stenosis, and urethroplasty for stricture, with the graft-type failure rates above.

**5. Investigation for a disorder of sex development** in proximal hypospadias with undescended testes, which is about 10 per cent of cases. Karyotype, hormonal profile, imaging.

**6. No surgery, where the opening is well-formed and the stream is forward**.

**Simple means.** This entry has a thin simple-means profile and that should be said first. - **Examining the newborn's genitalia, and not circumcising a boy with hypospadias.**

**This is the single most important low-cost act in the entry**: it costs nothing, takes seconds, and preserving the foreskin preserves the graft material on which the repair depends. Losing it converts a straightforward repair into a difficult one. - **Reassurance and accurate information for minor cases.** A well-formed forward-directed opening needs no operation, and telling the family so prevents unnecessary surgery. - **Sitting to urinate.** A behavioural adaptation that resolves the principal practical problem of an unrepaired distal hypospadias. Free, and for an adult who will never have access to surgery it is the whole of management. - **Post-operative catheter and dressing care taught to the parent**, which is the main determinant of whether a repair in a low-resource setting succeeds or fistulates. - **Hygiene, and recognising urinary retention or infection** after repair. - **Referral before any circumcision decision.**

The minimum chain: paediatric urological surgery with magnification and fine suture. There is no simple means, no drug and no improvisation that repairs hypospadias. The honest position is that for an unrepaired distal case the adaptation above is adequate for life, and for a proximal case it is not.

**Gaps.** Prevalence spans ten-fold, from 4 to 40 per 1,000, depending on whether mild cases are included, and the source states registries cannot reliably establish incidence or geographic variation, so the occurrence is not known even approximately. No trend is reported, despite the secular-increase hypothesis being the main driver of the endocrine-disruptor literature. The cause is unknown, the epigenetic model is explicitly unproven, and the 25 per cent identical-twin concordance rules out simple genetics without identifying what replaces it. The urethroplasty graft failure figures are flagged by the source itself as failing verification, and are printed with that flag. Patients were less satisfied than surgeons, so the surgical success rates are surgeon-assessed and the patient-assessed outcome is worse, with no reconciled figure. Pre-operative hormone treatment evidence is conflicting. **The WHO position of deferring until the child can consent and standard paediatric urological practice of operating in infancy are in direct conflict**, and the evidence that outcomes do not depend on age at repair is a single comparison. No prevalence estimate exists for females. No deaths, DALY, cost or cost-effectiveness figures were located for any part of this entry.

---

## Limb reduction defects

**What it is.** Part or all of a limb fails to form in the womb. A missing hand, a shortened forearm, absent fingers, or a missing leg. The child is born with the limb already absent; nothing was lost.

**Measured. No global figure was retrieved** for congenital limb anomalies, in the current or the prior round. GBD reports only the aggregate congenital anomalies figure of 54.8 million DALYs for 2023.

The standing figures in the published registry literature — approximately **4 to 7 per 10,000 live births** for all limb reduction defects combined, with transverse defects more common than longitudinal — are reported as the registry literature position and were not verified.

**Traumatic amputation, which is a different condition, is far more common: 180 million prevalent amputations and 5.5 million years lived with disability on the 2019 burden study**. That figure is for acquired amputation and belongs with the injury chapter; it is printed here to mark the scale difference.

Prosthesis access determines the burden. Globally, **only 5 to 35 per cent of people who need wheelchairs have access** — the nearest available proxy, since no equivalent figure for prosthetic coverage was located. The standing position is that a large majority of people needing prostheses and orthoses worldwide do not receive them.

There is no deaths figure. The condition does not kill.

**Where it starts. Amniotic band sequence** — fibrous bands constricting a developing limb, producing a transverse amputation-like defect — is one of the better-understood mechanisms. Vascular disruption during limb development is another.

**Thalidomide** is the historical and definitive teratogenic cause, producing characteristic phocomelia; the episode from 1957 to 1962 established teratology as a field and remains the

clearest demonstration that a limb reduction defect can have a single identifiable chemical cause. **Thalidomide is still in use for multiple myeloma and for leprosy reactions, and continues to produce cases where pregnancy prevention programmes fail**, notably in Brazil.

**Misoprostol taken in early pregnancy in an unsuccessful abortion attempt** is an established cause of limb defects and of Möbius sequence, documented particularly in Brazil. **This creates a direct link to the unsafe abortion entry: restricted abortion access produces a congenital anomaly.**

Also established: maternal diabetes, chorionic villus sampling before 10 weeks, maternal smoking, and some antiepileptics. Genetic syndromes — Holt-Oram, Fanconi anaemia, TAR syndrome, Roberts syndrome, the VACTERL association — account for a minority of cases and carry other anomalies that matter more. Consanguinity raises risk as it does generally. No effect sizes were located.

The cause is unknown in most cases. Limb development is well understood embryologically — the apical ectodermal ridge, the zone of polarising activity, the HOX gene expression pattern — and that understanding has not translated into identified causes for sporadic human cases. Most are isolated, sporadic and unexplained. The thalidomide and misoprostol examples show that chemical causes exist and are identifiable, which makes the absence of identified causes for the remainder a genuine gap rather than a theoretical one.

**Cure status.** RELIEF ONLY. The limb cannot be restored, and that must be stated without softening: no treatment makes the missing limb grow. Everything available is substitution with a prosthesis, adaptation by training the child to function with what is present, or surgical modification to make substitution or function better.

What that relief achieves is nonetheless very substantial, and the classification should not be read as a counsel of despair. Children with congenital limb difference, unlike adults with acquired amputation, have never had the limb and develop compensatory function from the start; functional outcomes are generally good, and many children with unilateral upper limb difference decline prosthetic use because they function better without it. **The measured burden is largely determined by access to prostheses, mobility aids, education and employment — social and logistical rather than medical.**

Where surgery helps: separating fused digits, lengthening a short segment, creating a functional pinch grip, revising a limb to accept a prosthesis, correcting associated deformity. These improve function and none cures.

**Prevention.** - **Thalidomide pregnancy prevention programmes — STRONG, and proven by the failure cases.** Mandatory contraception, pregnancy testing and restricted distribution for women of childbearing potential taking thalidomide or lenalidomide. The Brazilian cases demonstrate what happens when the programme is not enforced. The drug is EML-listed for multiple myeloma with that restriction attached. - **Reducing unsafe abortion by providing safe abortion access — STRONG** for the misoprostol-attributable fraction. This is a direct consequence of the unsafe abortion entry and is worth stating plainly: where abortion is restricted and misoprostol is used unsuccessfully, limb reduction defects and Möbius sequence result. **The preventive intervention is legal and logistical, not medical.** - **Pre-pregnancy diabetes control — MODERATE.** - **Avoiding chorionic villus sampling before 10 weeks — STRONG** for that iatrogenic route; a settled procedural rule. - **Maternal smoking cessation — WEAK.** - **Avoiding known teratogenic antiepileptics where alternatives exist — MODERATE.** - **Genetic counselling** for families with a syndromic cause, which informs and does not prevent. - **Folic acid — no established effect** on limb reduction defects. - **There is no prevention for the sporadic majority.** - **Prenatal ultrasound** detects many major limb defects from the second trimester; this is detection, and its consequences are preparation, referral, and in some cases termination.

**Treatment.** There is no drug. **1. Prosthetic fitting and rehabilitation.** Timing follows developmental milestones — a passive lower-limb prosthesis around the time of pulling to stand, with upper-limb fitting debated and often later. It requires repeated refitting through growth, which is the dominant cost and the dominant reason provision fails. **Note the measured preference: many children with unilateral upper-limb difference reject prostheses and function better without them.** Prescribing is therefore not automatic, and rejection is not failure.

**2. Occupational and physiotherapy.** Teaching function with the limb as it is. For unilateral upper-limb difference this is often more valuable than a prosthesis.

**3. Orthoses and mobility aids**, including wheelchairs, with the access figure above.

**4. Reconstructive surgery** — syndactyly release, digit transfer or pollicisation to create a thumb, limb lengthening by distraction osteogenesis, rotationplasty, and revision amputation to produce a prosthesis-tolerant residuum.

**5. Investigation for associated anomalies and for a syndrome.** Limb defects are a marker, and the cardiac, haematological and renal anomalies may matter more than the limb.

**6. Pain management** for the minority with pain. Phantom sensation is less common in congenital absence than in acquired amputation.

**7. Education, inclusion and vocational support.** The largest determinants of life outcome, and not medical.

**Simple means.** - **Teaching function early, by the parent.** A child with a limb difference develops compensatory strategies spontaneously, and supporting rather than correcting this is the single most valuable intervention and it costs nothing. The main harm in low-resource settings is not absent prosthetics but exclusion from school and from play. - **Locally made prostheses and orthoses.** The Jaipur Foot and comparable designs, made from rubber, wood, aluminium and locally available materials by trained technicians, cost of the order of tens of US dollars against thousands for imported components, are repairable locally, tolerate water and agricultural work, and are refittable as the child grows. **This is the limb-defect equivalent of the Steenbeek brace: a deliberate shortening of the supply chain to the point of local manufacture.** - **Crutches, sticks and locally made walking aids** from wood. - **Adapted tools and utensils** — a strap, a cuff, a modified handle. Occupational therapy in its cheapest form is a workshop and some imagination. - **Residual limb hygiene and skin inspection**, to prevent the ulceration that causes prosthesis abandonment. A mirror and a routine. - **Sock and liner management**, with improvised padding from cloth where liners are unavailable. - **School inclusion.** A decision, not a resource, and the measured determinant of adult outcome. - **Parent-to-parent contact and accurate information at birth.** As with Down syndrome, what the family is told at diagnosis shapes the child's life. - **Examining the newborn for associated anomalies** — looking at the heart, the kidneys and the blood count where a syndrome is suspected.

The minimum chain: **nothing, for the functional training and inclusion that matter most.** For a prosthesis, a local workshop and locally available materials, which is a real and demonstrated short chain rather than an aspiration.

**Gaps.** No global figure of any kind was retrieved, in the current or the prior round, and the registry range is reported as the literature position and is unverified. **For a condition with a known chemical cause in living memory, the absence of a current global count is a notable gap.** No deaths, DALY, cost or cost-effectiveness figures specific to limb reduction defects were located. No prosthetic coverage figure was located, and the wheelchair figure is used as a proxy and is not the same measure. The cause is unknown in most cases despite limb development being embryologically well characterised. The misoprostol-attributable fraction is not quantified anywhere located, though the causal link is established, and given its policy implications that is a consequential absence. Ongoing thalidomide-attributable cases are not globally counted, and the Brazilian cases are documented largely in regional literature. Prosthesis rejection rates and functional outcomes with and without prostheses are poorly quantified, particularly for children, and the prescribing convention is not well supported by outcome data. Transverse and longitudinal defects, and isolated and syndromic cases, are not separated in most available data, and they have different causes and different outcomes.

---

## Congenital cataract

**What it is.** The lens of the eye is cloudy at birth or becomes cloudy in the first weeks. Light cannot reach the retina, so the visual part of the brain never learns to see. If the lens is not removed within weeks, the blindness becomes permanent even if the eye is later cleared.

**Measured.** Birth prevalence: **about 1 to 6 cases per 10,000 live births. The source gives no citation for this figure and tags it as needing one**, and it is printed with that flag. Share of childhood vision loss: **nearly 10 per cent worldwide**, also unsourced on that page and printed with the flag. The source does describe congenital cataract as a significant cause of childhood blindness.

No global count of affected children, no deaths figure and no DALY figure was located. In Down syndrome, cataracts affect 15 per cent — one of the few quantified subpopulation figures available.

In low-income countries where treatment is unavailable, the condition may go untreated and vision may be lost, with no figure given. The standing position in the childhood-blindness literature is that cataract is among the leading avoidable causes of childhood blindness and that the avoidable fraction is concentrated in low- and middle-income countries. No trend is reported anywhere located.

**Where it starts.** The overall split, unsourced on the page consulted and printed with that flag: **about one third are part of a broader syndrome or disease, one third are isolated inherited traits, and one third have undetermined causes**.

**Approximately 50 per cent of cases may have a genetic cause, which is highly heterogeneous, with more than 25 loci and genes implicated**†. Autosomal dominant inheritance is the commonest pattern in isolated familial cataract.

**Congenital rubella** is listed as an infectious cause and given as the source's example of a syndromic cataract, with **no percentage given**. It is the classic preventable cause and the one with a vaccine. Other congenital infections — toxoplasmosis, cytomegalovirus, herpes, varicella — contribute.

Metabolic diseases — galactosaemia, Lowe syndrome, peroxisomal disorders — are described as more commonly associated with bilateral cataracts, unsourced, with a recommendation for a basic laboratory workup for bilateral cases of unknown cause. Prematurity, maternal diabetes, corticosteroid exposure, radiation and trauma are also named, and consanguinity is relevant given the autosomal recessive forms. No effect sizes were located.

The cause is unknown in about a third, by the source's own split. The genetics are described as highly heterogeneous with more than 25 loci, which is a statement that no single mechanism accounts for the inherited cases. The practical unknown that matters more: **the share of the global burden that is rubella-attributable is not quantified**, and that share is vaccine-preventable at a cost of cents.

**Cure status.** CURABLE — but only inside a window of weeks, and this is the entry's defining fact.

The lens can be removed and the eye optically corrected. But the visual cortex requires patterned visual input in early infancy to develop, and if it does not receive it the blindness becomes permanent regardless of later surgery. **The cataract is curable; the deprivation amblyopia it causes is RELIEF ONLY.** The window separates the two.

The surgical timing thresholds are the operative numbers of the entry: **visually significant unilateral cataracts should be removed before 6 weeks of age, and visually significant bilateral cataracts before 10 weeks**†.

Treatment options for children under 2 with bilateral visually affecting cataracts include intraocular lens implantation or lensectomy, on a 2022 Cochrane review; **the source does not report that review's findings**.

The source says early detection gives the most favourable outcome and that prompt surgery can restore vision, and **its claim that many individuals achieve good visual outcomes is unsourced, and it gives no quantitative success rates**. That is a significant evidential gap for the entry's central claim and it is reported as such rather than filled in. What is not in doubt: a baby whose dense bilateral cataracts are removed in the first weeks and who is then optically corrected and patched develops useful vision; a baby operated at two years does not. The effect is binary in time and the surgery itself is straightforward.

**Prevention.** - **Rubella vaccination — STRONG, and it is the clearest preventable cause.** WHO names rubella vaccination for children and women, and screening for rubella, varicella and syphilis, among its congenital-disorder prevention measures, **without quanti-**

**fying them**. Rubella-containing vaccine is EML-listed, off-patent and costs cents a dose, and congenital rubella syndrome has been eliminated in the Americas, which is the demonstration. **The rubella-attributable share of congenital cataract is not quantified anywhere located**, so the size of this preventable fraction is unknown. - **Avoiding corticosteroid and radiation exposure in pregnancy where avoidable — MODERATE.** - **Pre-pregnancy diabetes control — MODERATE.** - **Genetic counselling** for familial cases, which informs and does not prevent. - **There is no prevention for the genetic and idiopathic majority**, about two-thirds by the source's split.

Detection, which here is almost equivalent to cure because of the window: - **The newborn red reflex examination — STRONG, and it is the whole screening programme.** An ophthalmoscope or a direct light held at arm's length; a normal eye reflects red, and a cataractous eye shows a white or absent reflex. **Performed at the newborn check and at subsequent infant visits, it detects the cases inside the 6-to-10-week window.** It also detects retinoblastoma, which makes it doubly valuable. - **Universal newborn eye examination — STRONG** as policy; coverage is the gap and no coverage figure was located. - **Examining siblings and relatives** in familial cases.

**Treatment.** There is no drug. **1. Surgical removal of the lens, within the window** — before 6 weeks for unilateral and before 10 weeks for bilateral visually significant cataract†.

**2. Optical correction immediately after surgery.** An eye without a lens has no focusing power at all, so this is not optional and is part of the same intervention. - **Aphakic spectacles** — thick, cheap, immediately available, adjustable as the eye grows. **The low-chain option.** - **Contact lenses** — better optics, requiring handling, replacement and hygiene. - **Intraocular lens implantation**, an option for children under 2 with bilateral cataracts alongside lensectomy†. In unilateral cases the Infant Aphakia Treatment Study found no visual acuity advantage of primary intraocular lens over contact lens at age 5, with substantially more adverse events and reoperations in the lens group, **so the simpler option is not inferior**. The source consulted does not report these findings, and they are reported here as the standing position in the paediatric ophthalmology literature.

**3. Amblyopia treatment — occlusion of the better eye in unilateral cases. This is as important as the surgery and it is where most treatment failures occur**, because it depends on months of daily parental adherence. A patch costs pennies.

**4. Treatment of associated conditions** — glaucoma, which is a common long-term complication after infant cataract surgery and requires lifelong surveillance; posterior capsule opacification; retinal detachment; strabismus surgery.

**5. Investigation for a cause** — the basic workup for bilateral cases of unknown cause, and galactosaemia screening, because treating it has systemic consequences beyond the eye.

**6. Low vision rehabilitation and education** for the children in whom the window was missed. **This is where the untreated global burden sits**, and it is RELIEF ONLY.

**Simple means.** - **The red reflex test. A torch or an ophthalmoscope held at arm's length in a dim room.** This single examination, costing nothing and taking seconds, is what separates a curable condition from permanent blindness. **It is among the highest-value simple means in this chapter**, and it can be taught to any health worker or midwife. - **Teaching the mother to look at her baby's eyes** for a white pupil, and to come at once. In settings with no newborn examination, the parent is the screening programme. - **Aphakic spectacles.** Thick plus lenses in a cheap frame, adjusted as the child grows. Not elegant optics and entirely adequate, and the Infant Aphakia Treatment Study finding means the cheap option is not the inferior one. - **An eye patch** — adhesive or cloth — for amblyopia treatment. Pennies, and months of daily use, and the outcome depends on it more than on the surgical technique. - **Parent-delivered patching with a calendar and a reward chart.** Adherence is the intervention. - **Case-finding in the community**, and referral to a surgical outreach. - **Low vision aids** — magnifiers, large print, good lighting, preferential seating — for the children operated too late. Cheap and under-provided. - **Braille and education** where vision is not recoverable. - **Examining the newborn for the associated anomalies** that point to a syndrome or a metabolic cause.

The minimum chain: a torch for detection, and microsurgery with an operating microscope and paediatric anaesthesia for the cure. The detection is nearly free and the cure is not improvisable — and because the window is six to ten weeks, **a detection system without a**

**surgical service within reach does not save the sight.** That asymmetry is the practical core of the entry.

**Gaps.** The two headline figures — 1 to 6 per 10,000 births, and nearly 10 per cent of childhood vision loss — are both tagged as needing a citation on the source consulted, are printed with that flag, and **should not be treated as sourced.** The one-third split of causes is also unsourced. No quantitative surgical success rates are given, and the source's claim that many individuals achieve good outcomes is unsourced; **for an entry classified CURABLE, the absence of any success rate is the most serious gap.** The source does not report the findings of the 2022 Cochrane review it cites on intraocular lens against lensectomy, and the Infant Aphakia Treatment Study findings are not on it either and are reported as the standing literature position. The rubella-attributable share is not quantified, so the size of the vaccine-preventable fraction is unknown, and given that the vaccine costs cents that is a consequential absence. No global count of affected children, no DALY figure and no cost figure was located. No coverage figure for newborn red reflex screening was located, so the size of the detection gap is unknown. Long-term outcomes — glaucoma incidence after infant cataract surgery, final visual acuity, educational attainment — are thinly reported and almost absent for low-resource settings.

---

## Fetal alcohol spectrum disorder

**What it is.** Alcohol crosses the placenta and damages the developing brain. The child is left with lifelong difficulties in learning, attention, memory, impulse control and judgement. In the full form there are also characteristic facial features and growth restriction.

**Measured. The prevalence figures on the source consulted are internally inconsistent by a factor of six to ten, and all are printed.**

Global prevalence of fetal alcohol spectrum disorder: **7.7 per 1,000 people**, with no year given†. The infobox on the same page gives **1 in 20, approximately 390 million, to 1 in 13, approximately 600 million, for all types, marked as unconfirmed**†. The body text gives a general population estimate of **about 1 in 20, with some estimates as high as 1 in 7**, with no year†, which conflicts with the infobox's own 1-in-13 upper bound. The source is internally inconsistent in at least three places, and none of the figures can be relied on.

Full fetal alcohol syndrome prevalence: **0.2 to 9 per 1,000**, with no source and no year given†.

The condition is described as highly misdiagnosed and underdiagnosed, with true rates likely underestimated, so every prevalence figure is a floor.

Alcohol use in pregnancy globally: **about 1 in 10 women drink during pregnancy, and 20 per cent of those binge drink**, with no year given†. The highest reported alcohol use during pregnancy, cited to 2017: **Ireland 60 per cent, Belarus 47, Denmark 46, the United Kingdom 41, the Russian Federation 37**†. **These are alcohol-use-in-pregnancy figures, not prevalence figures for the disorder**, and the two are frequently conflated.

**Western Australia: a birth rate of 0.02 per 1,000 for non-Indigenous births and 2.76 per 1,000 for Indigenous births**† — **a 138-fold difference within one jurisdiction**, and the starkest inequality figure in this chapter.

**South Africa does not appear on the source consulted.** The Western Cape wine-region cohorts, which report the highest fetal alcohol syndrome prevalences measured anywhere, are the standing reference in this field and could not be sourced.

There is no deaths figure and no DALY figure.

**Where it starts.** The cause is known and is a single exposure, which distinguishes this entry from the rest of the chapter. **Prenatal alcohol exposure. No safe level of fetal alcohol exposure has been established**.

Risk estimates cited to 2017†: - **Any drinking during pregnancy: about 15 per cent risk of the spectrum disorder and about 1.5 per cent risk of the full syndrome.** - **Two standard drinks a day, or six in one session: 4.3 per cent risk of the full syndrome, about 1 in 23.** - **Alcohol-related congenital abnormalities: about 1 in 67 drinkers.** -

**Mothers with alcohol use disorder: about one third of their children have the full syndrome**.

**Low-to-moderate drinking, under 12 g of ethanol a day: the evidence is inconsistent and contradictory**.

**Randomised trials on pregnant women are considered unethical, so all risk estimates come from observational data**. This is the central methodological constraint of the field and it is why the dose-response at low intake cannot be settled.

Modifying factors in the wider literature — maternal nutrition, maternal and fetal alcohol dehydrogenase variants, binge pattern, timing in gestation, smoking, and socioeconomic deprivation — determine why the same exposure produces different outcomes, and none is quantified in the source consulted.

Two things are genuinely not known: **why only a minority of exposed children are affected**, and **whether there is a threshold below which no harm occurs.** The second cannot be answered by the available method, because observational data cannot distinguish a true threshold from confounding and a trial is not permissible. Abstinence is therefore recommended universally on precautionary grounds, which is a defensible policy and is not the same as a demonstrated dose-response. The source states the limitation directly: it presents recommendations and risk data and **does not include trial evidence showing that abstinence reduces incidence**.

**Cure status.** RELIEF ONLY. The brain injury is permanent and nothing reverses it. Prenatal alcohol exposure causes structural and functional brain damage established before birth. There is no treatment that removes it, no medication that targets it, and no developmental process that compensates for it. Every intervention is management of consequences — educational accommodation, behavioural support, treatment of co-occurring attention deficit hyperactivity disorder and mental illness, and structuring the environment so that impaired judgement and memory are less costly.

What relief achieves is nonetheless substantial and measurable in the literature on secondary disabilities: early diagnosis, a stable caring home, and absence of violence exposure are repeatedly associated with markedly lower rates of school exclusion, unemployment, mental illness, substance misuse and incarceration in affected individuals. **The primary disability is fixed; the secondary disabilities are largely preventable**, and that distinction is where all the clinical value lies.

Diagnostic criteria matter here because the classification depends on them. The full syndrome requires all of: height or weight at or below the tenth percentile; all three facial features — smooth philtrum, thin vermilion, short palpebral fissures; clinically significant central nervous system impairment; and confirmed or unknown prenatal alcohol exposure. Partial fetal alcohol syndrome requires two or three facial features, impairment in three or more brain domains, and confirmed exposure. Alcohol-related neurodevelopmental disorder requires minimal or no facial features, impairment in three or more domains, and confirmed exposure. **Four North American diagnostic systems exist, they agree on the full syndrome's criteria and differ on the other conditions, and the Canadian 2016 guidelines removed growth as a diagnostic criterion**†.

**Prevention. This is the only entry in this chapter where the condition is 100 per cent preventable by a single avoidable exposure, and that should be stated first.** - **Abstinence from alcohol during pregnancy and while trying to conceive**, recommended by the United States Surgeon General, the Centers for Disease Control and Prevention, the American College of Obstetricians and Gynecologists, the American Academy of Pediatrics, WHO and NICE. **STRONG on mechanism and on the precautionary principle**, and the source notes explicitly that it does not include trial evidence showing that abstinence reduces incidence, because such a trial is not possible. The honest grading is STRONG for the recommendation and not formally demonstrated by trial for the effect size. - **Alcohol warning labels — WEAK.** United States alcohol containers have carried warning labels since 1988, and their effect on drinking in pregnancy is small in the evaluation literature. - **Screening and brief intervention in antenatal care — MODERATE.** Structured brief interventions reduce alcohol consumption in pregnancy in trials; the effect on incidence of the disorder has not been measured. - **Treating maternal alcohol use disorder — MODERATE** for the highest-risk group: about one third of children of mothers with alcohol use disorder have the

full syndrome, so this group carries a very large share of the severe cases and is the highest-yield target. - **Contraception for women with alcohol use disorder who do not wish to conceive — MODERATE.** Much prenatal alcohol exposure occurs before pregnancy is recognised, so preventing unintended pregnancy in heavy drinkers prevents exposure that no antenatal intervention can reach. This is the same timing logic as folic acid. - **Population alcohol policy — MODERATE at population level, CONTESTED in attribution.** Pricing, availability restriction and marketing restriction reduce population consumption, including among women of childbearing age. The disorder-specific effect has not been measured. - **Addressing the structural determinants** behind the 138-fold Indigenous and non-Indigenous disparity in Western Australia — dispossession, poverty, trauma, and the absence of services. **The disparity figure is measured; the interventions that would close it are not.**

**Treatment.** There is no treatment for the brain injury. Treatment is management. **1. Early diagnosis.** The strongest single predictor of better long-term outcome in the secondary-disability literature. It requires a clinician who will ask about prenatal alcohol exposure and a system that will record the answer, and **the source states the condition is highly misdiagnosed and underdiagnosed**.

**2. A stable, structured caring environment.** Repeatedly the strongest protective factor against the secondary disabilities. Not a medical intervention.

**3. Educational accommodation and individualised support.** Externalising the executive functions the child lacks — routine, visual structure, repetition, concrete instruction, supervision — rather than expecting internal regulation that is not available.

**4. Treatment of co-occurring conditions** — attention deficit hyperactivity disorder, with a reported stimulant response less reliable than in the idiopathic form; anxiety; depression; sleep disorder; epilepsy. Methylphenidate is EML-listed, off-patent and low cost. These treatments work on the comorbidity, not on the disorder.

**5. Speech and language therapy, occupational therapy and physiotherapy** as indicated.

**6. Treatment of associated physical anomalies** — cardiac, renal, skeletal, vision and hearing.

**7. Caregiver training and support.** Parent- and carer-directed behavioural programmes adapted for the disorder have a small and real evidence base.

**8. Transition and adult support** — supported employment, supported decision-making, and intervention in the justice system, where affected adults are heavily over-represented.

**No pharmacological treatment targets the disorder itself and no candidate is close.**

**Simple means.** - **Asking the question.** Prenatal alcohol exposure is ascertained by asking, and the diagnosis is impossible without it. Non-judgemental enquiry in antenatal care and in paediatric assessment costs nothing and is the gateway to everything else. - **Telling women that no safe level has been established, before conception.** Information, delivered once, is the entire preventive technology for a 100-per-cent-preventable condition. The limitation is timing: the message must arrive before the pregnancy is recognised. - **Contraception for heavy drinkers who do not wish to conceive.** Cheap, and it reaches the exposure window that antenatal care cannot. - **A structured, predictable daily routine** at home and at school. The single most effective management intervention, and it requires nothing but consistency. - **Visual schedules, written reminders, simplified instructions, consistent carers.** Externalising memory and executive function with paper and routine. - **Supervision appropriate to functional rather than chronological age.** A decision, not a resource, and it prevents a large share of the secondary disabilities. - **School inclusion with accommodation**, and avoiding exclusion, which is the proximate cause of much of the adult outcome. - **Measuring and plotting growth, and examining the face.** The facial features and growth restriction are diagnosed by a ruler, a photograph and a trained eye: palpebral fissure length is measured with a plastic ruler, and philtrum and vermilion are graded against a printed lip-philtrum guide. **The diagnostic instrument for fetal alcohol syndrome is a printed card.** - **Caregiver support groups and parent-to-parent contact.** - **Avoiding punitive framing of the mother.** Practical rather than sentimental: maternal shame and fear of child removal are the main documented barriers to disclosure, and without disclosure there is no diagnosis.

The minimum chain: a conversation and a printed card. For a condition with no treatment, essentially all of the available value is in low-chain detection and environmental management.

**Gaps. The prevalence figures on the source consulted are mutually inconsistent by a factor of six to ten** — 7.7 per 1,000 globally; 1 in 20 to 1 in 13 in the infobox, marked unconfirmed; 1 in 20 with some estimates as high as 1 in 7 in the text. All are printed and none can be relied on; for a condition of this importance this is the worst quantitative evidence base in the chapter. The full syndrome prevalence figure has no source and no year, and several other figures carry no year at all. South Africa is absent from the source consulted, and the Western Cape cohorts report the highest measured prevalences in the world, so their absence materially understates the upper end of the global range. Alcohol-use-in-pregnancy figures are routinely misread as prevalence figures for the disorder; they are not, and the source lists them under a heading that invites the confusion. Four diagnostic systems disagree on everything except the full syndrome, and the Canadian 2016 guidelines removed growth as a criterion, so prevalence comparisons across jurisdictions are partly comparisons of diagnostic systems. No trial evidence that abstinence reduces incidence exists and cannot ethically be generated, and the dose-response at low intake is inconsistent and contradictory and will remain so. The 138-fold Western Australian disparity is measured and unexplained in the source, and no intervention evidence addresses it. There is no deaths figure, no DALY figure, no cost figure and no cost-effectiveness analysis of any intervention. Underdiagnosis is acknowledged by the source and unquantified, so every prevalence figure is a floor.

---

## ICD-11 Chapter 22 — Injury, poisoning or certain other consequences of external causes

Seventeen entries covering thirteen named conditions: poisoning is written as one general entry plus four agent-class sub-entries.

**A structural note that governs every figure below.** Chapter 22 codes the **nature of the lesion** — fracture, burn, laceration, poisoning effect. Chapter 23 codes the **external cause** — fall, road crash, animal contact, intent. **GBD reports injury burden by external cause, not by lesion type.** Every burden figure in these entries therefore attaches to the paired external cause, and that is

---

The chapter-level denominators are these. Total injury deaths: **4.4 million a year**, nearly 8 per cent of all deaths, split into **3.16 million unintentional** and **1.25 million violence-related**; about **90 per cent of injury-related deaths are in low- and middle-income countries**, and injuries and violence cause an estimated **10 per cent of all years lived with disability**. Twice as many males as females are killed by injuries and vio-

Road injuries accounted for **75.3 million DALYs (59.8 to 89.2)** in 2023, the 6th leading DALY cause, with the age-standardised rate down 13.3 per cent (−25.5 to 2.9) since 2010, **not statistically significant**. Falls accounted for **74.3 million DALYs (58.9 to 95.0)**, the 8th leading cause, and **53.1 million years lived with disability (38.4 to 72.2)**, the 4th leading such cause. Unintentional injuries

---

As lesions rather than causes: **440 million prevalent fractures and 26 million years lived with disability**, and **180 million prevalent traumatic amputations with 5.5 million years lived with disability**, both on the 2019 burden study; and **about 1 billion people affected by orodental trauma**.

---

**The governing finding for this chapter is the Lancet Commission on Global Surgery, 2015.** Its figures were read off the report itself in the retrieval round of October 2026.

- **About 5 billion people lack access to safe, affordable surgical and anaesthesia care when needed**. The model's own bounds are 4.8 billion as a lower and 5.3 billion as an upper bound, and 5 billion is the rounded midpoint.
- **143 million addi-**

---

Each Bellwether procedure is the irreducible requirement for a group of conditions in these four chapters. Caesarean section resolves obstructed labour and prevents obstetric fistula and a large share of neonatal encephalopathy. Laparotomy resolves ruptured ectopic pregnancy, perforation from unsafe abortion, and abdominal bleeding from road traffic injury. Open fracture care prevents limb

For a large number of entries below, the honest cure status is CURABLE and the honest simple-means section ends with a sentence saying that nothing improvisable substitutes for an operation. The conditions concerned are not uncertain, not poorly understood and not awaiting research. They are curable conditions whose cure is a first-level hospital, and about 5 billion people do not have ac-

## Road traffic injury

**What it is.** Injury from a crash on a road — a car, a motorcycle, a bicycle, a truck, or a pedestrian struck by one. The lesions are fractures, head injury, chest and abdominal injury, and open wounds. It is the leading cause of death for young people.

**Measured.** Annual deaths: **approximately 1.16 million**. **A second WHO page gives a different figure for the same quantity, and both are printed.** The cross-cutting injuries and violence sheet gives road traffic as about one in three of 4.4 million injury deaths, which is approximately **1.47 million**; the standalone road traffic sheet gives 1.16 million. The two pages use different, unstated data years. The Global Status Report on Road Safety 2023 gives a third figure, **1.19 million**, a 5 per cent drop since 2010, covering 2010 to 2021. All three stand, unresolved.

Non-fatal injuries: **20 to 50 million more each year**, many leaving a disability — a two-and-a-half-fold uncertainty on the morbidity burden.

DALYs: **75.3 million, the 6th leading DALY cause in 2023**, with the age-standardised rate down 13.3 per cent (−25.5 to 2.9) since 2010 — **not statistically significant, so the global rate cannot be said to have fallen**.

**The leading cause of death for children and young adults aged 5 to 29**. Two thirds of fatalities are among people aged 18 to 59, and the male fatality risk is about **3 times** the female.

**92 per cent of road deaths occur in low- and middle-income countries**, which have **about 60 per cent of the world's vehicles**. The body text of the same page gives more than 90 per cent, and both are printed. Road crashes cost most countries **3 per cent of GDP**.

Vulnerable road users account for **53 per cent of road traffic deaths — pedestrians 23 per cent, powered two- and three-wheeler riders 21, cyclists 6, micro-mobility users 3 — against 30 per cent for occupants of cars and other four-wheeled light vehicles**. Pedestrian deaths rose 3 per cent to **274,000** between 2010 and 2021, and cyclist deaths rose nearly 20 per cent to **71,000**. **Eighty per cent of the world's roads fail pedestrian safety standards and 0.2 per cent have cycle lanes**.

Regional shares of global road traffic deaths: South-East Asia 28 per cent, Western Pacific 25, Africa 19, the Americas 12, Eastern Mediterranean 11, Europe 5.

The target is at least a **50 per cent reduction** in deaths and injuries by 2030.

**Where it starts.** This is the best-quantified risk-factor set in the chapter. - **Speed. Each 1 per cent increase in mean speed produces a 4 per cent increase in fatal crash risk and a 3 per cent increase in serious crash risk**. **Pedestrian death risk is 4.5 times higher at 65 km/h than at 50**. **Car-to-car side impact fatality risk is 85 per cent at 65 km/h**. - **Drink-driving.** Crash risk rises at low blood alcohol levels and **increases significantly at a blood alcohol concentration of 0.04 g/dl or higher**. For drug-driving, **amphetamine users have about 5 times the fatal crash risk of non-users**. - **Mobile phone use. Drivers using a phone are about 4 times more likely to be in a crash**. - **Non-use of helmets, seat belts and child restraints**, with the effect sizes given under prevention. - **Vehicle fleet and road design.** The mismatch between 92 per cent of the deaths and 60 per cent of the vehicles is the summary statistic: the deaths are where the roads, the vehicles and the trauma care are worst, not where the traffic is heaviest. - Young age, male sex, pedestrian and motorcyclist exposure, night driving, and unsafe public transport.

Little about the mechanism is unknown; this is one of the most completely characterised causes in the book. What is genuinely unresolved is **why the global age-standardised rate has not fallen significantly** despite half a century of known effective interventions and two decades of global target-setting. The interventions work where they are implemented. The measured global rate reflects that they are largely not.

**That gap can now be sized, and the sizing is in the legislation data rather than on the fact sheet.** The road traffic injuries fact sheet carries **no legislation data at all**. The Global Status Report on Road Safety 2023, dated 13 December 2023, carries it: - **Six countries have laws meeting WHO best practice on all five risk factors** — speeding, drink-driving, motorcycle helmets, seat belts and child restraints. - **140 countries, about**

**two thirds of UN Member States, have laws meeting best practice for at least one of the five**. - **Twenty-three countries changed their laws to meet best practice since the 2018 report**. - **Thirty-five countries legislate on all key vehicle safety features**. - **Fifty-one countries require safety inspections covering all road users**.

WHO's reachable pages give these counts **by the number of risk factors covered**, not as a separate country count for each of the five individually. The per-factor counts are in the full report, which did not render as text. So no claim of the form "N countries have best-practice speed laws" is made here: the sourceable structure is six and 140.

**Cure status.** The classification is by lesion, and the chapter's structure requires that it be stated that way. Most road traffic injury: CURABLE. Fractures unite, lacerations heal, spleens and livers are repaired or removed, and the patient returns to normal life. The determinant is whether surgery, blood and anaesthesia are available within hours. Traumatic brain injury, for the established injury: RELIEF ONLY. Spinal cord injury: RELIEF ONLY. Traumatic amputation: RELIEF ONLY — 180 million prevalent amputations and 5.5 million years lived with disability.

Stated as one line: a road traffic injury is curable in the majority and unpreventable in its consequences for the minority who sustain brain or cord injury. The whole of the public health value is in prevention.

**Prevention.** This is the richest prevention section in the book and every figure is measured.

**Speed management — STRONG.** The relationship is a dose-response — 1 per cent more mean speed for 4 per cent more fatal crash risk — so **the intervention is continuous: any reduction in mean speed reduces deaths proportionally**. Pedestrian death risk falls 4.5-fold going from 65 to 50 km/h. **Thirty km/h zones in residential and school areas are the WHO-recommended standard**, and the published evaluation literature consistently reports large reductions in pedestrian casualties following their introduction. The instruments are urban speed limits, enforcement including automated enforcement, traffic calming, and road design that enforces speed physically.

**Helmets — STRONG. Correct helmet use reduces the risk of death in a crash by more than 6 times and the risk of brain injury by up to 74 per cent**. **This is the largest single measured protective effect in this chapter.** The instruments are a mandatory helmet law, enforcement, and standards so that the helmets sold actually protect.

**Seat belts — STRONG. Wearing a seat belt reduces the risk of death among vehicle occupants by up to 50 per cent**. The instruments are a mandatory wearing law covering all seating positions, enforcement, and fitment requirements.

**Child restraints — STRONG. Child restraints can reduce infant deaths by 71 per cent**. The instruments are a mandatory law, availability and affordability of restraints, and vehicle anchorage requirements.

**Drink-driving law — STRONG.** Risk rises from low blood alcohol and increases significantly at 0.04 g/dl or higher. The WHO-recommended legal limit is **0.05 g/dl for the general population and 0.02 g/dl for young and novice drivers**. The instruments are blood alcohol limits, random breath testing, graduated licensing and alcohol-ignition interlocks. The published evaluation literature on random breath testing and on lowering limits reports substantial reductions in alcohol-related crash deaths, and **no effect size is given on the WHO fact sheet**.

**Mobile phone restriction — MODERATE.** A four-fold crash risk from the exposure, and a weaker legislative effect size, because enforcement is difficult.

Other established measures, MODERATE, with **no effect sizes on the WHO fact sheet**: - **Safe road infrastructure** — separated footways and cycleways, safe crossings, roundabouts, median barriers, lighting. Eighty per cent of the world's roads fail pedestrian safety standards. - **Vehicle safety standards** — electronic stability control, anti-lock brakes, airbags, pedestrian-protective front-end design, and the UN vehicle regulations. Thirty-five countries legislate on all key vehicle safety features. - **Motorcycle-specific measures** — daytime running lights, antilock brakes, rider training. - **Post-crash care**, which determines whether a survivable injury is survived. - **The Safe System approach** — designing so that human error does not produce death, rather than relying on individual compliance.

**Treatment.** Treatment is trauma care, and the single largest drug finding is CRASH-2.

**1. Tranexamic acid, given within 3 hours of injury. The best-evidenced drug in trauma.** The CRASH-2 trial randomised **20,211 adult trauma patients** within 8 hours of injury at 274 hospitals in 40 countries; 10,096 were allocated to tranexamic acid and 10,115 to placebo, with 10,060 and 10,067 analysed. - **All-cause mortality: 14.5 per cent, 1,463 patients, against 16.0 per cent, 1,613. Relative risk 0.91 (95 per cent CI 0.85 to 0.97), p = 0.0035.** An absolute reduction of 1.5 percentage points and a **number needed to treat of about 67**†. - **Death due to bleeding: 4.9 per cent, 489 patients, against 5.7 per cent, 574. Relative risk 0.85 (0.76 to 0.96), p = 0.0077**†. - Regimen: 1 g loading dose over 10 minutes, then 1 g by infusion over 8 hours†. - **The timing finding, consistent with the WOMAN trial: benefit is confined to administration within 3 hours, and later administration showed no benefit and, in the bleeding-death analysis, possible harm**. The summary page consulted gives no subgroup results by time, and the finding is reported as the published position of the trial collaboration.

Tranexamic acid is EML-listed for haemorrhage not elsewhere classified, injection 100 mg/mL, off-patent, at **a few US dollars a gram**†. **A reduction in all-cause trauma mortality of 1.5 percentage points for a drug costing a couple of dollars, deliverable by intravenous injection anywhere, is among the highest effect-per-euro results in the whole of this book.** CRASH-2 did not demonstrate cost-effectiveness: the trial aimed to assess it and reports no result. Published analyses since have estimated costs per life-year in the low tens of dollars in low-income settings, and no figure is asserted here.

**2. Haemorrhage control and resuscitation** — direct pressure, tourniquets, pelvic binders, blood transfusion, damage-control surgery. **Blood availability is the determinant and it is the commonest absent input.**

**3. Airway management and ventilation.**

**4. Surgery** — laparotomy for abdominal bleeding, thoracotomy, external and definitive fixation of fractures, debridement of open wounds. **Two of the three Bellwether procedures, laparotomy and open fracture care, are road-trauma procedures**.

**5. Antibiotics and tetanus prophylaxis for open wounds.**

**6. Tranexamic acid for head-injured patients**, where the effect is confined to mild-to-moderate injury and the overall result was null; the figures are in the traumatic brain injury entry.

**7. Rehabilitation** — physiotherapy, prosthetics, orthotics, and the long-term care of brain and cord injury.

**Simple means.** - **A helmet. Reduces death risk more than 6-fold and brain injury risk by up to 74 per cent**. A manufactured object costing tens of dollars, requiring no infrastructure, no power and no training. **Nothing in this book has a better ratio of protection to cost and complexity.** - **A seat belt**, already fitted to most vehicles. **Up to 50 per cent reduction in occupant death**, and the intervention is the act of fastening it. - **A child restraint — 71 per cent reduction in infant deaths**. - **Direct pressure on a bleeding wound, and a tourniquet.** Bystander haemorrhage control has the shortest possible chain: hands, cloth, and in the limb case an improvised or commercial tourniquet. **A commercial windlass tourniquet costs tens of dollars; a cloth and a stick costs nothing.** The military and civilian evidence for prehospital tourniquets in limb exsanguination is strong. - **The recovery position.** An unconscious breathing casualty placed on their side does not aspirate or obstruct. **It costs nothing, requires no equipment, and is taught in minutes.** - **Not moving a casualty with suspected spinal injury, and manual in-line stabilisation.** - **Splinting a fracture with whatever is at hand** — a board, a rolled newspaper, a padded stick, the other leg. - **Lay first responder training.** Programmes training taxi drivers, bus drivers, police and community volunteers in basic trauma first aid — airway, bleeding, position, transport — have been evaluated in Ghana, Uganda, Cambodia and elsewhere with reported reductions in prehospital mortality. **The intervention is a two-day course and a small kit.** The evidence is pre-post and observational rather than randomised. - **Organised transport** — a radio, a phone number, and an agreement with whoever owns a vehicle. **In most of the world the ambulance is a taxi**, and formalising that is a real intervention. - **High-visibility clothing and reflectors** for pedestrians and cyclists, and daytime running lights on motorcycles. - **Separating pedestrians from traffic**

**with a kerb, a bollard or a painted footway.** - **Speed humps.** Concrete, and they enforce the single most powerful variable above without any enforcement personnel.

The minimum chain: a helmet, a belt, hands on a wound, and a side-lying position. For the survivable abdominal and limb injuries, laparotomy and fracture care, and that is the Bellwether requirement with no substitute.

**Gaps.** The global age-standardised rate has not fallen significantly, and no analysis located separates implementation failure from exposure growth. **Two WHO pages give different death totals for the same quantity — approximately 1.16 million on the standalone fact sheet and approximately 1.47 million implied by the cross-cutting injuries sheet — and the 2023 status report gives 1.19 million; all three stand, unresolved**, because the pages use different and unstated data years. The road traffic injuries fact sheet carries no legislation coverage data at all, and the status report's figures are given by number of risk factors covered rather than per factor, so the per-factor country counts remain unsourceable from reachable pages. WHO gives no effect size for drink-driving legislation, for infrastructure measures, for vehicle standards or for post-crash care, though all are recommended. The 92 per cent and "over 90 per cent" low- and middle-income share figures differ within the same WHO page; both printed. CRASH-2's cost-effectiveness was not reported by the trial, and the cost-per-life-year figures in circulation are modelled. CRASH-2's timing subgroup results are not on the page consulted and are reported as the collaboration's published position. Lay first responder training evidence is pre-post, not randomised. Non-fatal injury is given as a 20-to-50 million range. Disability outcomes after road injury in low- and middle-income settings are very thinly measured.

---

## Falls and fragility fracture

**What it is.** A person falls to the ground. In children it is usually from a height; in older people it is usually from standing. In an older person with weak bone the fall breaks the hip, the wrist or the spine, and a broken hip at eighty is frequently the end of independent life.

**Measured.** Annual fatal falls: an estimated **684,000**. **The second leading cause of unintentional injury death worldwide**, after road traffic injuries. Non-fatal falls requiring medical attention: about **37.3 million** a year.

**The DALY figures differ roughly two-fold between the two main sources and both are printed.** The WHO falls fact sheet gives **over 38 million DALYs** a year, of which **nearly 40 per cent occur in children**, and notes explicitly that this may **understate** the impact on older adults, who have fewer life years to lose. GBD 2023 gives **74.3 million DALYs (58.9 to 95.0), the 8th leading DALY cause**, and **53.1 million years lived with disability (38.4 to 72.2), the 4th leading such cause**. The age-standardised DALY rate is down 11.8 per cent (6.1 to 16.3) since 2010.

**Over 80 per cent of fall-related deaths occur in low- and middle-income countries**, and the Western Pacific and South-East Asia regions account for **60 per cent** of these deaths. Death rates are highest among adults over 60 in all regions. In the United States, **20 to 30 per cent of older people who fall suffer moderate to severe injuries**.

Costs: the average health system cost per fall injury in people aged 65 and over is **US$3,611 in Finland and US$1,049 in Australia**. In China, per fatal child fall, there are 4 permanent disabilities, 13 hospitalisations over 10 days, 24 hospitalisations of 1 to 9 days, and 690 cases seeking care or missing school or work.

Falls are a leading cause of traumatic spinal cord injury alongside road traffic injuries, and a leading cause of traumatic brain injury in older people.

**Where it starts.** Age: risk of death or serious injury rises with age and is highest over 60 in every region, through the combination of higher fall frequency and lower bone strength. Osteoporosis and low bone mineral density are the fragility in fragility fracture, with fracture risk rising steeply as bone density falls. Previous fall and previous fracture are among the strongest predictors. Muscle weakness, impaired gait and balance, and sarcopenia contribute.

**Psychotropic medication** — benzodiazepines, antipsychotics, antidepressants, sedatives — is one of the most consistently measured and most modifiable risks. Polypharmacy, ortho-

static hypotension and antihypertensives raise risk. Visual impairment contributes, including treatable cataract, and multifocal spectacles increase outdoor fall risk. Cognitive impairment and dementia, Parkinson's disease, stroke and peripheral neuropathy all raise risk, as does vitamin D deficiency in deficient individuals and alcohol. Environmental hazards — loose rugs, poor lighting, no handrails, slippery floors, uneven ground — are the proximate causes. In children: developmental stage, unguarded windows and balconies, roofs, trees, stairs, and in low-income settings work at height. In workers: construction and work at height. **No effect sizes are given for any risk factor on the WHO falls fact sheet**.

Two things are not known. How much of the fall risk in an individual older person is modifiable, and in what order to address it: the multifactorial interventions below work, and which component carries the effect is not established, because the trials bundle gait training, home modification, medication review and vision correction and the components have not been reliably separated. And **why the global burden is so heavily concentrated in low- and middle-income countries**, at over 80 per cent of deaths, when the condition is framed in the literature as a problem of ageing high-income populations. WHO itself notes that the DALY metric misrepresents the age distribution.

**Cure status.** Two things must be separated and they have different statuses. The fracture: CURABLE. A broken wrist, a broken hip, a vertebral compression fracture — these unite. Surgical fixation or arthroplasty of a hip fracture restores walking in the majority, and the bone heals. The underlying osteoporosis: CONTROLLABLE. Bisphosphonates and the other agents reduce fracture risk substantially and do not restore normal bone. The deviation remains and the treatment is long-term. The fall tendency: CONTROLLABLE. Multifactorial intervention reduces fall rate; it does not remove the propensity.

**But the outcome of a hip fracture at advanced age is not the outcome of the fracture.** One-year mortality after hip fracture in older people is substantial in every published cohort, and a large share of survivors never regain their previous mobility or independence. **The fracture is cured and the person does not recover**, and that is the honest statement.

**Prevention. WHO's falls fact sheet lists interventions and reports no effect sizes for any of them**. The gradings below note that, and the effect sizes come from the wider trial literature and are flagged.

For older people, WHO's list: - **Gait, balance and functional training — STRONG.** The best-evidenced single component. The Cochrane reviews of exercise for fall prevention in community-dwelling older people report reductions in fall rate of the order of 20 to 25 per cent†; no effect size appears on the WHO page. - **Tai Chi — MODERATE.** Named specifically by WHO. Trials report reduced fall rate and effect sizes vary. - **Home assessment and modification — MODERATE**, with the effect concentrated in those at higher risk. - **Reducing or withdrawing psychotropic drugs — STRONG.** Among the clearest modifiable causes, and deprescribing trials report reduced falls. **It costs nothing and saves drug expenditure.** - **Multifactorial interventions — MODERATE**, with the component-attribution problem above. - **Vitamin D supplements for those who are deficient — MODERATE.** WHO specifies "for those who are deficient", which is the current and narrowed position: high-dose and universal supplementation has not reduced falls and in some trials increased them.

For children and adolescents, WHO's list: - **Parenting programmes for low-income and marginalised families — MODERATE.** - **Informing parents about fall risks and supporting home risk reduction — MODERATE.** - **Window guards — STRONG on the available evidence, and they are the specific measure with the best-documented history.** New York City's window-guard programme from 1972 combined guard distribution and legislation with public education and reported a very large fall in child falls from windows in the targeted districts — an often-cited reduction of the order of 95 per cent in the intervention area, and a 35 per cent city-wide decline in child fall deaths over the programme period. **These figures are from the programme-evaluation literature and were not verifiable against a source fetched in the retrieval round**. New York City's Health Code has required window guards in apartments with children under 11 since 1976, and similar requirements exist elsewhere. **A window guard costs tens of dollars; the alternative is a child falling several storeys.** - **Balcony and stair gates; roof parapets.**

For workers: - **Stricter workplace safety regulation in high-risk occupations such as construction — MODERATE.** - **Multicomponent workplace safety programmes — MODERATE.** - **Harnesses and fall-arrest systems for work at heights.**

Basic environmental measures, which WHO describes as prudent even without strong research support: fencing off dangerous areas; **playground standards requiring soft surfaces and limited fall heights**; building standards and landlord-required home modifications; accessible neighbourhoods and public spaces; and adequate staff-to-resident ratios in residential care.

**The only quantified prevention outcome on the WHO page is a modelled Canadian estimate: a 20 per cent reduction in fall incidence among children under 10 could produce net savings of over US$120 million a year**. A model, not a result.

For the fracture rather than the fall: - **Bisphosphonates in osteoporosis — STRONG.** - **Calcium and vitamin D in the deficient — MODERATE.** - **Hip protectors — CONTESTED.** They reduce hip fracture in nursing-home residents in some trials; adherence is poor and the pooled effect is uncertain. - **Smoking cessation and reducing alcohol — MODERATE** for bone density.

**Treatment. 1. Surgical fixation or replacement of the fractured hip, early.** Internal fixation for undisplaced intracapsular and for extracapsular fractures; hemiarthroplasty or total hip replacement for displaced intracapsular fractures. **Early surgery, within 24 to 48 hours, is associated with lower mortality and better function** in the cohort and registry literature. It requires orthopaedic surgery, anaesthesia and an implant — **the implant is the cost, and implant availability is the constraint in low-resource settings.**

**2. Fracture management generally.**

**3. Bisphosphonates for osteoporosis** — alendronate, risedronate, zoledronic acid. **Reductions in vertebral fracture of the order of 40 to 70 per cent and in hip fracture of the order of 40 to 50 per cent** in the pivotal trials in women with osteoporosis†; those figures are from the trial literature and were not verified against a source fetched in the retrieval round.

**No bisphosphonate is on the WHO Essential Medicines List for osteoporosis, and this must be stated precisely. Alendronate is not on the list at all: a live query of the electronic list returns zero recommendations, zero medicines and zero therapeutic equivalents for it, with every filter count on the page at zero, so the result is not a filter artefact. Zoledronic acid is listed only under Supportive medicines, section 8.2.5, on the complementary list, for malignant neoplasm metastasis in bone or bone marrow and for osteogenesis imperfecta. The word osteoporosis does not appear on its record**. Both are off-patent. Cost is a few US dollars a month for oral alendronate, and zoledronic acid is a once-yearly infusion and now cheap as a generic.

**A 40 to 50 per cent reduction in hip fracture for a few dollars a month is one of the better effect-per-euro results in the chapter**, and treatment rates after a first fragility fracture are low everywhere, which is the measured failure.

**4. Denosumab, teriparatide, romosozumab** — more effective in some comparisons, substantially more expensive, not off-patent for all, and not EML-listed in the sections reachable.

**5. Calcium and vitamin D** in the deficient. EML-listed, off-patent, cents.

**6. Analgesia** — paracetamol, non-steroidal anti-inflammatory drugs with caution in older people, opioids sparingly. Vertebral fracture pain is often undertreated.

**7. Rehabilitation and early mobilisation.** As important as the operation for function, and labour rather than technology.

**8. Orthogeriatric co-management.** Joint orthopaedic and geriatric care of the hip fracture patient reduces mortality and length of stay in trial and registry evidence.

**9. Delirium prevention, pressure-area care, nutrition and thromboprophylaxis** in the admitted older patient.

**Simple means.** - **Exercise: standing on one leg, sit-to-stand repetitions, heel-toe walking, Tai Chi.** The best-evidenced fall-prevention intervention in the world requires no equipment and no facility. **A group of older people doing balance exercises in a**

**courtyard is the intervention**, and WHO names Tai Chi specifically. - **Stopping a psychotropic drug.** Free, and it saves money. One of the clearest modifiable causes. - **Home modification with no purchased technology** — removing loose rugs and clutter, moving the bed, improving lighting, a nightlight on the route to the toilet, a chair in the washing area. - **A grab rail and a handrail.** Wood or pipe, locally fitted, tens of dollars at most. - **Non-slip footwear, and not walking in socks.** - **Window guards and stair gates for children. Tens of dollars against a fatal fall**, and the measure is improvisable from bars or mesh. - **A soft surface under playground equipment** — sand, wood chips, or earth rather than concrete. Free or nearly so, and it converts a fatal fall into a bruise. - **Roof parapets and balcony railings.** - **Vision: cataract surgery, and single-vision rather than multifocal spectacles for outdoor walking.** The second is free advice. - **Splinting and immobilising a suspected fracture** before transport. - **Getting the person up off the floor and keeping them warm.** A long lie after a fall causes hypothermia, pressure injury and rhabdomyolysis, and the intervention is being found — which is why a daily check on an older person living alone is a medical intervention. - **Early mobilisation after a fracture** — walking the patient, which is labour rather than equipment, and is the strongest determinant of recovered function. - **A stick or a locally made walking frame.**

The minimum chain: **nothing, for the exercise and the environmental measures that carry most of the prevention.** For the hip fracture, orthopaedic surgery and an implant, with no substitute — an unoperated displaced hip fracture in an older person means immobility, and immobility at that age means death.

**Gaps. WHO and GBD differ roughly two-fold on DALYs, at over 38 million against 74.3 million, and both are printed.** WHO reports no effect size for any prevention measure, and the only quantified figure on its fact sheet is a modelled Canadian cost saving; the effect sizes above come from the trial literature and are flagged as unverified. WHO states its own DALY figure may understate the impact on older adults, so the metric misrepresents the condition's main population. Nearly 40 per cent of fall DALYs occur in children and over 80 per cent of fall deaths are in low- and middle-income countries, which is at odds with the framing of falls as a geriatric high-income problem, and no analysis located reconciles this. The New York window-guard figures could not be verified. Multifactorial intervention components have not been separated, so the priority ordering for an individual is not established. Vitamin D's role has narrowed to the deficient only, after universal and high-dose supplementation failed and in some trials increased falls, so sources published before that shift give the opposite advice. Hip protectors are contested. Osteoporosis treatment rates after a first fragility fracture are low everywhere and the size of that gap is not quantified in any source reached. The falls fact sheet is the oldest in the WHO set, printed in April 2021, and gives **no data year** for most of its figures beyond "each year". Cost figures exist for only two high-income countries and none for the countries carrying 80 per cent of the deaths.

---

## Burns

**What it is.** Skin and deeper tissue destroyed by heat, flame, hot liquid, electricity or chemicals. A burn kills by fluid loss and infection in the days after, not usually at the moment. Survivors are left with scars that contract and pull joints out of position.

**Measured.** Annual burn deaths: an estimated **180,000**. The share in low- and middle-income countries is given as the vast majority in the key facts and the majority in the body text — wording rather than a figure. **WHO gives no exact share.**

**Non-fatal burns: no global count is given.** WHO calls them a leading cause of morbidity. Country figures: **India, over 1 million people moderately or severely burned each year; Bangladesh, nearly 173,000 children; the United States, over 410,000 burn injuries in 2008 with approximately 40,000 requiring hospitalisation**. In Bangladesh, Colombia, Egypt and Pakistan, **17 per cent of children with burns have a temporary disability and 18 per cent a permanent disability**. In Nepal burns account for 5 per cent of disabilities and are the second most common injury.

Geography: almost **two thirds** of burn deaths occur in the WHO African and South-East Asia Regions. **Burn injuries requiring medical care are nearly 20 times more frequent in the Western Pacific Region than in the Americas**. Children under 5 in the African Region

have **over twice** the burn death incidence of children under 5 worldwide, and boys under 5 in low- and middle-income countries of the Eastern Mediterranean Region are almost **twice** as likely to die from burns as boys in the European Region. **The child death rate from burns is over 7 times higher in low- and middle-income countries than in high-income countries**. Burns are the **fifth** most common cause of non-fatal childhood injuries.

**Community surveys in Bangladesh and Ethiopia found 80 to 90 per cent of burns occur at home**.

Healthcare cost: a 2014 systematic review gives a mean total cost per patient of **US$88,218, range US$704 to 717,306**, and South Africa an estimated **US$26 million** annually for kerosene cookstove burns.

GBD's fire, heat and hot substances DALY figure was not retrievable, in the current or the prior round.

**Where it starts. Cooking.** Open fires, three-stone stoves, unstable stoves at floor level, cooking at ground level with children nearby, loose clothing. The 80-to-90-per-cent-at-home finding identifies the kitchen as the site.

**Scalds from hot liquids** are the dominant mechanism in young children and the reason the under-5 figures are what they are: hot water, tea, cooking oil, water heated for washing. **Kerosene and paraffin appliances** — lamps, stoves and heaters, with adulterated fuel, unstable appliances and explosion. Open flame for lighting, candles, household fires. **Hot tap water**, a scald source entirely controlled by the thermostat setting. Electricity, through unsafe wiring, illegal connections and overhead lines. Chemicals, fireworks, industrial exposure.

**Intentional burning**, including acid attack and intimate-partner and dowry-related violence, is a recognised and substantial category in parts of South Asia.

**Epilepsy** — a seizure near an open fire — is a recognised and preventable route. Poverty, crowding, non-fire-resistant housing, and the absence of a smoke alarm or escape route complete the picture. **No effect sizes are given for any risk factor on the WHO burns fact sheet**.

What is not known is the non-fatal burden. WHO gives country figures and no global count, and the ratio of non-fatal to fatal burns differs by an order of magnitude between regions — the 20-fold Western Pacific and Americas difference is a statement about both exposure and ascertainment. Also not known: the share that is intentional, which is systematically under-ascertained because of how it is reported.

**Cure status.** Small and superficial burns: SELF-LIMITING with supportive care. A superficial burn re-epithelialises in days to weeks with nothing but cooling, cleaning and dressing. Deep and extensive burns: CURABLE, with survival a function of resources. Fluid resuscitation, infection control and skin grafting make them survivable, and burn mortality for a given burn size differs several-fold between well-resourced burn centres and settings without fluid, blood, antibiotics or grafting capacity. Hypertrophic and contractural scarring: RELIEF ONLY. Scar contracture across a joint or the neck is permanent without surgical release, and it recurs.

**The survivor of a major burn is not restored.** The functional, cosmetic and psychological burden is lifelong, and in children the contractures tighten with growth and require repeated surgery through childhood. **WHO provides no treatment outcome statistics** on the fact sheet, which is a gap for an entry whose cure status depends on them.

**Prevention.** WHO recommends the measures below and **gives no effect sizes for smoke alarms, water temperature regulation or cookstove safety**. - **Smoke alarms — STRONG.** WHO names smoke detectors. **The effect size is not on the WHO page.** The standing position in the injury-prevention literature, from case-control and surveillance studies, is that a working smoke alarm **roughly halves the risk of death in a house fire**, and that figure was not verified against a source fetched in the retrieval round. **A smoke alarm costs a few US dollars to tens of dollars and lasts years.** The documented failure mode is not absence but **non-functioning alarms with dead or removed batteries**, which is why installation programmes with ten-year sealed-battery alarms outperform give-away schemes. On the returns side, WHO's cross-cutting injuries sheet gives **US$1 spent on smoke detectors saving US$65**. - **Lowering hot water tap temperature — STRONG.** WHO names it.

Setting the domestic hot water thermostat to a maximum of about 50 °C, or fitting thermostatic mixing valves at the tap, prevents tap-water scalds, which are a meaningful share of childhood scalds in countries with piped hot water. **Cost: zero for a thermostat adjustment.** Jurisdictions with regulated maximum delivery temperatures report reductions in tap-water scald admissions. No effect size on the WHO page. - **Safer cookstoves and enclosing fires — STRONG.** WHO names both. Raising the cooking surface above child height, enclosing the flame and stabilising the stove address the mechanism the at-home finding identifies. The clean-cookstove literature measures air pollution outcomes more than burn outcomes, and **the burn-specific effect size is not established.** - **Fire-retardant sleepwear — MODERATE.** WHO names it. The historical evidence is the fall in childhood nightwear ignition injuries following flammability standards in the United States and the United Kingdom. - **Sprinklers — STRONG** in the fire-engineering literature, for buildings. - **Separating cooking from living and sleeping space; keeping hot liquids out of reach; not carrying a child while cooking; stove guards.** - **Kerosene appliance safety, child-resistant fuel containers, and regulating fuel adulteration — MODERATE.** - **Electrical safety regulation and residual current devices — MODERATE.** - **Treating epilepsy**, which removes the seizure-near-fire route. Phenobarbital is EML-listed for epilepsy or seizures, off-patent, and works out at about US$0.017 a 30 mg tablet on October 2026 indicative prices, **about US$6.24 a patient-year at one tablet a day**. An unusually direct cross-chapter prevention. - **Smoke-free policies and self-extinguishing cigarettes** for the fires they start. - **Escape planning and building standards.**

**Treatment. 1. Stop the burning, then cool with cool running water for about 20 minutes.** WHO's first aid instruction, and it is a treatment with a time-dependent effect: cooling within the first hours reduces burn depth and the need for grafting. **Water, and twenty minutes.**

**2. Fluid resuscitation**, the intervention that converted major burns from uniformly fatal to survivable. Lactated Ringer's or Hartmann's solution by the Parkland or a modified formula for burns above about 15 to 20 per cent body surface area in adults and 10 per cent in children, and **oral rehydration where intravenous access is unavailable**, which is a genuine option for moderate burns. Compound sodium lactate is EML-listed, off-patent, at **a few US dollars a litre**.

**3. Wound care and infection control.** Cleaning, debridement, a topical antimicrobial dressing, and clean dressing changes. **Silver sulfadiazine** is the traditional topical agent, EML-listed, off-patent and cheap; **honey and paraffin gauze are evidenced alternatives**. **Systemic prophylactic antibiotics are not indicated**; antibiotics treat established infection.

**4. Tetanus prophylaxis.** A burn is a tetanus-prone wound. EML-listed, off-patent, cents.

**5. Analgesia.** Burns are among the most painful injuries and are routinely undertreated. Paracetamol, non-steroidal anti-inflammatory drugs, oral morphine. Morphine is EML-listed for pain, off-patent, and works out at **about US$0.57 an ampoule** of 10 mg/mL injection on October 2026 indicative prices — **its absence in most low-resource burn care is an access failure, not a cost one.**

**6. Escharotomy** for circumferential full-thickness burns compromising circulation or breathing, and **early excision and skin grafting** for deep burns, which shortens the course and improves outcome.

**7. Nutrition.** A major burn is a hypermetabolic state, and high-energy high-protein feeding is part of treatment and is deliverable with food.

**8. Physiotherapy, splinting and pressure garments from early on, to limit contracture. This is the intervention that determines the survivor's function, and it is the one most often absent.**

**9. Reconstructive surgery** for contracture release, often repeatedly through childhood.

**10. WHO's explicit don'ts: no ice, no oils, no pastes, and do not open blisters**. Named because the harmful traditional applications are widespread.

**Simple means.** - **Cool running water for 20 minutes. The single most effective first aid act in this entry, free, and effective for hours after the burn.** It reduces depth, reduces pain and reduces grafting need. - **Stop, drop and roll; smothering flames with**

**a blanket.** - **Removing hot wet clothing and jewellery** before swelling. - **Covering the burn with a clean dry cloth or cling film.** Cling film is an excellent temporary burn dressing — sterile from the roll, transparent, non-adherent and universally available. - **Oral rehydration solution.** For moderate burns where intravenous fluid is unavailable, oral rehydration is a real and evidenced route: the gut absorbs, and the burn's fluid requirement can be met by mouth in a conscious patient with a moderate burn. **Sugar, salt and water**, at about US$0.048 a sachet on October 2026 indicative prices. - **Honey as a burn dressing.** Cochrane-reviewed evidence supports honey for partial-thickness burns, with faster healing than some conventional dressings in the pooled trials. **Cheap, locally available, antibacterial and non-adherent.** The evidence is of moderate quality and heterogeneous. - **Boiled and cooled water, clean cloth and soap** for dressing changes. - **Paraffin or petrolatum gauze** — cheap, non-adherent. - **Splinting in the anti-contracture position with locally made splints** — plaster, wood, or moulded plastic. **The position in which a burn is immobilised determines whether the joint works afterwards**, and this is free knowledge applied with free material. - **Range-of-movement exercises taught to the patient and family, done daily.** This is the whole of contracture prevention where no physiotherapist exists, and it works. - **Pressure garments improvised from elastic bandage or tubular bandage.** - **Raising the cooking fire off the ground; a stove guard; a separate cooking space.** The prevention is a change in the kitchen. - **A smoke alarm** — a few dollars. - **Turning down the water heater thermostat** — free. - **Teaching the family not to apply ice, oil, paste, ash or toothpaste.** A conversation that prevents a deeper burn.

The minimum chain: water, clean cloth and oral rehydration salts. That set manages a moderate burn. For a major burn, intravenous fluid, blood, surgery and grafting, with no substitute.

**Gaps.** WHO gives no global non-fatal burn count and no exact low- and middle-income death share; the country figures are not a global estimate and the United States figure is from 2008. WHO gives no effect sizes for smoke alarms, hot water temperature regulation, cookstove safety or any other prevention measure, though it recommends all of them, and the smoke alarm figure could not be verified. WHO provides no treatment outcome statistics, so burn survival by burn size and setting — the figure that would quantify the resource gradient — is not available here. GBD's fire, heat and hot substances DALY figure was not retrievable, in the current or the prior round. The 20-fold Western Pacific and Americas difference in burns requiring medical care mixes real exposure difference with ascertainment difference, and the components are not separated. The intentional-burn share is systematically underascertained and no figure was located. The honey evidence is moderate-quality and heterogeneous. Contracture outcomes and long-term function in survivors are almost unmeasured in low-resource settings, where most survivors are. Several WHO figures carry no year.

---

## Drowning

**What it is.** Breathing is impaired by immersion or submersion in liquid. It happens silently and in minutes, often in shallow water, and most often to a small child who was out of sight for a short time.

**Measured.** Annual drowning deaths: about **300,000**. **The global drowning death rate fell 38 per cent since 2000, from 6.1 to 3.8 per 100,000 population**, and WHO states the decline falls short of what is needed for the related Sustainable Development Goals. This is one of the clearer measured declines in the chapter. DALYs: **17.0 million, the 40th leading DALY cause**.

Age: **children under 5 account for nearly a quarter of all drowning deaths** on the key facts, and the body text instead gives ages **0 to 29 as 57 per cent** of drowning deaths, with the highest rates among ages 0 to 4. Both are printed; the key facts figures appear nowhere in the body, which offers a different age cut. Drowning is the **4th leading cause of death for ages 1 to 4 and the 3rd for ages 5 to 14** globally; the cross-cutting injuries sheet instead gives it as the **sixth** leading cause of death for children aged 5 to 14.

Sex: the male drowning death rate is more than **twice** the female rate.

Geography: **over half of global drownings occur in the Western Pacific and South-East Asia regions**. The Eastern Mediterranean region has the highest under-5 drowning rate at **16.8 per 100,000**. In the Western Pacific, children aged 5 to 14 die from drowning

more often than from any other cause. **92 per cent of drowning deaths occur in low- and middle-income countries**, where rates are more than **three times** higher than in high-income countries.

Fishers: more than **32,000** die while working each year, and **drowning accounts for 75 per cent of flood disaster deaths**.

**WHO's investment case for day care plus basic swimming, scaled up to 2050: 774,000 fewer children drowning, 178,000 fewer severe non-fatal injuries, projected savings exceeding US$400 billion, and a return of 9 times the cost**. These are model projections rather than measured results.

**Where it starts.** Age and developmental stage: toddlers are mobile, top-heavy, drawn to water and unable to self-rescue, which is where the under-5 quarter-share comes from. **Proximity of unprotected water to the home** — open wells, water storage vessels, ponds, irrigation ditches, rivers, flooded fields. In the high-burden rural settings this is the dominant exposure: the water is a few metres from the door and there is no barrier. **A lapse of supervision, typically brief**; the toddler-drowning literature consistently finds supervision interruptions measured in minutes. Inability to swim. Occupational and transport exposure — fishing, ferry and small-boat travel without flotation, overcrowded vessels. Flooding and extreme weather. Alcohol in adolescent and adult drowning. Male sex, through exposure and risk behaviour. **Epilepsy and some cardiac conditions** raise drowning risk substantially, including in baths. **No effect sizes are given for any risk factor on the WHO drowning fact sheet**.

What is genuinely not known is the effect sizes for the interventions. **WHO recommends barriers, supervised childcare and swimming instruction and gives no effect size for any of them**, which is remarkable for a condition with 300,000 annual deaths and a published investment case. The investment case figures are model outputs. The non-fatal burden, including drowning-related neurological injury, is addressed on the WHO page only through the modelled figure.

**Cure status.** The classification depends entirely on the interval, and that is the central fact. A rescued drowning victim who is breathing, or who is successfully resuscitated quickly: CURABLE. There is no residual condition. Water in the lungs clears, and the much-feared secondary drowning is largely a myth — a person who is well six to eight hours after immersion does not deteriorate later. A drowning victim resuscitated after prolonged hypoxia: RELIEF ONLY, for the hypoxic-ischaemic brain injury. Permanent, severe, and the reason drowning's non-fatal burden is so heavy. **The surviving child with severe neurological injury is the worst outcome of the condition, worse in burden terms than death.**

In between, the outcome is a function of minutes. This is why every item in prevention and simple means is about prevention and immediate rescue, and why there is no meaningful treatment section for the established injury.

**One real exception that changes the rule:** in cold-water submersion with rapid deep hypothermia, survival with intact neurology has been documented after very prolonged submersion, because the cold protects the brain. This is why prolonged resuscitation is attempted in cold-water drowning and not in warm-water drowning.

**Prevention. WHO lists these interventions and says of the first two only that they greatly reduce or can reduce risk, giving no effect size for any of them**. - **Barriers and access control — STRONG.** WHO names **covering wells, doorway barriers, playpens and pool fencing**, and says these greatly reduce exposure and risk, with no effect size. The standing position in the injury-prevention literature is that **four-sided isolation pool fencing substantially reduces child drowning risk** compared with no fencing or with three-sided fencing; that was not verified against a source fetched in the retrieval round. **A well cover, a doorway barrier or a playpen costs a few dollars and is improvisable from local materials.** - **Supervised childcare for pre-school children — STRONG.** WHO says it can reduce drowning risk, with no effect size. This is the intervention with the strongest field evidence in the high-burden settings: community crèches in rural Bangladesh that take toddlers for the high-risk daytime hours have reported very large reductions in drowning in the enrolled age group. **WHO's own investment case pairs day care with swimming instruction and projects 774,000 fewer child drownings to 2050**. Cost per child-place is low, of the order of tens of dollars per child per year in the published pro-

gramme figures. - **Basic swimming, water safety and safe rescue skills for school-age children — STRONG, with a specific caveat WHO attaches.** WHO recommends **safety-tested curricula** and gives no effect size. The evidence from the Bangladesh swimming programmes and comparable schemes supports a protective effect in the taught age group; WHO's cross-cutting injuries sheet gives swimming and rescue training in Bangladesh as returning **US$3,000 per death averted**. **The caveat matters: swimming instruction is recommended for school-age children, not as a substitute for barriers and supervision in the under-5 group, where it does not work.** A toddler who can swim a little still drowns, and teaching a young child to swim can increase exposure. Conflating the two age groups is the standard error in this field. - **Safe rescue and resuscitation training for bystanders — STRONG** on mechanism, with no effect size given. WHO specifies "safe rescue", because **rescuer drowning is a documented and substantial cause of death** — the person who goes in after the child. - **Boating, shipping and ferry regulation, and personal flotation devices — MODERATE**, described by WHO without quantified effects. - **Flood early warning systems and flood risk management — MODERATE**, described without quantified effects. - **National water safety strategies and coordinated policy** — recommended, unquantified. - **Removing or draining unnecessary water hazards, and covering water storage vessels.** - **Alcohol restriction around water — MODERATE** for the adolescent and adult share. - **Treating epilepsy, and advising on bathing and swimming supervision** — a direct and cheap cross-chapter prevention.

**Treatment.** Treatment is rescue and resuscitation, and the window is minutes. No drug treats drowning.

**1. Remove the person from the water, safely.** Safely is load-bearing: **reach or throw, do not go**, because rescuer drowning is a major cause of death. A stick, a rope, a float, a boat.

**2. Rescue breathing, immediately — and this is where drowning differs from cardiac arrest.** Drowning is a **hypoxic** arrest, so **ventilation is the priority and should not be deferred.** Current resuscitation guidance for drowning specifies starting with **rescue breaths**, commonly five initial breaths, before chest compressions, and giving ventilations throughout — unlike the compression-only approach appropriate for adult cardiac arrest. **Compression-only bystander resuscitation is the wrong algorithm for a drowned child**, and that distinction is the most important piece of free knowledge in the entry.

**3. Chest compressions** where there is no pulse, with ventilations at the standard ratio.

**4. Oxygen and airway management**, with intubation and mechanical ventilation for those who remain unconscious or hypoxic.

**5. Do not attempt to drain water from the lungs**, and **abdominal thrusts are contraindicated** — they delay ventilation and cause aspiration of stomach contents. Another widely held belief that causes harm.

**6. Rewarming** in cold-water drowning, with prolonged resuscitation attempted because of the neuroprotection above.

**7. Observation.** A person who is fully well with normal oxygen saturation and no respiratory symptoms six to eight hours after immersion does not need admission. **Secondary drowning as a delayed deterioration in an asymptomatic person is not a real entity**, and reporting it as one generates unnecessary admissions and parental fear.

**8. Supportive intensive care** for established lung injury and for hypoxic brain injury. **No specific neuroprotective treatment has been shown to work**, and therapeutic hypothermia after drowning has not been established as beneficial.

**9. Rehabilitation** for the survivor with neurological injury. Relief only.

**Simple means.** This entry is almost entirely simple means, which is why its 38-per-cent decline since 2000 is credible and why the remaining burden is a failure of implementation rather than of technology. - **A well cover.** Wood, metal or concrete over an open well. A few dollars, permanent. - **A doorway barrier or a playpen.** WHO names both. A bamboo or wooden barrier at the threshold keeps a crawling toddler inside; a playpen keeps them in one place while the mother works. **Locally made from bamboo, wood or netting for a few dollars.** - **Covering water storage vessels and draining unnecessary standing water.** Free. - **A fence around a pond or a pool.** Four-sided isolation fencing is the evidenced

form. - **Community day care for toddlers during the high-risk daytime hours.** A room, a trained local woman, and a group of children. **Tens of dollars per child per year**, and it is the intervention WHO's investment case is built on. - **Supervision as an explicit, assigned task** — naming who is watching, rather than assuming someone is. Free, and the toddler-drowning literature shows the lapse is usually brief and unassigned. - **Swimming and safe-rescue instruction for school-age children**, taught in a pond or a fenced-off section of river by trained local instructors. Low cost, and WHO specifies safety-tested curricula. - **Reach or throw, don't go.** A stick, a rope, an empty sealed plastic container as a float. **This single rule prevents rescuer drowning**, and it costs nothing to teach. - **Rescue breathing.** Mouth-to-mouth, started at once, by anyone. **The highest-value free act in the entry.** Five initial breaths and continued ventilation — not compression-only. - **Improvised flotation** — sealed plastic jerrycans or bottles in a net, used as life jackets on small boats in several river-transport settings. - **Teaching that abdominal thrusts and draining water are wrong**, and that an asymptomatic child at eight hours is well. - **A whistle, and a flood warning by radio or phone.**

The minimum chain: a well cover, a doorway barrier, an assigned pair of eyes, and the knowledge to blow into a child's mouth. Nothing in that list requires manufacture beyond local materials.

**Gaps. WHO gives no effect size for any prevention measure** — not for barriers, not for supervised childcare, not for swimming instruction — despite recommending all of them for a cause of 300,000 annual deaths; this is the largest evidential gap in the entry, and the gradings rest on programme evaluations and the injury-prevention literature rather than on figures from a WHO source. The investment case figures are model projections to 2050, not measured results, and the model's assumptions are not on the page. The pool fencing effect size could not be verified. **The non-fatal burden is not counted:** drowning's survivors with hypoxic brain injury — the worst outcome of the condition — appear only inside a modelled figure, and there is no measured global count. The 38 per cent rate decline since 2000 is not attributed to any intervention, and whether it reflects barriers, urbanisation, falling fertility, piped water or better reporting is not separated. Swimming instruction's age boundary is critical and routinely blurred. Rescuer drowning is named by WHO and not quantified. Ferry, small-boat and flood drowning are mentioned without figures and are likely substantially under-ascertained. The key facts and the body of the WHO page use different age cuts for the child share, and the cross-cutting injuries sheet gives a different rank for ages 5 to 14; both printed. The GBD DALY figure and the WHO death count are consistent in scale and come from different estimation frameworks.

---

### Poisoning

**A note on the scope of this entry and its four sub-entries.** These five entries report epidemiology, the **classes** of agent involved, and treatment — antidotes, decontamination and supportive care. They do not give lethal doses, do not compare agents by lethality or potency, and do not describe how exposure is achieved. Where the published prevention evidence turns on restricting access to a class

**What it is.** A substance taken into the body causes harm by its chemical action. It may be a medicine, an agricultural chemical, a household product, a gas, a metal, or venom from an animal. The harm may be immediate or build up over years.

**Measured. GBD's poisonings external-cause death figure was not retrievable**, in the current or the prior round. A WHO chemical safety page gives **unintentional poisoning deaths of 106,683 in 2016**, and states that **47 per cent of Member States have a poisons centre** as of 1 January 2023 and that **20 per cent of global suicides are due to pesticide self-poisoning**, with no year printed for the last.

Self-harm overall: **35.2 million DALYs, the 25th leading DALY cause**, and about **746,000 deaths** in 2021, 1.3 per cent of global deaths. Pesticide self-poisoning is a large component.

**Lead: more than 3.5 million deaths globally in 2023**, mainly from cardiovascular effects, and **more than 71.5 million DALYs**. **This is by far the largest single poisoning burden in the chapter and it dwarfs the acute poisoning figures.**

———

Pesticides: an estimated **1 million serious unintentional poisonings a year, plus about 2 million hospitalisations for pesticide suicide attempts**†, with the source stating these are likely undercounts. A survey in the Asian region suggested **up to 25 million agricultural workers in the developing world may have a poisoning episode each year**. **Pesticide self-poisoning accounts for roughly one third**

Carbon monoxide: described as the most common cause of injury and death from poisoning worldwide, and in many industrialised countries the cause of **more than 50 per cent of fatal poisonings**†. **No global figure exists.**

---

Snakebite: about **5.4 million bites, 1.8 to 2.7 million envenomings, and about 81,410 to 137,880 deaths each year**, with amputations and permanent disabilities roughly **three times** the number of deaths.

**Where it starts.** At class level:

- **Intent.** Poisoning divides into unintentional, which is overwhelmingly children and occupational; self-harm, which is overwhelmingly adults and the dominant mortality share; and occupational exposure. **The prevention evidence differs completely between them.**
- **Availability and storage.** The single most consistent determinant across all poi-

---

What is genuinely not known is the true totals. **Every figure above is described by its own source as an undercount.** Poisoning is underascertained because many deaths occur at home without a cause being recorded, because self-harm is stigmatised and legally fraught in many jurisdictions, and because chronic poisoning — lead above all — is attributed to its downstream cardiovascular and neurological effects rather than to the

**Cure status.** Acute poisoning: CURABLE. With timely supportive care and, where one exists, an antidote, the great majority of acutely poisoned patients recover completely with no residual condition. Supportive care alone — airway, breathing, circulation, and time for the body to eliminate the substance — cures most poisoning, because most substances are eliminated. Organophosphate delayed neu-

---

**Prevention.** The prevention evidence for poisoning is unusually strong and it is almost entirely about **restricting access to the agent**, not about changing the person. Three measures carry nearly all of it.

———

**1. Pesticide regulation — STRONG, and the Sri Lanka data is the best natural experiment in the whole of injury prevention.** The figures are in the pesticide subentry below. As policy: successive national bans on named agents, implemented under a national pesticides control statute, with about 93,000 lives saved over twenty years at a direct government cost of under US$50 per life saved, and with na-

———

**2. Child-resistant packaging — STRONG.** Containers that a young child cannot open within a reasonable time. The United States Poison Prevention Packaging Act of **1970** required it for specified hazardous household substances and medicines, and the subsequent surveillance literature attributes a very large fall in child poisoning deaths to it — the most commonly cited figure being a decline of the order of **45 per cent or more**

Related and evidenced: **blister or unit-dose packaging** of medicines, and **limits on the quantity sold in a single pack**. Both reduce the amount accessible in one episode, and national restrictions of this kind have been followed by measured falls in deaths and in liver transplant listings. WHO and the WHO and UN Environment Programme chemical safety framework recommend child-resistant packaging, safe stor-

**3. Safe storage — STRONG.** Locked or out-of-reach storage of medicines, agricultural chemicals, fuels and household chemicals, keeping substances in their original labelled containers.

Other established measures: - **Carbon monoxide alarms and appliance regulation — STRONG.** - **Removing lead from petrol, paint, pipes, cookware, cosmetics and toys — STRONG. The global phase-out of leaded petrol, completed in 2021, is the largest single poisoning-prevention achievement in history by burden averted.** - **Occupational controls** — personal protective equipment, training, cholinesterase monitoring, substitution

**Treatment.** The general principles are here; agent-class specifics are in the subentries.

**1. Supportive care. This cures most poisoning and it is first, not last.** Airway protection, ventilation, oxygen, intravenous fluids, treatment of seizures, correction of acidosis and electrolytes, temperature control, and management of arrhythmia and hypotension. **Most poisons are eliminated by the body if the patient is kept alive**, and the great majority of poisoning deaths

---

**2. Seizure control** — lorazepam, diazepam, phenobarbital or phenytoin. All EML-listed, off-patent, cents; phenobarbital works out at about US$0.017 a tablet on October 2026 indicative prices.

**3. Decontamination, with its indications now narrow.** - **Skin and eye decontamination — do this, and do it early.** Remove clothing, wash with soap and water, shampoo the hair, **flush eyes with water for 10 to 15 minutes**. The dominant route of occupational pesticide exposure is the skin, so this is a high-yield measure. - **Activated charcoal** may reduce absorption **if given within 60**

**4. Antidotes, where one exists for the class** — see the subentries. **For most poisons there is no antidote**, which is why supportive care comes first.

**5. Observation and psychiatric assessment** after self-poisoning, with means restriction advice to the household as part of discharge. **This is the treatment step with the strongest prevention evidence attached and the one most often omitted.**

---

**Simple means.** - **The recovery position and airway management by a bystander.** An unconscious poisoned person placed on their side does not aspirate. **This single free act is the highest-value simple means in the entry**, because aspiration and airway obstruction are what kill the unconscious poisoned patient before they reach care. - **Washing the skin with soap and water, and flush-**

The minimum chain: a sidelying position, water and soap, and the container brought with the patient. For the specific antidotes, manufactured drugs with no substitute — and for most poisons there is no antidote at all, so the simple means above are not second-best, they are the main treatment.

---

**Gaps.** GBD's global poisoning death figure could not be retrieved, in the current or the prior round, so the entry has no verified global acute-poisoning denominator; and **the WHO poisoning fact sheet itself could not be read on four attempts and may have been retired.** Every figure above is described by its own source as an undercount. The child-resistant packaging effect sizes could not be verified and are reported as the regulatory

## Pesticide poisoning

*The constraint stated above applies in full: no lethal doses, no comparison of agents by lethality, no description of how exposure is achieved.*

**What it is.** An agricultural chemical gets into the body. Most deaths worldwide follow deliberate self-poisoning rather than accidents at work, which is why the prevention evidence in this entry is about regulating availability rather than about treating exposure.

**Measured.** About **1 million serious unintentional poisonings a year, plus about 2 million hospitalisations for pesticide suicide attempts**, with the source stating these are likely undercounts. A survey in the Asian region suggested **up to 25 million agricultural workers in the developing world may have a poisoning episode each year**.

**Pesticide self-poisoning accounts for roughly one third of suicides worldwide**; a WHO chemical safety page gives **20 per cent of global suicides**, with no year printed. Both printed.

Canada records more than 6,000 acute poisoning cases†.

Occupational risk: agricultural workers face the highest risk, and **exposure is mainly through the skin**, with inhalation contributing in greenhouses, tractor cabs and closed spaces. Long-term exposure is linked to neurological disease, reproductive harm and some cancers, and **no global case counts** are given.

The mortality is overwhelmingly rural, agricultural, and in South and Southeast Asia, sub-Saharan Africa and parts of Latin America.

**Where it starts.** At class level: - **Cholinesterase inhibitors, the organophosphates and carbamates: the most commonly reported class in occupational poisonings globally**. **Some organophosphates can cause delayed, often irreversible nerve damage**. - **Organochlorines: persistent and bioaccumulative.** The source links one of them and its metabolite to endocrine disruption and tags that claim as needing a citation. - **Chlorophenoxy herbicides**, relevant to treatment because of urinary alkalinisation. - **Bipyridyl herbicides**, the class subject to the Sri Lankan restrictions of 2008 to 2011. - **Availability in the household.** The determinant of the self-harm mortality: the agent is in the home or the field because it is an agricultural input, and the self-harm is frequently impulsive and low-planning. - **Occupation, skin exposure, absence of protective equipment, mixing and loading, backpack sprayer leakage, re-entry to treated fields.** - **Alcohol co-ingestion.** - **No effect sizes are given for any risk factor on the source consulted**, apart from the prevention figures below.

What is not known is the true incidence. The headline figures date from 1990 and are described as undercounts, and the 25-million figure is a regional survey extrapolation. **Chronic health effects of long-term low-level occupational exposure are established as associations and not quantified**, which is the largest open question for the hundreds of millions of people who handle these chemicals for a living.

**Cure status.** Acute cholinesterase-inhibitor poisoning: CURABLE. Acute cholinergic crisis is survivable and reversible with atropine, airway management and ventilation, and a patient who survives the acute phase recovers. Deaths occur overwhelmingly where ventilators and atropine are not available and the interval to care is long. Organophosphate-induced delayed polyneuropathy, and in some agents a persistent neurobehavioural deficit: RELIEF ONLY. The source states plainly that some organophosphates can cause delayed, often irreversible nerve damage. Organochlorine and chlorophenoxy poisoning: CURABLE. Managed supportively, with recovery usual.

**Prevention. This is the strongest prevention evidence in the whole of this chapter, and it comes from one country, as policy and population data.**

The Sri Lankan regulatory sequence, under its Control of Pesticides Act:

| Year | Measure |
|---|---|
| 1984 | Parathion and methyl-parathion banned |
| 1992–1995 | Methamidophos and monocrotophos banned |
| 1998 | Endosulfan banned immediately after a rise in deaths; WHO Class I pesticides and several Class II pesticides also banned from 1998 |
| 2008–2011 | Dimethoate, fenthion and paraquat banned |

**The source gives two totals that do not agree, and both are printed:** one statement says the bans resulted in **36 pesticides being phased out**; another says that as of 2018, **41 pesticides had been banned and 11 insecticides restricted**†.

The measured outcome, as population data: - **Suicide rates rose about eight-fold from 1950 to the 1990s, peaking at 47 per 100,000 in 1995**†. - **Pesticide poisoning accounted for more than two thirds of suicides** at that peak. - **The overall suicide rate fell by 70 per cent over roughly two decades**†. The source gives no endpoint rate and no endpoint year. Applying 70 per cent to the 1995 peak gives about 14 per 100,000, and that is arithmetic rather than a figure from the source. - **After the 2008 to 2011 bans, suicide rates fell by 50 per cent**†. The source does not state clearly whether this is pesticide-specific or overall. - **About 93,000 lives saved over 20 years**†. - **A direct government cost of less than US$50 per life saved**†.

**That last figure is the single most important number in this chapter.** A regulatory act, costing the government under US$50 per life saved, saved about 93,000 lives in one country over twenty years. No clinical intervention in this book approaches it.

Two further figures from the same source, reported because they address the standard objection: **pesticide use rose from 1,571 tons in 1990 to 2,260 tons in 2018**, so the bans did not reduce overall pesticide use — they removed specific agents; and **from 2002 to 2016 Class II pesticide products fell by 29 per cent**†. **In 1978, over 1,000 people died from pesticide poisoning in Sri Lanka**†. The agricultural-output question was studied, and the bans were implemented without the agricultural collapse that was predicted.

**A provenance caveat, stated because it matters.** The source carrying these figures **does not tie specific figures to specific studies.** Its reference list includes the relevant primary work — papers of 2007 on the impact of pesticide regulations on suicide, of 2017 on the impact of the 2008 to 2011 restrictions, of 2003 on the influence of regulation on acute poisoning deaths, of 2014 on suicide in Sri Lanka from 1975 to 2012, and of 2008 on effects on agricultural output — **and it does not state which study reports the 70 per cent decline, the 93,000 lives, or the under-US$50 cost.** Those primaries could not be fetched. The figures are reported with that provenance stated.

Other prevention: - **Household storage boxes — NEGATIVE.** The large cluster-randomised trial of lockable household pesticide storage in Sri Lanka **did not demonstrate a reduction in self-poisoning**. **Access restriction works at the national-regulatory level and did not work at the household level in trial.** Reported as a negative because it is one. - **Personal protective equipment and training — MODERATE. One study found a 55 per cent lower risk of acute poisoning among farmers who adopted extra protective measures and received education**. - **Chemical-resistant gloves — STRONG for exposure. Gloves reduced contamination by 33 to 86 per cent**. A direct, measured, cheap intervention on the dominant dermal route. - **Baseline cholinesterase monitoring** for regular users of carbamates or organophosphates, recommended, which detects exposure before symptoms. - **Safe storage and labelling**, cited as ways to prevent accidental poisonings. - **Bt cotton adoption in India was associated with 2.4 to 9 million fewer poisoning cases a year**† — a very wide range and an indirect mechanism, through reduced spraying. - **Substitution with less hazardous formulations, closed-transfer systems, and restricting WHO Class I agents.** The WHO hazard classification is the instrument the Sri Lankan bans used.

**Treatment. 1. Atropine, in adequate doses, for cholinesterase-inhibitor poisoning. The antidote, and the single most important drug in the entry.** It reverses the muscarinic effects, and the endpoint is clearance of respiratory secretions and adequate oxygenation, reached by rapid dose escalation and then an infusion. **Under-dosing is the commonest treatment failure** in the published series. **Atropine is EML-listed under specific antidotes, for pesticide exposure**, and also under preoperative medication. Off-patent, **cents an ampoule** — and a full treatment course may require very many ampoules, so the practical constraint is stock depth at the clinic rather than unit price.

**2. Airway management and mechanical ventilation. This determines survival.** Respiratory failure from secretions, bronchospasm, central depression and muscle weakness is the mechanism of death, and **the 10-to-20-per-cent case fatality is largely a statement about ventilator and airway availability.**

**3. Oximes — pralidoxime, obidoxime.** They reactivate the inhibited enzyme in principle. **The evidence of clinical benefit is weak and contested:** randomised and quasi-randomised trials and the Cochrane review have not demonstrated a mortality benefit, and practice differs internationally. **Pralidoxime's EML status could not be confirmed** against the sections reachable. Reported as contested, not as standard. The source consulted does not discuss atropine or pralidoxime at all, which is itself notable; the atropine information above comes from the Essential Medicines List and standard toxicological practice.

**4. Seizure control** — lorazepam, phenytoin, phenobarbital or diazepam, with **diazepam particularly for organochlorines**. All EML-listed, off-patent, cents.

**5. Decontamination.** - **Skin and eye: remove clothing, wash with soap and water, shampoo the hair, flush eyes with water for 10 to 15 minutes.** High-yield, because the skin is the main route. - **Activated charcoal** within 60 minutes may reduce absorption, and it is **not effective for malathion**. EML-listed, off-patent, cheap. - **Gastric lavage: not routine**, considered only within 60 minutes for life-threatening ingestion, and **contraindicated for hydrocarbons**, which many formulations are based on. - **Syrup of ipecac: not recommended.** - **Urinary alkalinisation** for chlorophenoxy herbicide poisoning, **and the evidence is poor** by the source's own statement.

**6. Supportive care** — fluids, oxygen, correction of acidosis and electrolytes, temperature control, and intensive care where available.

**7. Psychiatric assessment and means restriction advice** after self-poisoning.

**Simple means.** - **The recovery position.** The patient is drowning in their own secretions, and **side-lying with the head dependent allows them to drain and prevents aspiration.** Free, immediate, and the highest-value bystander act. - **Soap and water on the skin, and water in the eyes for 10 to 15 minutes.** It addresses the dominant exposure route with the cheapest possible material. - **Removing and disposing of contaminated clothing**, including protecting the person who removes it. - **Suctioning or wiping secretions, and positioning for drainage**, where no suction device exists. - **Bag-and-mask ventilation.** The same self-inflating bag as the newborn resuscitation entry, costing tens of dollars, is what bridges a poisoned patient to a ventilator or substitutes for one during transport. **Hand ventilation by relays of family members has been described in the field literature as the practical reality in settings without ventilators**, and it is the difference between the 10-to-20-per-cent case fatality and a much higher one. - **Chemical-resistant gloves — reduced contamination by 33 to 86 per cent**†. A manufactured item costing a few dollars, with a measured effect on the main exposure route. - **Bringing the container or the label.** Identifying the class determines whether atropine is indicated. Free. - **Not giving milk, oil or salt water, and not inducing vomiting.** - **Washing sprayer equipment away from water sources; not blowing out blocked nozzles; spraying downwind; covering the skin.** - **Lockable storage**, with the honest caveat that the cluster-randomised trial of household storage boxes was negative, so this is reasonable practice rather than demonstrated prevention. - **The regulatory act itself**, which is the cheapest intervention in this book at under US$50 per life saved, and which requires no supply chain at all — only a decision.

The minimum chain: a side-lying position and water as first aid; atropine ampoules and a means of ventilating for the cure. Atropine is cents and there is no substitute for it or for the airway.

**Gaps.** The Sri Lanka figures — the 70 per cent decline, the 93,000 lives, the under-US$50 cost per life — **are not tied to specific studies by the source consulted.** The relevant primaries are named in its reference list and could not be fetched, so the figures are reported with that provenance stated and should be verified against those primaries. The source gives two incompatible totals for pesticides banned, at 36 phased out and 41 banned with 11 restricted as of 2018; both printed. The 50 per cent fall after the 2008 to 2011 bans does not state whether it is pesticide-specific or overall, and the 70 per cent decline has no stated endpoint rate or year. The headline incidence figures are from 1990 and are described as undercounts, and the 25-million figure is a regional extrapolation. The source consulted does not discuss atropine or pralidoxime, the entry's two antidotes. Oxime benefit is unproven and contested, practice differs internationally on the same evidence, and pralidoxime's EML status could not be confirmed. The household storage box trial was negative while national bans

are strongly positive, which is an important discrepancy in the level at which the intervention works. Chronic occupational exposure effects are associations without quantification, for a very large exposed population. The Bt cotton figure spans a nearly four-fold range and rests on an indirect mechanism. Urinary alkalinisation is used despite poor evidence, by the source's own statement.

---

## Carbon monoxide poisoning

*The constraint stated above applies in full.*

**What it is.** A colourless odourless gas produced whenever carbon burns incompletely. It binds to the blood's oxygen carrier far more tightly than oxygen does, so the blood circulates without delivering oxygen. The symptoms — headache, nausea, confusion — are mistaken for influenza, and the person does not know they are being poisoned.

**Measured.** Described as the most common cause of injury and death from poisoning worldwide, and in many industrialised countries the cause of **more than 50 per cent of fatal poisonings**†. **No global figure is given.**

United States, non-fire cases: more than **20,000 emergency visits a year and more than 400 deaths a year**†. A broader estimate gives more than **40,000 people a year** seeking medical attention†. Mortality figures: more than **500 unintentional deaths a year and more than 2,000 suicides a year**, with no year stated on the source†. Between 1979 and 1988, **56,133 deaths were recorded, 25,889 of them suicides**†. About **200 deaths a year** are linked to home fuel-burning heating equipment, with no year stated.

Country examples: **New Zealand, 206 deaths in 2001 to 2002, 43.9 per cent of poisoning deaths; South Korea, 1,950 poisonings and 254 deaths from 2001 to 2003; Jerusalem, 3.53 poisonings per 100,000 people a year from 2001 to 2006; Australia, 95 per cent of carbon monoxide poisoning deaths attributed to gas space heaters**.

Cases rise in winter, largely from heating equipment, and **during power outages**, when people use fuel-burning devices indoors. **The true number is unknown because many non-lethal exposures go undetected**, by the source's own statement.

**No global figure, no GBD series and no low- and middle-income data were located. Every figure above is from a high-income country.**

**Where it starts.** At class level, the source's list: - **Combustion heating and cooking** — furnaces, space heaters, stoves, wood-burning stoves, especially when faulty or poorly ventilated. Australia attributes 95 per cent of its deaths to gas space heaters. - **Engines in enclosed or semi-enclosed spaces.** - **Portable fuel-powered equipment** — propane devices and petrol-powered tools used in enclosed or semi-enclosed spaces. **Generator use indoors during a power outage is the classic cluster mechanism.** - **Diving equipment** — faulty diving air compressors. - **Confined natural and industrial spaces** — caves with decomposing organic matter, and coal mine afterdamp. - **Tobacco smoke, and fires.** - **Chemical metabolism: dichloromethane** in some paint strippers, **which the body metabolises into carbon monoxide** — an exposure route with no combustion at all. **The United States Environmental Protection Agency banned consumer use of dichloromethane in paint strippers, effective November 2019**. - **Risk factors for delayed neurological effects: older age, loss of consciousness, and initial neurological abnormalities**. - **No effect sizes** are given for any risk factor.

What is not known is the global burden. **There is no global figure, no retrievable GBD series, and no data from the low- and middle-income settings where solid-fuel and biomass cooking and heating are near-universal and the exposure is therefore likely highest.** The condition's epidemiology is described entirely from high-income countries with piped gas and automobiles. The source also acknowledges that the true number is unknown because non-lethal exposures go undetected, and the presentation mimics viral illness, so misdiagnosis is systematic rather than occasional.

**Cure status.** The acute poisoning: CURABLE. Oxygen displaces carbon monoxide from haemoglobin, and a patient treated before hypoxic injury has occurred recovers completely. The elimination is measurable: the gas's half-life falls **from about 320 minutes on room air to about 80 minutes on a non-rebreather mask, and to about 23 minutes at three**

**atmospheres**. The delayed neurological sequelae: RELIEF ONLY, and this part is substantial. **Delayed neurological effects can develop in up to 50 per cent of poisoned people after 2 to 40 days** — cognitive impairment, personality change, movement disorder, parkinsonism. Follow-up and supportive care are often needed, and nothing reverses established injury.

**A correction that must be stated, and it is a warning rather than a treatment option.** The source consulted contains a sentence claiming that **an eight-to-twelve-week course of corticosteroids prevents delayed neurological effects. That sentence has no citation, the cited discussion does not support it, and the source itself flags it. It is not established practice and should not be acted on.** It is printed here only so that a reader who encounters the claim elsewhere knows its status.

**Prevention.** - **Carbon monoxide alarms — STRONG, and they are the only reliable detection method because the gas has no smell.** The United States Consumer Product Safety Commission recommends at least one detector per home, preferably one per level, and states that they are as important to home safety as smoke detectors. Detectors sound an alarm at relatively high levels, allowing people to evacuate and ventilate, and **unlike smoke detectors they do not need to be near the ceiling**, because the gas mixes with air rather than rising. **The source does not report outcome studies quantifying how much detectors reduce deaths or injuries**, which is a significant gap for the entry's central intervention. **A carbon monoxide alarm costs tens of dollars and lasts years**. - **Standards.** The 2009 edition of the relevant fire protection standard specifies: residential detectors on every level including basements and outside sleeping areas, with new mains-powered units needing battery backup and interconnection; and non-residential battery backup running notification devices for at least 12 hours, ceiling-mounted detectors in rooms with permanent fuel-burning appliances, and coverage on every habitable level and ventilation zone. **The standard is not necessarily enforced by law**. - **Legislation — MODERATE where enacted, and patchy.** Massachusetts has required detectors in all residences with potential sources since April 2006, enforced by municipal inspectors, and **the law followed a 2005 death of a 7-year-old when snow blocked a heating vent**. Other jurisdictions may have no requirement, or may require detectors only for new construction or at sale. - **Product regulation — STRONG where applied**, as in the 2019 dichloromethane ban. - **Appliance measures — STRONG:** proper venting of gas appliances, cleaning chimneys, maintaining vehicle exhaust systems, and annual servicing of gas appliances. - **Public education on safe use of heaters, generators and engines — MODERATE.** The specific messages with the highest yield: never run a generator or petrol engine indoors or in an attached garage; never use a charcoal or gas barbecue indoors; clear snow from vehicle exhausts and from heating vents. - **No effect size is given for any of these on the source consulted**.

**Treatment. 1. Remove the person from the source, without endangering others.** The source states this first. **Rescuer poisoning is the documented hazard**, because the gas is undetectable.

**2. Normobaric oxygen, high flow, by non-rebreather mask. The standard treatment.** It shortens the gas's half-life from about 320 minutes on room air to about 80 minutes. Continue until symptoms resolve and carboxyhaemoglobin falls below about **3 per cent in non-smokers or 10 per cent in smokers**. **Pregnant patients receive oxygen for longer**, because fetal haemoglobin binds carbon monoxide more avidly and the fetus clears it more slowly. Oxygen is EML-listed and off-patent, and the cost is the cost of delivery — a concentrator, a cylinder or a piped supply. An oxygen concentrator runs on mains or solar power and removes the cylinder chain.

**3. Cardiopulmonary resuscitation** where the patient is unconscious and pulseless.

**4. Hyperbaric oxygen — CONTESTED, and the evidence must be reported as mixed.** At three atmospheres the half-life falls to about 23 minutes. **Of six randomised controlled trials comparing it with normobaric oxygen, four reported better outcomes with hyperbaric oxygen and two found no benefit, and some trials have methodological criticisms**. A 2005 review concluded the evidence neither confirms nor excludes a meaningful benefit and called for a large, well-designed multicentre trial, and two later authoritative sources state that the benefit over standard high-flow oxygen is unclear. The practical consequence: hyperbaric oxygen requires a chamber, which exists in very few places, and its

benefit over the universally available alternative is not established. **The treatment that works is the high-flow oxygen above.**

**5. Supportive care** — intravenous fluids for hypotension, vasopressors for myocardial depression, standard advanced life support for arrhythmias, and management of seizures, pulmonary oedema and acidosis. Sodium bicarbonate for severe metabolic acidosis is controversial.

**6. Follow-up for delayed neurological effects**, in up to 50 per cent at 2 to 40 days. Supportive care and rehabilitation; nothing prevents or reverses them, and **the uncited corticosteroid claim above should not be acted on.**

**7. Carboxyhaemoglobin measurement** by co-oximetry on a blood gas. **A standard pulse oximeter reads falsely normal in carbon monoxide poisoning**, because it cannot distinguish carboxyhaemoglobin from oxyhaemoglobin. This is a trap and it belongs in the treatment section: **the reassuring saturation reading is wrong.**

**Simple means.** - **Opening the windows and doors, and getting the person out into fresh air.** Free, immediate, and the first and most effective act. **Breathing air begins the elimination.** - **Not entering an enclosed space to rescue someone without ventilating first.** Free knowledge that prevents the rescuer becoming the second casualty. - **The recovery position** for the unconscious breathing casualty. - **Mouth-to-mouth rescue breathing and cardiopulmonary resuscitation.** - **Oxygen from a concentrator** — mains or solar powered, no cylinder chain. This is the actual treatment and it is close to a simple means in a clinic that has power. - **A carbon monoxide alarm.** Tens of dollars, battery or mains, lasting years. **The gas has no smell, so there is no biological detection — the alarm is the only detection.** - **Chimney sweeping and flue clearing.** A brush, and it addresses the dominant residential mechanism. - **Ventilation openings in the cooking and heating space, kept unblocked.** In solid-fuel and biomass-using households this is the principal structural prevention and it costs nothing to keep clear. - **Never running a generator, petrol engine, charcoal brazier or gas barbecue indoors or in an attached space.** A rule, taught in one sentence, that addresses the outage-cluster mechanism. - **Keeping vehicle exhausts and heating vents clear.** - **Suspecting it.** The presentation mimics influenza, and **a whole household with simultaneous headache and nausea is the pattern.** Asking whether others in the house are also unwell is free and is the diagnostic act. - **Never using a charcoal or wood fire for indoor heating in a sealed room**, which is the dominant mechanism in cold-climate low-income settings.

The minimum chain: an open window and fresh air as first aid; an alarm for prevention; oxygen for treatment. The alarm is the only item that must be bought, and it is the only possible detection.

**Gaps. There is no global figure.** The condition is described as the most common cause of poisoning death worldwide and no global count exists in any source reached, and no GBD series was retrievable. **Every quantified figure is from a high-income country** — the United States, New Zealand, South Korea, Australia, Israel — and **there are no data from the low- and middle-income settings where solid-fuel and biomass heating and cooking are near-universal and the exposure is likely highest.** That is the largest gap in the entry. No outcome studies quantifying the effect of alarms on deaths or injuries are reported on the source consulted, for the entry's central preventive intervention. **The source contains an uncited and unsupported claim that corticosteroids prevent delayed neurological effects, flagged by the source itself, and it is printed here as a warning rather than as a treatment option.** Hyperbaric oxygen is genuinely unresolved after decades — four of six randomised trials positive, two null, methodological criticisms of some, and two authoritative reviews stating the benefit is unclear — and a definitive trial has been called for and not done. Several figures carry no year. Non-lethal exposures go undetected by the source's own statement, so all morbidity figures are floors. Delayed neurological effects occur in "up to 50 per cent", a wide and unbounded figure with no central estimate. Misdiagnosis as viral illness is systematic and unquantified.

---

## Lead poisoning

*The constraint stated above applies in full.*

**What it is.** Lead enters the body from paint, dust, water pipes, petrol residues, pottery glaze, cosmetics, cookware or battery recycling. It accumulates in bone over years. In a child it lowers intelligence permanently; in an adult it raises blood pressure and causes heart disease and strokes.

**Measured. More than 3.5 million deaths globally in 2023, mainly from cardiovascular effects**, and **more than 71.5 million DALYs lost worldwide in 2023**. Lead exposure ranks tenth among the top ten risks by health loss in 2023.

**This is the largest single poisoning burden in this chapter by two orders of magnitude**, and it is larger than road traffic injury deaths at about 1.16 million, falls at 684,000, drowning at 300,000 and burns at 180,000 combined.

Blood lead thresholds: **decreased intelligence, behavioural difficulties and learning problems may be associated with blood lead as low as 3.5 µg/dL in children**, and **WHO guidance recommends identifying and stopping the source of exposure at 5 µg/dL or above**†.

**"There is no level of exposure to lead that is known to be without harmful effects"**, verbatim.

**WHO's page states that lead can reduce IQ in children and gives no point figure**. The standing figure in the literature is of the order of several IQ points lost per 10 µg/dL increment at low blood lead levels, with a steeper slope at the lowest concentrations; **no figure is asserted here**, because it could not be sourced.

**WHO's page gives no count of children with elevated blood lead**. The widely cited figure of approximately 800 million children with blood lead at or above 5 µg/dL comes from a 2020 report and **was not verifiable against a source fetched in the retrieval round**, so the number of affected children is not asserted in this entry.

Main sources of exposure: mining, smelting, manufacturing and recycling; **lead-acid batteries, which account for most global lead consumption**; paint, solder, ceramic glazes, toys, jewellery, some traditional cosmetics and medicines, and lead plumbing. The routes are inhaling particles from burning lead-containing materials, and ingesting contaminated dust, soil, water or food.

**Where it starts.** WHO's list, with the mechanisms it names: - **Informal and unregulated lead-acid battery recycling.** WHO names lead-acid batteries as accounting for most global lead consumption, and informal recycling is the dominant modern point source in low- and middle-income countries. - **Mining, smelting, manufacturing and recycling** — occupational and community exposure, including take-home dust on workers' clothing. - **Lead paint** — in housing stock, and still manufactured and sold in many countries. - **Lead plumbing** — pipes, solder and brass fittings, with the leaching rate depending on water chemistry. - **Ceramic glazes and cookware**, including lead-glazed pottery used for food and drink. - **Some traditional cosmetics and medicines**, and **spices and foods adulterated with lead chromate for colour.** - **Toys, jewellery and consumer goods.** - **Contaminated soil and dust**, including the legacy of leaded petrol, which persists in urban soils for decades after the fuel is withdrawn. - **Age: children absorb a far higher fraction of ingested lead than adults, and the developing brain is the vulnerable organ.** Hand-to-mouth behaviour and pica raise intake. - **Nutritional status: iron and calcium deficiency increase lead absorption** — so the anaemic child absorbs more lead, which is a direct interaction between two entries in this book. - **No effect sizes are given for any risk factor on the WHO page.**

What is not known is the shape of the dose-response at the lowest levels, which is the question that matters most. **WHO states there is no known safe level**, and the evidence is that the IQ slope is steepest at the lowest blood lead concentrations — meaning the harm per microgram is greatest where exposure is lowest, and there is no threshold to aim for. That makes the condition unusual: **the policy target is zero and there is no defensible intermediate standard.** Also not known: how much of the 3.5 million cardiovascular deaths is attributable to current against historical exposure, since bone lead is a decades-long internal reservoir.

**Cure status.** This must be stated plainly because it is the central fact of the entry and it is widely misunderstood. What has already happened: RELIEF ONLY. **The neurodevelopmental deficit in a child who has been exposed is permanent.** Lowered IQ, attention

and behavioural problems, and reduced educational attainment do not reverse when the exposure stops and do not reverse with chelation. **No treatment recovers lost cognitive capacity.** Further accumulation: CONTROLLABLE. Removing the exposure stops it — which is why WHO's guidance at 5 µg/dL is to **identify and stop the source**, not to treat the child. That is control, not cure.

**Chelation** lowers blood lead and is used for severe poisoning. **It has not been shown to improve cognitive outcomes:** a randomised trial of succimer in children with moderately elevated blood lead **lowered blood lead and produced no improvement in cognitive, behavioural or neuropsychological outcomes**. **This is the decisive negative result in the entry and it is why lead poisoning is a prevention problem and not a treatment problem.** That finding is reported as the standing literature position; it is not on the WHO page and was not verified against the primary.

The adult cardiovascular burden — the 3.5 million deaths — follows from accumulated exposure and is addressed by treating the hypertension and cardiovascular disease, not the lead.

**Prevention. Everything of value in this entry is here.** Lead poisoning is the clearest case in the book of a condition where regulation is the whole of medicine. - **Removing lead from petrol — STRONG, and it is the largest completed poisoning-prevention achievement in history by burden averted.** The global phase-out was **completed in 2021**, when the last country ceased sales. Population blood lead levels fell by large multiples in every country that did it — the United States recorded a fall of roughly 80 per cent in mean child blood lead across the 1976 to 1991 period spanning its phase-out†. **The figures could not be verified against a source fetched in the retrieval round** and are reported as the standing position. **The intervention was a regulatory act with no clinical component.** - **Eliminating lead paint — STRONG.** WHO and the UN Environment Programme's alliance works toward legally binding controls in every country; a substantial number of countries still have none, and lead paint continues to be manufactured and sold. **The cost of reformulating paint is small and the measure is purely regulatory.** - **Regulating and formalising lead-acid battery recycling — STRONG, and it is the highest-yield remaining action.** WHO names lead-acid batteries as most of global lead consumption. Informal recycling — smelting batteries in residential areas, often with children present — is the dominant modern point source. The measures are producer responsibility, licensed recycling, and closing informal smelters. - **Removing lead plumbing, and controlling water chemistry where it remains — STRONG.** Pipe replacement, with corrosion control as the interim measure. - **Regulating ceramic glazes, cookware, cosmetics, toys, jewellery and spices — STRONG** where enforced. - **Occupational controls — STRONG.** Enclosure, ventilation, respiratory protection, changing facilities and laundering of work clothes on site to prevent take-home dust, and blood lead monitoring with removal from exposure above action levels. - **Blood lead screening of children in high-risk areas — MODERATE**, as a case-finding tool, with the explicit purpose of finding and removing the source rather than treating the child. - **Soil remediation, dust control, wet cleaning and hand-washing before eating — MODERATE** in contaminated areas. - **Correcting iron and calcium deficiency — MODERATE.** It reduces lead absorption and it is cheap. - **WHO's framing is explicit: identify and stop the source of exposure**. The prevention is the treatment.

**Treatment.** The honest ordering is source removal first, chelation a distant second. **1. Identify and remove the source of exposure.** WHO's recommendation at 5 µg/dL and above. **This is the treatment.** It is an environmental and regulatory act rather than a clinical one, and for the whole household and often the whole neighbourhood rather than the individual child.

**2. Nutritional support — iron and calcium repletion**, which reduces further absorption. EML-listed, off-patent, about a cent a tablet for iron on October 2026 indicative prices.

**3. Chelation therapy, for severe poisoning** — encephalopathy and very high blood lead. The agents are **succimer** orally, **sodium calcium edetate** parenterally, and **dimercaprol** for lead encephalopathy, given with edetate. **Dimercaprol and sodium calcium edetate are on the WHO Essential Medicines List under specific antidotes**. Off-patent, moderate cost, with availability the constraint. **The indication is severe poisoning, not moderate elevation:** the randomised trial above showed that chelating children with moderately elevated blood lead lowers the blood level and does not improve cognitive outcome. **Chela-**

**tion is therefore not a treatment for the harm; it is a treatment for acute severe toxicity.** It carries real risks — nephrotoxicity, redistribution of lead to the brain with some agents, mineral depletion — and **chelation without removing the source is futile, because the child returns to the exposure.**

**4. Supportive treatment of lead encephalopathy** — seizure control, management of raised intracranial pressure, intensive care.

**5. Treating the consequences** — anaemia, hypertension and cardiovascular disease in adults, and educational and behavioural support for affected children. Relief, and it is where most of the lifetime cost falls.

**6. Developmental and educational assessment and support** for affected children. The permanent deficit is managed rather than cured, and early educational intervention is the only measure with a demonstrated effect on functional outcome.

**Simple means.** - **Hand-washing before eating, and wet-wiping surfaces rather than dry sweeping.** Lead reaches children as dust on hands and food. Soap and a damp cloth, and in contaminated housing this is a real and measurable reduction in intake. - **Wet mopping; damp dust control; removing shoes at the door; covering bare contaminated soil with grass, matting or clean soil.** - **Not storing or cooking acidic food in lead-glazed pottery**, and not using leaded cookware. Free knowledge. - **Workers changing and washing clothes before going home.** Take-home dust is a documented route to the worker's own children, and the countermeasure is a change of clothes and a wash. - **Moving informal battery smelting away from homes and away from children** — and the honest statement is that the real measure is closing it, which is regulatory. - **Iron-rich food and iron supplementation**, which reduces absorption and costs about a cent a tablet. - **Breastfeeding and adequate nutrition generally.** A well-nourished child absorbs less. - **Keeping children away from renovation and paint-stripping work**; wet-sanding rather than dry-sanding; not burning painted wood. - **Running the tap before drinking where lead pipes are present**, and using cold water for drinking and cooking. - **Avoiding lead-containing traditional cosmetics and medicines** — a conversation. - **Checking what is in the house:** pottery, cosmetics, spices, paint, imported cookware.

**What the chain minimally requires, stated plainly: nothing manufactured — and also, almost nothing that a household can do is sufficient.** The simple means above reduce intake at the margin. **The interventions that produced the measured reductions in population blood lead were national regulatory acts: removing lead from petrol, from paint, from pipes and from recycling.** This is the entry where simple means matter least and policy matters most, and saying otherwise would misdirect effort.

**Gaps.** WHO gives no IQ point figure despite stating that lead reduces IQ in children: the dose-response figure most needed for policy is not on the page, and the literature figure could not be verified. WHO gives no count of children with elevated blood lead, and the widely cited figure of about 800 million could not be verified, so the number of affected children is not asserted here. The leaded petrol phase-out effect figures could not be verified and are reported as the standing position. The chelation trial finding is not on the WHO page and was not verified against the primary, and it is nonetheless the decisive statement for the entry's cure status. The dose-response at the lowest exposures is unresolved and WHO states there is no known safe level, so there is no defensible intermediate standard. The split between current and historical exposure in the 3.5 million cardiovascular deaths is not separated, because bone lead is a decades-long reservoir. The 3.5 million deaths are an attributable-burden estimate overlapping with the cardiovascular cause counts, and cannot be added to them. **WHO's two thresholds differ** — harm associated from 3.5 µg/dL, action recommended at 5 µg/dL — which is a policy gap rather than an evidential one and follows from there being no threshold. Lead burden is attributed to its downstream effects in the cause-of-death accounts, so it is invisible in the poisoning figures and visible only in the risk-factor accounts. No cost or cost-effectiveness figure for any lead intervention was located, for the largest poisoning burden in the chapter.

---

## Snakebite envenoming

*The constraint stated above applies in full, including no comparison of species by lethality.*

**What it is.** A venomous snake bites, usually a farmer or a child in a rural area. The venom destroys tissue around the bite, or stops the blood clotting, or paralyses the breathing muscles. Treatment is an antiserum made by immunising horses or sheep, and in most of the places where the bites happen it is not available.

**Measured. About 5.4 million people are bitten by snakes each year.** Envenomings: **1.8 to 2.7 million cases** a year. Deaths: **about 81,410 to 137,880 each year. Amputations and permanent disabilities: roughly three times the number of deaths each year** — so of the order of 250,000 to 400,000 people permanently disabled annually. **The disability burden exceeds the mortality burden threefold, which is unusual among the entries in this chapter.**

Geography: most cases in Africa, Asia and Latin America. **Asia has up to 2 million envenomings a year. Africa has an estimated 435,000 to 580,000 bites a year that need treatment. The highest burden falls where health systems are weakest**.

Most affected: agricultural workers, children, women, and farmers in poor rural communities in low- and middle-income countries. **Children often suffer more severe effects**.

**The WHO 2030 target is a 50 per cent reduction in snakebite envenoming mortality and disability**, pursued through four objectives — empowering communities, ensuring safe and effective treatment, strengthening health systems, and increasing partnerships and resources. Snakebite envenoming was added to the WHO list of neglected tropical diseases in 2017, which is the institutional marker of how long it was absent from the global health agenda.

**Where it starts. Agricultural work.** Barefoot or sandalled work in fields, especially planting and harvesting, and especially in the rainy season. The exposure is occupational and it is unavoidable for the people who have it. **Walking at night without a light. Sleeping on the floor**, the dominant mechanism for bites by nocturnal species that enter dwellings, and the reason bed nets have an effect. **Children**, who have smaller body mass for a given envenoming and whom WHO states often suffer more severe effects. **Housing** — thatch, mud walls, stored grain and rodent presence, which attract snakes. **Monsoon and flooding**, which displace snakes into human dwellings and produce seasonal peaks. **Distance from a facility holding antivenom**, which is the determinant of outcome rather than of risk. **No effect sizes are given for any risk factor on the WHO page**.

What is not known is the true numbers. **The ranges WHO publishes are very wide — envenomings 1.8 to 2.7 million, deaths 81,410 to 137,880, a 1.7-fold span on mortality**† — because most deaths occur at home in rural areas without registration, and because many bitten people go to traditional healers and are never recorded. India's community-based mortality surveys have repeatedly found snakebite deaths an order of magnitude above official hospital-based figures, which is the best illustration available of how the under-ascertainment works. **The species distribution responsible for the burden is also incompletely mapped in much of Africa**, which matters directly because antivenoms are species- and region-specific.

**Cure status.** Systemic envenoming: CURABLE with antivenom. **Antivenom works and it works dramatically.** Neurotoxic envenoming with respiratory paralysis reverses — a patient being hand-ventilated regains breathing. Haemotoxic envenoming with incoagulable blood corrects. The effect is one of the clearest in medicine, and **it is time-dependent**: the earlier the antivenom, the more of the envenoming is reversible. Tissue already destroyed: RELIEF ONLY. Local necrosis, compartment syndrome and the limb loss that follows are established before or despite treatment, and **the amputations and permanent disabilities at three times the death rate are the measure of it.**

**And the first classification is conditional on a supply that is failing.** WHO's own account is that antivenom availability has declined or disappeared in some areas, that manufacturers have left the market, and that **many believe antivenom supply failure is imminent in Africa and parts of Asia**. **A condition is only curable if the cure exists where the patients are**, and for snakebite that is increasingly not the case.

**Prevention.** - **Footwear — STRONG on mechanism, unquantified.** Boots or closed shoes for field work. **No effect size is given on the WHO page** and none was located. **Cost: a pair of boots.** The intervention is obvious, cheap and almost completely unstudied, which is itself a finding. - **Sleeping on a raised bed, and using a bed net tucked in — MOD-**

**ERATE.** The bed net, distributed for malaria, is also a snakebite intervention for nocturnal species that enter dwellings. A rare case of one cheap item serving two unrelated conditions. - **A torch or lamp when walking at night — MODERATE** on mechanism, unquantified. - **Clearing vegetation and rubble around dwellings; controlling rodents; storing grain away from living space — MODERATE.** It removes what attracts snakes. - **Not reaching into holes, under rocks or into grain stores without looking; using a stick ahead on paths — MODERATE.** - **Community education.** WHO's first strategic objective is empowering communities, which in practice means teaching avoidance, correct first aid, and the necessity of going to a facility rather than a traditional healer. Unquantified. - **Occupational measures** — protective clothing and timing of fieldwork. - **WHO gives no effect size for any preventive measure**. For a condition with up to 137,880 annual deaths, the entire prevention evidence base is mechanism and plausibility.

**Treatment. 1. Antivenom — the treatment, and the supply problem is the entry's defining feature.** The mechanism is antibodies raised in horses or sheep against the venoms of the species of the region, which bind and neutralise circulating venom. **It must match the species or species group of the region:** an antivenom raised against Indian species does not reliably treat African envenoming. This is why antivenom is not one product and why the market fragments.

Antivenom immunoglobulin appears on the WHO Essential Medicines List under sera and immunoglobulins, and the snake-specific wording was not visible in the sections reachable. It is off-patent: these are biological products whose constraint is manufacturing capacity and venom supply, not patent. **WHO states that the price of some antivenom products has dramatically increased in the last 20 years, making treatment unaffordable for most people who need it, and gives no price figure**. Published figures for a full treatment course in sub-Saharan Africa have been reported in the range of tens to several hundred US dollars, often many times a household's monthly income, and **no figure is asserted here**.

Adverse reactions — early anaphylactoid reactions and late serum sickness — are common and manageable with adrenaline and antihistamines, and the fear of them is one reason antivenom is withheld. **Adrenaline must be drawn up before antivenom is given**, which is a procedural rule with a fatal failure mode.

The supply problems, in WHO's own terms: - **Very few countries can produce snake venoms of adequate quality for antivenom manufacture, and many manufacturers rely on common commercial sources.** - **Low demand has led several manufacturers to stop production.** - **Antivenom availability has declined or disappeared in some areas.** - **Inappropriate, untested or fake products have undermined confidence in antivenom therapy.** This is the mechanism of market collapse: ineffective products are sold, clinicians observe that antivenom does not work, demand falls further, and manufacturers exit. - **Many believe antivenom supply failure is imminent in Africa and parts of Asia.**

**2. Airway management and mechanical ventilation** for neurotoxic envenoming with respiratory paralysis. **This is life-saving independent of antivenom** — a paralysed patient who is ventilated survives until the venom is cleared or neutralised, and **hand ventilation with a bag and mask has sustained patients for hours in field reports**.

**3. Supportive care** — intravenous fluids, transfusion and blood products for coagulopathy, renal replacement therapy for acute kidney injury, which is a major cause of death and of long-term morbidity after some envenomings, and management of shock.

**4. Wound care, debridement and fasciotomy** where indicated for compartment syndrome — with the caveat that fasciotomy is over-performed and should follow measured compartment pressures and correction of coagulopathy rather than clinical impression alone.

**5. Tetanus prophylaxis.** A bite is a tetanus-prone wound. EML-listed, off-patent, cents.

**6. Antibiotics only for established infection**, not prophylactically.

**7. Analgesia** — paracetamol and opioids. **Non-steroidal anti-inflammatory drugs are avoided** in haemotoxic envenoming because of the bleeding risk.

**8. Rehabilitation, prosthetics and physiotherapy** for the survivors with tissue loss — the group three times larger than the dead.

**9. Psychological support.** Post-traumatic symptoms after snakebite are documented and untreated.

**Simple means.** - **Reassure, immobilise, and transport. The whole of correct first aid.** Keep the patient calm and still, immobilise the bitten limb with a splint or sling in a neutral position, keep it at or below heart level, and move the patient to a facility as fast as possible. **It costs nothing.** - **Pressure immobilisation bandaging** — a broad firm bandage over the bitten limb plus a splint, for neurotoxic envenoming where transport will be prolonged. The evidence is strongest for Australian elapid bites and the technique is harder to apply correctly than it appears; **it is not recommended where local necrosis is expected**, because it concentrates the venom. - **Removing rings, bangles and tight clothing** before swelling. Free, and it prevents digital ischaemia. - **What not to do, and this is the highest-value free knowledge in the entry: no tourniquet, no cutting, no sucking, no suction devices, no electric shock, no ice, no cautery, no herbal application, no black stone, and no attempt to catch or kill the snake. Every one of these is harmful and all are widely practised.** Tight arterial tourniquets cause limb loss and contribute to the amputation figure above. **Teaching their abandonment is free and prevents disability.** - **A photograph of the snake if it is already dead, from a safe distance.** Identification guides treatment and costs nothing. **Not pursuing the snake.** - **Bag-and-mask ventilation.** The same self-inflating bag as the newborn resuscitation entry, costing tens of dollars. **A relay of family members hand-ventilating a paralysed patient is a documented practice and it keeps people alive without a ventilator and without antivenom.** For neurotoxic envenoming this is the single most valuable low-cost intervention available. - **Organised transport** — a motorcycle, a phone number, a stretcher. - **Boots, a torch, a tucked-in bed net, a raised bed, and a cleared yard** — the prevention, all of it cheap. - **Knowing which facility holds antivenom**, and going there rather than to a nearer one that does not. A piece of local information that determines survival. - **Not going to a traditional healer first.** The measured determinant is the interval to antivenom, and the detour is the commonest cause of its loss.

The minimum chain: a splint, calm, and transport as first aid; a bag and mask to sustain a paralysed patient; and antivenom, for which there is no substitute and whose supply is failing.

**Gaps.** The ranges are very wide — envenomings 1.8 to 2.7 million and deaths 81,410 to 137,880, a 1.7-fold span — because deaths occur at home and are not registered, and community surveys find figures an order of magnitude above hospital-based ones. **WHO gives no price for antivenom** while stating that prices have risen dramatically and that treatment is unaffordable for most who need it, so the central economic fact of the entry is unquantified. **WHO gives no effect size for any preventive measure:** footwear, torches and bed nets are recommended on mechanism alone, and for a condition of this size the prevention evidence base is essentially empty, which is a research gap rather than an evidential ambiguity. Antivenom supply failure is described as imminent in Africa and parts of Asia and is not quantified, with no figures for manufacturing capacity, market size or the number of facilities holding stock. Fake and untested products have undermined confidence and their market share is unquantified. The species distribution driving the burden is incompletely mapped in much of Africa, which directly limits antivenom development and procurement. The disability burden has no breakdown by type, limb or cause — venom necrosis against tourniquet against fasciotomy — so the preventable iatrogenic share is unknown. Pressure immobilisation bandaging's evidence is largely Australian and its applicability to African and Asian envenoming with local necrosis is contested. No cost-effectiveness analysis of antivenom provision was located, for a condition with a WHO 2030 target attached, and that target has no published baseline year on the fact sheet.

---

### Traumatic brain injury

**What it is.** A blow or jolt to the head damages the brain. The injury at the moment of impact is one thing; the swelling, bleeding and oxygen starvation over the following hours is another, and that second part is what treatment addresses. Most are mild and recover; the severe ones kill or disable permanently.

**Measured. No global annual incidence figure, no global death count and no global DALY figure were located.** The condition is described as a leading cause of death and disability around the globe without a number. Every quantified figure below is from a single high-income country or region.

United States: about **2 million people have a traumatic brain injury each year**, with roughly **675,000 emergency department visits and 500,000 hospitalisations**†.

Yearly incidence per 100,000: **180 to 250 in the United States; 281 in France; 361 in South Africa; 322 in Australia; 430 in England**†. **The European aggregate incidence of hospitalisations and fatalities is 235 per 100,000**†. **Mild traumatic brain injury incidence may be 100 to 600 per 100,000 a year**†.

**Global incidence is rising, largely because of motor vehicle use in low- and middle-income countries**. Case fatality: **about 21 per cent by 30 days in the United States**†. Severe injury mortality in Iraq War soldiers was 30 to 50 per cent†. **The fraction of hospitalised patients who died fell from almost half in the 1970s to about a quarter in the early 2000s**†.

---

Severity split: a WHO study estimated **70 to 90 per cent of treated head injuries are mild**, and a United States study found moderate and severe injuries each make up 10 per cent with the rest mild.

Causes: in the United States the most common are violence, transportation accidents, construction mishaps and sports. **Falls are the leading cause in children aged 2 to 4**, with traffic accidents competing in older children†. **Abuse causes 19 per cent of paediatric brain trauma cases**†. Data for 2021 to 2025 show people aged 75 and over had the most deaths and hospitalisations†.

---

Sex: **men have about twice the rate of women and a four-fold risk of fatal head injury**. **Traumatic brain injury causes more years of disability in Europe than any other cause** — a statement of relative burden without a figure.

**Where it starts.** Falls, the leading cause in young children and in people over 75. Road traffic injury, with the rising global incidence attributed to motor vehicle growth in low- and middle-income countries. Violence, including firearms. **Child abuse, at 19 per cent of paediatric brain trauma**†. Sport and recreation; occupational injury including construction; military blast exposure. Male sex, at about twice the

---

A great deal is not known, and the gaps are consequential. - **Why no treatment for the primary injury has succeeded.** Dozens of neuroprotective agents have reached phase III and failed. The primary injury is mechanical and immediate; the secondary cascade is understood in outline and has not proved druggable. - **The relationship between repeated mild injury and chronic traumatic encephalopa-**

**Cure status.** Mild injury: SELF-LIMITING. **Most mild traumatic brain injury resolves within three weeks**. **Permanent disability is estimated at 10 per cent for mild injuries**, so a tenth do not, and nothing identifies them in advance. Moderate and severe injury, for the established injury: RELIEF ONLY. **Permanent disability is estimated at 66 per cent for moderate and 100 per cent for severe**

What mitigation achieves is nonetheless large and measurable: **the fraction of hospitalised patients who died fell from almost half in the 1970s to about a quarter in the early 2000s**†, achieved by intensive care, surgery and systematised trauma management rather than by any treatment for the brain itself.

Recovery continues longer than is often assumed: **neurological improvement usually continues for two or more years after injury**. **Over 90 per cent of people with moderate injury live independently, and most people with severe closed head injury either die or regain independent living** — a bimodal outcome. Coma is a strong predictor of poor outcome, and sub-arach-

———

**Prevention.** Prevention of traumatic brain injury is prevention of its causes, and the effect sizes come from the road traffic injury and falls entries. - **Helmets — STRONG. Correct helmet use reduces the risk of death in a crash by more than 6 times and the risk of brain injury by up to 74 per cent. The source consulted for this entry gives no quantified effect sizes for helmets or seat belts**, noting

**Treatment.** The single largest positive drug result is confined to a subgroup, and several once-standard treatments are now known to be harmful.

———

**1. Tranexamic acid within 3 hours — effective in mild-to-moderate injury, null overall.** The CRASH-3 trial randomised **12,737 patients** at 175 hospitals in 29 countries, recruiting from July 2012 to January 2019, with **9,127 analysed within 3 hours of injury** — 4,613 on tranexamic acid and 4,514 on placebo.
- **Primary outcome, 28-day in-hospital head-injury death, treated within 3 hours: 18.5 per cent against 19.8**

**The honest summary: CRASH-3 was null on its primary outcome and positive in a prespecified mild-to-moderate subgroup, with the trial's own summary noting the subgroup result may be a false positive.** That is a weaker result than CRASH-2 in general trauma, where the all-cause mortality effect was significant at a relative risk of 0.91 (0.85 to 0.97)†. Tranexamic acid is EML-listed, off-patent, **a few US dollars a**

---

**2. Prevention of secondary injury — the core of management.** Maintaining oxygenation and blood pressure, avoiding hypoxia and hypotension, each of which independently worsens outcome, controlling intracranial pressure, maintaining cerebral perfusion pressure, and treating fever and seizures. **These are process measures rather than products, and they carry most of the**

**3. Surgical evacuation of an extradural or subdural haematoma. Time-critical and definitively life-saving** — an extradural haematoma evacuated early produces full recovery, and left alone it kills a patient whose brain was otherwise undamaged. **This is the clearest curative surgical intervention in the entry.** It requires neurosurgical capacity, or in its absence a trained general surgeon performing burr-

**4. Osmotic therapy — hypertonic saline or mannitol**, which appear similarly effective for intracranial pressure. Mannitol is EML-listed, off-patent, cheap.

**5. Decompressive craniectomy — CONTESTED.** Primary decompressive craniectomy is performed routinely during haematoma surgery. Secondary decompressive craniectomy, done for persistently raised intracranial pressure, lowers the pressure and shortens intensive care stay. **Compared with standard medical therapy, however, it is associated with worse Glasgow Coma Scale scores and higher rates**

**6. Seizure prophylaxis and treatment** — phenytoin or levetiracetam for early post-traumatic seizures. EML-listed, off-patent, cheap.

**7. Negative and harmful results, reported as such because they were once standard.** - **Corticosteroids are linked to higher death risk and are not recommended.** The CRASH trial of methylprednisolone in head injury, reported in **2004, found increased mortality** and ended decades of routine use. A definitive and important negative. - **Hypothermia** is not discussed on the source consulted, which notes only that body

**8. Rehabilitation** — physical, occupational, speech, cognitive and behavioural. Neurological improvement usually continues for two or more years, so rehabilitation has a long window. This is where most of the function is recovered and where provision is thinnest.

**Simple means.** - **A helmet. Up to 74 per cent reduction in brain injury risk and more than 6-fold reduction in death risk**. **This is the single highest-value item in the entry and in much of this chapter** — a manufactured object costing tens of dollars, requiring no infrastructure. - **A seat belt and a child restraint.** - **The recovery position**, for the unconscious breathing casualty.

---

The minimum chain: a helmet for prevention, a sidelying position and a clear airway for first aid, and a written list of warning signs on discharge. For the haematoma, surgery, with no substitute — and burr-hole drainage by a trained general surgeon is the low-resource form of it.

**Gaps.** **There is no global incidence figure, no global death count and no global DALY figure**, for a condition described as a leading cause of death and disability worldwide; **this is the largest data gap in this chapter**, and every quantified figure above is from a single high-income country or region. The source consulted gives no helmet or seat belt effect sizes, and those come from WHO. CRASH-3 was null on its

## Spinal cord injury

**What it is.** The spinal cord is damaged, so signals no longer pass between the brain and the body below the injury. Movement and sensation are lost below that level, and so is control of the bladder and bowel. The cord does not regenerate.

**Measured.** Prevalence: about **15.4 million people living with spinal cord injury in 2021**, which the key facts round to over 15 million. Disability burden: **over 4.5 million years lived with disability in 2021**.

**Annual incidence: not reported** on the WHO fact sheet. No global incidence figure was located, in the current or the prior round.

Males are more often affected, with consistently higher prevalence and years lived with disability, and **no ratio is given**.

Causes are ranked by WHO without percentage shares: traumatic causes lead, in the order **falls and road traffic injuries, then violence including self-harm and attempted suicide, then work- or sports-related injuries. Non-traumatic causes — tumours, degenerative and vascular conditions — are increasing, especially in ageing populations.**

Mortality is highest in the first year after injury and remains elevated relative to the general population. **In-hospital mortality is nearly three times higher in low- and middle-income countries than in high-income countries**. **This three-fold figure is the central measured inequality of the entry.**

**Life expectancy is not quantified.** WHO states it correlates strongly with neurological impairment and with **preventable secondary conditions** — and preventable is the operative word, because those are what kill.

**Economic costs: no monetary figures.** WHO states that global estimates are limited by data, that indirect costs such as lost earnings often exceed direct costs, and that direct costs peak in the first year.

**Adults with spinal cord injury face unemployment rates above 60 per cent. Children with spinal cord injury are less likely to start school and less likely to advance once enrolled**.

**Wheelchair access: globally, only 5 to 35 per cent of people who need wheelchairs have access**. **This single figure determines more of the burden than any clinical variable.**

**Where it starts.** WHO's ranking, without shares: falls, with the older-person low-energy fall onto a degenerative cervical spine an increasing mechanism; road traffic injuries; violence, including self-harm; and work- and sports-related injuries — diving into shallow water, rugby and other collision sport, horse riding, falls from height at work. Non-traumatic causes are increasing, especially in ageing populations, and include tuberculosis of the spine, which is a major non-traumatic cause in high-burden settings and is treatable. Male sex, alcohol, and the absence of protective measures — window guards, fall protection at work, helmets, seat belts — complete the picture. **WHO gives no figures for any risk factor**.

Three things are not known. The annual incidence globally: WHO does not report it. The shares attributable to each cause, so the targeting of prevention cannot be quantified. And the fundamental one: **why the mammalian central nervous system does not regenerate axons across a cord lesion.** Decades of work have produced an understanding of the inhibitory environment of the glial scar and no clinical treatment. **Every announced cure for spinal cord injury over fifty years has failed to replicate**, and that record should temper any statement about imminent regenerative therapy.

**Cure status.** RELIEF ONLY. The cord does not regenerate and no treatment restores function below the lesion. This is unambiguous and must be stated without hedging. Surgical decompression and stabilisation prevent further damage and allow mobilisation; they do not restore lost function. **Methylprednisolone**, given for decades on the basis of the NASCIS trials, has been withdrawn from most guidelines because the benefit was a post-hoc subgroup finding and the harms — infection, pneumonia, gastrointestinal bleeding — were real. **No pharmacological neuroprotective or regenerative treatment has succeeded.** Cell

transplantation, epidural stimulation and brain-computer interfaces are research interventions with early-phase findings and no established clinical benefit.

**What relief achieves is nevertheless the whole of the entry's value, and it is large.** WHO's own framing says it: life expectancy correlates with **preventable secondary conditions**. **People with spinal cord injury die of pressure ulcers, urinary sepsis, respiratory infection and venous thromboembolism — all preventable with care that requires almost nothing manufactured.** The three-fold in-hospital mortality difference between low- and high-income countries is not a difference in the cord injury; **it is a difference in nursing, catheter care and turning.** And the 5-to-35-per-cent wheelchair access figure determines whether the person lives in a bed or in a community.

So the injury is RELIEF ONLY and the mortality is largely preventable. Those two statements are not in tension and both must be made.

**Prevention. WHO names these interventions and gives no figures for any of them**. The gradings draw on the effect sizes established in the road traffic injury and falls entries. - **Road infrastructure and vehicle improvements — STRONG** (WHO names them). The underlying effect sizes are speed management, seat belts at up to 50 per cent reduction in occupant death, and helmets at more than 6-fold reduction in death risk. - **Window guards — STRONG** (WHO names them specifically). Tens of dollars. - **Alcohol policies — MODERATE** (WHO names them). - **Firearm access controls — STRONG** for the violence share (WHO names them), on the means-restriction principle. - **Violence and suicide prevention — MODERATE** (WHO names them). - **Fall prevention in older people — STRONG** — exercise and balance training, psychotropic drug withdrawal, home modification. **With the ageing-population shift above, this is the growing preventive frontier for spinal cord injury.** - **Fall protection at work — harnesses, guard rails, scaffold standards — MODERATE.** - **Not diving into water of unknown depth — a rule, free, and it addresses a recognised cause in young men.** - **Sports rule changes.** The banning of the spear tackle in rugby and of head-first tackling in American football followed measured clusters of cervical cord injury and were followed by measured reductions. - **Treating spinal tuberculosis early — STRONG** for that non-traumatic cause, with cheap EML-listed drugs. - **Prehospital spinal immobilisation — CONTESTED.** Long assumed essential, it is now recognised to carry harms — pressure injury, airway compromise, raised intracranial pressure, delay — and the evidence that rigid collars and backboards prevent secondary cord injury is weak. Current practice has moved toward **minimal handling and manual in-line stabilisation** rather than routine rigid immobilisation. Reported as contested because it is.

**Treatment.** The most valuable items are nursing and bladder care, not surgery or drugs.

**1. Prevention of secondary conditions. This is first because it determines survival**, and because WHO identifies preventable secondary conditions as the determinant of life expectancy. - **Pressure ulcer prevention — turning every 2 to 3 hours, pressure-relieving surfaces, skin inspection, nutrition.** A pressure ulcer over the sacrum or ischium progresses to osteomyelitis and sepsis and is a leading cause of death. **It is prevented by turning a patient, which is labour.** - **Bladder management — clean intermittent catheterisation. Urinary sepsis and renal failure were historically the leading cause of death in spinal cord injury, and intermittent catheterisation is what changed that.** Reusable catheters, clean water and soap. - **Bowel management** — a scheduled programme with diet, fluid, suppositories and digital stimulation. - **Respiratory care** — assisted coughing, positioning, breathing exercises. Pneumonia is a leading cause of death in cervical injury. - **Venous thromboembolism prophylaxis** — low molecular weight heparin, early mobilisation, compression. - **Nutrition.**

**2. Surgical decompression and stabilisation.** Early decompression within 24 hours is associated with better neurological outcomes in prospective cohort evidence, and the randomised evidence is limited. Stabilisation permits early mobilisation, which is what prevents the complications above. **It does not restore lost function.**

**3. Maintaining spinal cord perfusion** — avoiding hypotension, managing neurogenic shock, and treating **autonomic dysreflexia**, which is a hypertensive emergency triggered by a blocked catheter or an impacted bowel in injuries above T6 and which kills if not recognised. **Recognising it and removing the trigger is free and life-saving.**

**4. Rehabilitation — the principal treatment.** Physiotherapy, occupational therapy, transfer and wheelchair skills, functional electrical stimulation where available, and training for independent living. **This is the intervention with the largest effect on outcome and it is labour and time rather than technology.**

**5. Spasticity management** — baclofen, EML-listed, off-patent, cents; physiotherapy; positioning; and botulinum toxin and intrathecal baclofen in specialist settings.

**6. Neuropathic pain management** — amitriptyline, gabapentin or carbamazepine. Amitriptyline and carbamazepine are EML-listed, off-patent, cents a day. Neuropathic pain after spinal cord injury is common, severe and undertreated.

**7. Bladder and bowel surgery, sexual and fertility care, and management of heterotopic ossification and syringomyelia** as they arise.

**8. Assistive technology — wheelchairs, cushions, transfer boards, orthoses. With 5 to 35 per cent access globally, this is the largest unmet need in the entry**. A badly fitted wheelchair with no pressure-relieving cushion causes the ulcer that causes the death, so provision must include fitting and a cushion.

**9. Methylprednisolone — not recommended.** Withdrawn from most guidelines: the NASCIS benefit was a post-hoc subgroup finding and the harms were real. Reported because it was standard for twenty years.

**Simple means.** This entry is, in practice, almost entirely simple means — which is why the three-fold mortality difference between rich and poor settings is so damning. - **Turning the patient every two to three hours, and inspecting the skin. The single highest-value act in the entry.** It prevents the pressure ulcer that causes the sepsis that causes the death. It requires hands, a clock and a willing family member, and it can be taught in one session. **A pressure-relieving mattress can be improvised from foam, and sheepskin, cushions and folded blankets are used to offload bony prominences.** - **Clean intermittent catheterisation, taught to the patient or family.** Reusable catheters washed with soap and water. **This is what converted spinal cord injury from a condition that killed by renal failure into one in which people live for decades**, and it is improvisable to a degree that long-term indwelling catheters are not — indwelling catheters cause more infection and more stones. - **A bowel programme** — timing, fluid, fibre, and digital stimulation. No equipment. - **Assisted coughing** — a carer's hands on the abdomen timed with the patient's effort. It prevents pneumonia in cervical injury. Free. - **Positioning, passive range-of-movement exercises and splinting** to prevent contractures, taught to the family and done daily. Free, and it determines whether a hand can be used. - **Recognising autonomic dysreflexia** — sudden severe headache and very high blood pressure in an injury above T6 — **and the response: sit the person up, loosen clothing, check the catheter for a blockage, check for a loaded bowel. Free knowledge that prevents a stroke.** - **A locally made wheelchair, with a pressure-relieving cushion.** Appropriate-technology wheelchairs built for rough ground from local materials, with the WHO wheelchair provision guidelines specifying fitting and a cushion as part of provision. **Tens to low hundreds of dollars against thousands for imported designs**. A cushion improvised from foam is better than no cushion. - **A transfer board, a rope ladder on the bed, a grab rail** — plywood and rope. - **Manual in-line stabilisation and minimal handling at the scene**, rather than rough transfer. Free, and the rigid-collar question is contested. - **Drinking enough fluid**, which reduces stones and infection. - **Peer support, and return to school and work.** With unemployment above 60 per cent and children less likely to start school, these are the measured outcomes, and inclusion is a decision rather than a resource. - **Family training.** Everything above is deliverable by a trained family member, and in most of the world it has to be.

The minimum chain: **hands to turn the patient, a reusable catheter, soap and water, and a cushion.** That list is the difference between dying within a year and living for decades, and it contains nothing that cannot be had.

**Gaps.** WHO reports no annual incidence figure: prevalence and years lived with disability are given and incidence is not, and no global incidence estimate exists in any source reached. WHO gives no percentage shares for any cause, only a ranking, so prevention cannot be targeted quantitatively. WHO gives no effect size for any preventive measure, despite naming road infrastructure, window guards, alcohol policy, firearm controls, and violence and suicide

prevention. There are no monetary cost figures at all, with WHO stating global estimates are limited by data. Life expectancy is not quantified, only described as correlating with impairment and preventable secondary conditions. **The wheelchair access figure spans 5 to 35 per cent — a seven-fold range, which is the measure of how poorly provision is counted.** Prehospital rigid immobilisation is contested and long-standing practice is not supported by good evidence either way. No pharmacological treatment works, and methylprednisolone was standard for twenty years on a post-hoc subgroup finding. Early surgical decompression rests largely on prospective cohort rather than randomised evidence. The three-fold in-hospital mortality difference between low- and high-income countries is reported and not decomposed: how much is nursing, how much surgery and how much intensive care is not established. Non-traumatic spinal cord injury is increasing and is not separately quantified anywhere located.

---

## Fractures

**What it is.** A bone breaks. If the skin stays intact it is closed; if the bone or the wound communicates with the outside it is open, and then infection is the main danger. Most fractures heal if the ends are held in reasonable position for long enough.

**Measured. 440 million prevalent fractures and 26 million years lived with disability**, both on the 2019 burden study. **No global annual incidence figure and no deaths figure** specific to fractures were located. GBD reports injury burden by external cause rather than by lesion, so the mortality attaches to falls at 74.3 million DALYs and road injuries at 75.3 million DALYs rather than to fracture.

Traumatic amputation, as a related lesion: **180 million prevalent and 5.5 million years lived with disability** on the 2019 study.

The dominant causes are falls and road traffic injury, and the fragility-fracture burden in older people is covered in the falls entry.

**Open fracture care is one of the three Bellwether procedures**, alongside laparotomy and caesarean section — which is the clearest institutional statement of this lesion's importance: the capacity to manage an open fracture is treated as part of the irreducible minimum of surgical care.

The burden follows road traffic injury, where 92 per cent of deaths are in low- and middle-income countries, and falls, where over 80 per cent are.

**Where it starts.** Mechanical force exceeding bone strength, by two routes: **high-energy trauma on normal bone** — road crashes, falls from height, violence, crush — and **low-energy force on weak bone**, the fragility route.

Osteoporosis and low bone density dominate in older people and in women after the menopause. Age at both extremes matters: children's bones fail differently, with greenstick, buckle and physeal injuries, and older people's fail at low energy. Previous fracture is among the strongest predictors of the next. Falls and road traffic injury are the proximate causes, with occupational and sporting exposure behind them. **Pathological fracture** occurs through bone weakened by tumour, metastasis, infection, or metabolic bone disease including rickets and osteomalacia, the last nutritional and preventable with vitamin D. Stress fracture follows repetitive loading. Osteogenesis imperfecta and other genetic bone fragility account for a small share with very different management. **Malnutrition and vitamin D deficiency** produce rickets in children, with deformity and fracture, **and it is preventable for cents.** No effect sizes beyond those in the falls entry were located.

What is not known is the global incidence. GBD's structure gives prevalence and years lived with disability for fracture as a lesion and no incidence, and the cause-level accounting means a fracture's mortality is counted against the fall or the crash. **What proportion of the 440 million prevalent fractures were adequately treated is not known and not estimated anywhere located** — which is the number that would size the global orthopaedic gap. Also unresolved: optimal management for many specific fractures, where operative and non-operative treatment have been compared with surprising results.

**Cure status.** CURABLE. Fractures heal, and this is one of the most reliable cures in medicine. Bone is one of the few tissues that repairs itself with original tissue rather than scar. Held in

reasonable alignment and given time, a fracture unites and the limb works. **The treatment requirement is reduction and immobilisation, not restoration** — the body does the healing.

The qualifications, each real: - **Open fractures** carry infection risk, and an infected non-union is a limb-threatening and sometimes life-threatening problem requiring prolonged treatment. Early debridement, antibiotics and skeletal stabilisation are what prevent it, and this is why open fracture care is a Bellwether procedure. - **Non-union and malunion** occur in a minority and need further surgery. - **Intra-articular fractures** that heal with an irregular joint surface produce post-traumatic osteoarthritis — CONTROLLABLE, not cured. - **The hip fracture in an older person is cured as a fracture and frequently not survived as an event.** - **Growth plate injuries in children** can cause progressive deformity as the child grows. - **Compartment syndrome and neurovascular injury** cause permanent loss if missed.

So the lesion is CURABLE, and the common failures are infection, missed compartment syndrome, and the frailty of the patient rather than the behaviour of the bone.

**Prevention.** - **Everything in the road traffic injury entry — STRONG**, with the measured effect sizes: speed management at 1 per cent mean speed for 4 per cent fatal crash risk, helmets at more than 6-fold death reduction, seat belts at up to 50 per cent, child restraints at 71 per cent. - **Everything in the falls entry — STRONG**: exercise and balance training, psychotropic drug withdrawal, home modification, window guards, playground surfacing, workplace fall protection. - **Bisphosphonates in osteoporosis — STRONG. Reductions in vertebral fracture of the order of 40 to 70 per cent and hip fracture 40 to 50 per cent** in the pivotal trials in women with osteoporosis; those figures are from the trial literature and were not verified. **Alendronate is not on the WHO Essential Medicines List at all, and no bisphosphonate is listed for osteoporosis**. Off-patent, a few US dollars a month. - **Calcium and vitamin D in the deficient — MODERATE.** - **Vitamin D for rickets prevention — STRONG.** Cents a dose, EML-listed, and it prevents the deformity and fracture of nutritional rickets outright. - **Fracture liaison services — MODERATE.** Systematically starting osteoporosis treatment after a first fragility fracture. **Treatment rates after a first fracture are low everywhere** and this is the identified gap. - **Hip protectors — CONTESTED.** - **Smoking cessation and reducing alcohol — MODERATE** for bone density and for fall risk. - **Occupational safety regulation — MODERATE.** - **Protective equipment in sport — MODERATE.**

**Treatment. 1. For open fractures: early debridement, irrigation, antibiotics and skeletal stabilisation. This is the time-critical sequence and it is what prevents the infection that threatens the limb.** - **Antibiotics as early as possible** — a first-generation cephalosporin or equivalent, and **the evidence favours early administration over any particular agent.** EML-listed, off-patent, cheap. - **Tetanus prophylaxis.** EML-listed, off-patent, cents. - **Debridement of dead tissue and foreign material**, repeated as needed. - **Stabilisation** — external or internal fixation depending on contamination and soft tissue. - **Soft tissue cover** — flaps for exposed bone. - **This is a Bellwether procedure**.

**2. Reduction and immobilisation for closed fractures.** - **Closed reduction and casting or splinting** for the majority. **Plaster of Paris and a trained pair of hands.** - **Traction** for selected femoral fractures, especially in children; Perkins and gallows traction are standing low-resource techniques. - **Internal fixation** — plates, screws, intramedullary nails — where it gives better function or earlier mobilisation. **The implant is the cost and the constraint.** The SIGN intramedullary nail is specifically relevant: a nail system designed for use without an image intensifier, supplied free to surgeons in low- and middle-income countries, with a large published series. **An implant designed around the absence of the equipment the standard technique requires.** - **Arthroplasty** for displaced intracapsular hip fractures in older people.

**3. Analgesia.** Paracetamol, non-steroidal anti-inflammatory drugs, opioids. **Regional nerve blocks** — a femoral or fascia iliaca block for a hip or femoral fracture — give excellent analgesia with cheap local anaesthetic and a needle, and reduce opioid need. Lidocaine and bupivacaine are EML-listed, off-patent, cents.

**4. Early mobilisation and physiotherapy.** It determines function, and it is labour.

**5. Treatment of the underlying bone disease** — osteoporosis, vitamin D deficiency, tumour.

**6. Important instances where operative and non-operative treatment proved equivalent**, reported because they bear on what is actually needed. - **Displaced distal radius fractures in older people:** several trials have found no functional advantage of fixation over cast treatment at one year. - **Many clavicle, humeral shaft and proximal humerus fractures:** trials and meta-analyses have found non-operative management equivalent in function for large subgroups. - **Tibial shaft and ankle fractures in defined groups** have similar findings. - **The general direction of the evidence is that fixation is used more widely than its demonstrated advantage supports**, which is relevant for settings where implants are unaffordable: **cast treatment is often not a compromise.**

**7. Compartment pressure measurement and fasciotomy** where compartment syndrome is suspected. Time-critical, and missed compartment syndrome causes permanent loss.

**8. Amputation** where the limb is unsalvageable, followed by prosthetic rehabilitation.

**Simple means.** This entry is rich in them, and several are also the best treatment. - **Splinting with whatever is at hand.** A board, a rolled newspaper or magazine, a padded stick, a folded blanket, cardboard, or the opposite limb bound to the injured one. **Immobilising a fracture before transport reduces pain, bleeding and further soft tissue damage.** Free, and it is the single most useful first aid act for a fracture. - **Plaster of Paris.** Rolls of plaster bandage and water — **a few US dollars of material** — and a trained pair of hands cure the large majority of fractures. **This is the same material as the Ponseti method**, and it is the backbone of orthopaedic care everywhere that implants are unaffordable. The equivalence evidence above means this is frequently not a second-best choice. - **A sling and a broad arm bandage.** - **Traction improvised with weights and a frame** — a standing technique for femoral fractures in children and adults where fixation is unavailable. - **Direct pressure and a dressing for the bleeding open fracture; covering the wound with a clean dressing and not probing it.** - **A tourniquet for catastrophic limb haemorrhage.** Commercial windlass tourniquets cost tens of dollars; a cloth and a stick costs nothing. - **Elevation and ice** for swelling. - **Checking the pulse, sensation and movement distal to the fracture, before and after splinting**, and loosening anything that compromises them. **This free examination detects the neurovascular injury and the developing compartment syndrome**, which are the catastrophic missable complications. - **Nerve blocks with cheap local anaesthetic** — a syringe, a needle and a vial. Transformative analgesia for a hip fracture at almost no cost. - **Early mobilisation and walking the patient** — labour, and the determinant of recovered function, especially after a hip fracture. - **Locally made crutches, sticks and walking frames** from wood. - **Clinical diagnosis without radiography.** Many fractures are diagnosed and managed adequately on examination where no X-ray exists, and the Ottawa ankle and knee rules are decision tools on a card that safely reduce the need for imaging. - **Vitamin D for rickets** — cents. - **Turning and skin care** for the immobilised patient.

The minimum chain: **plaster, water, a splint and trained hands.** For the open fracture, antibiotics, debridement and stabilisation — the Bellwether requirement, with no substitute.

**Gaps.** There is no global annual incidence figure and no deaths figure for fractures as a lesion; GBD's structure attributes mortality to the external cause, and the available figures of 440 million prevalent and 26 million years lived with disability are both from the **2019** burden study rather than 2023. **What proportion of the 440 million prevalent fractures received adequate treatment is not known or estimated anywhere located**, and that is the number that would size the global orthopaedic gap. The bisphosphonate effect sizes are from the trial literature and were not verified. The operative-against-non-operative equivalence findings are specific to defined fracture patterns and populations and are frequently over-generalised in both directions; they are printed because they bear directly on what low-resource settings need, and they should not be read as a general argument against fixation. Osteoporosis treatment rates after a first fragility fracture are low everywhere and the size of that gap is unquantified. Open fracture infection rates by setting are not globally reported, so the consequence of the Bellwether gap is not measured. Implant availability and cost in low- and middle-income settings are not quantified in any source reached, despite being the binding constraint. No cost or cost-effectiveness figures for fracture care were located

beyond the Lancet Commission framing. The SIGN nail programme's published series is large and is not a randomised comparison.

---

## Open wounds

**What it is.** The skin is cut, torn or punctured so that the tissue underneath is exposed. Bleeding is the immediate danger, infection the one that follows. Most heal if cleaned, closed where appropriate, and protected.

**Measured. No global incidence figure and no deaths figure** for open wounds and lacerations were located, in the current or the prior round. GBD reports injury burden by external cause rather than by lesion, so the mortality attaches to road injuries at 75.3 million DALYs, falls at 74.3 million, interpersonal violence at 30.2 million and animal contact.

**Oro-dental trauma: about 1 billion people affected** — the only billion-scale lesion figure in the chapter, and it includes wounds to the mouth and lips.

Two open-wound consequences are counted: **neonatal tetanus, 7,700 deaths in 2021, down 84 per cent from 46,898 in 2000**; and **rabies, 15,800 deaths in 2023** on GBD against **44,203 in 2021** on WHO's Global Health Estimates. Non-neonatal tetanus deaths were not retrievable.

**The relevant burden figure for this entry is not a wound count but a care-access count: about 5 billion people lack access to safe, affordable surgery and anaesthesia care when needed**. Wound care is the lowest tier of that gap.

**Where it starts.** Road traffic injury, falls, interpersonal violence, occupational injury from machinery, blades and glass, animal and human bites, burns with open areas, agricultural injury, domestic injury. Crush and blast mechanisms produce wounds with far more devitalised tissue than their surface appearance suggests.

**Contamination at the moment of wounding** — soil, manure, saliva, seawater, organic material — determines infection risk far more than wound size does. **Delay to cleaning** is the single most consistent determinant of whether a wound becomes infected. Host factors raise risk: diabetes, peripheral vascular disease, malnutrition, immunosuppression, HIV, smoking, age. Absence of tetanus immunisation and a retained foreign body complete the picture. No effect sizes were located.

What is not known is the incidence. **This is among the most common lesions in human medicine and there is no global count of any kind.** Also genuinely contested: much of the standard wound-care practice. The optimal irrigation fluid, the optimal irrigation pressure, the time window beyond which a wound should not be closed primarily, the value of prophylactic antibiotics for most clean wounds, and whether tap water is as good as sterile saline — these have been studied and the answers are either no difference or insufficient evidence, which is a different situation from the risk factors being unknown.

**Cure status.** Most open wounds: CURABLE, and for most SELF-LIMITING with basic care. Skin heals. A clean wound closed or left to granulate heals, and the patient recovers completely apart from a scar. **The treatment requirement is cleaning, haemostasis and protection; the body does the repair.** Infection: CURABLE, with urgency. It converts a self-limiting wound into a condition requiring antibiotics and sometimes surgery, and in the extreme into necrotising infection or sepsis. Tetanus, from a contaminated wound in an unimmunised person: RELIEF ONLY, and frequently fatal. **A few cents of vaccine prevents it; an intensive care unit often cannot cure it.** Rabies, from an animal bite wound: RELIEF ONLY, and essentially always fatal once symptomatic. Post-exposure prophylaxis prevents it completely. Chronic wounds — in diabetes, venous disease or pressure injury: CONTROLLABLE rather than curable, and they behave as a different condition. Scarring and contracture across a joint: RELIEF ONLY without surgical release.

So the great majority of open wounds are curable with soap, water and a dressing, and the deaths come from three specific preventable complications — haemorrhage, tetanus and rabies — each of which has a cheap countermeasure.

**Prevention.** - **Prevention of the causing injury**, with the effect sizes in the road traffic injury and falls entries, plus occupational safety regulation. - **Tetanus immunisation —**

**STRONG, and it is the clearest preventive in this entry.** WHO recommends 6 doses over a lifetime, and neonatal tetanus deaths fell 84 per cent between 2000 and 2021 with immunisation scale-up. **Cents a dose, EML-listed, off-patent**. An immunised person does not get tetanus from a dirty wound. - **Rabies pre-exposure and post-exposure prophylaxis, and dog vaccination — STRONG.** - **Occupational measures** — machine guarding, gloves, eye protection, blade handling, footwear. - **Removing hazards** — broken glass, sharp fencing, exposed machinery. - **Footwear**, which prevents penetrating foot wounds, the classic tetanus route, and snakebite. - **Hand hygiene and clean technique in any procedure** that creates a wound. - **Treating the host conditions** — glycaemic control in diabetes, nutrition, smoking cessation. - **Dog population management and bite prevention education.**

**Treatment. 1. Haemorrhage control. First, because it is what kills within minutes.** - **Direct pressure** — the first and usually sufficient measure. - **A tourniquet** for catastrophic limb bleeding. **Commercial windlass tourniquets cost tens of dollars; the improvised cloth-and-stick version costs nothing.** The military and civilian evidence for prehospital tourniquets in limb exsanguination is strong. - **Wound packing and pressure** for junctional bleeding, with haemostatic dressings where available. - **Tranexamic acid** for significant traumatic haemorrhage, **within 3 hours**: all-cause mortality 14.5 against 16.0 per cent, relative risk 0.91 (0.85 to 0.97); death due to bleeding 4.9 against 5.7 per cent, relative risk 0.85 (0.76 to 0.96), over 20,211 patients in 40 countries. EML-listed, off-patent, a few US dollars a gram.

**2. Cleaning. The determinant of infection.** - **Irrigation with a large volume under moderate pressure. Potable tap water is as effective as sterile saline for cleaning most wounds** in the trial and Cochrane evidence, which is a finding of real practical consequence where saline is unavailable. - **Removal of foreign material and devitalised tissue — debridement. This is the single most important anti-infective measure, more than any antibiotic.** - **Soap and water for the surrounding skin.**

**3. Tetanus prophylaxis.** Vaccine, and tetanus immunoglobulin for high-risk wounds in inadequately immunised people. EML-listed, off-patent, cents for the vaccine.

**4. Rabies post-exposure prophylaxis for animal bites — immediate thorough wound washing with soap and water for 15 minutes**, vaccine, and rabies immunoglobulin for the most severe exposure category.

**5. Closure, where appropriate.** - **Sutures, staples, adhesive strips or tissue adhesive. Adhesive strips and tissue adhesive are equivalent to sutures for many small low-tension wounds** and need no anaesthesia and no removal visit. - **Delayed primary closure or healing by secondary intention** for contaminated wounds, bites, and wounds presenting late. **Closing a contaminated wound primarily causes the infection.** - **Local anaesthetic — lidocaine.** EML-listed, off-patent, cents a vial. Suturing without anaesthesia is a real and avoidable cruelty, and the drug costs almost nothing.

**6. Antibiotics — selectively, not routinely.** - **Prophylactic antibiotics are not indicated for most clean simple wounds.** They are indicated for bites, especially hand and cat bites, heavily contaminated wounds, open fractures, wounds with devitalised tissue, and immunocompromised or diabetic patients. - **Amoxicillin-clavulanate** is the standard for bites, and a first-generation cephalosporin for other indications. EML-listed, off-patent, cheap. - **Treating established infection**, and **recognising necrotising infection**, which requires immediate extensive surgical debridement and in which delay is lethal.

**7. Dressing and protection. Simple non-adherent dressings are as good as expensive modern dressings for most acute wounds** in the trial evidence. Moist wound healing for granulating wounds.

**8. Elevation, immobilisation and analgesia.**

**9. Skin grafting and flap coverage** for large tissue loss, and negative pressure wound therapy where available.

**10. Nutrition.** Wound healing is a metabolic demand and protein-energy support matters in large wounds.

**Simple means.** This entry is almost entirely simple means, and the treatment with the best evidence is among the simplest. - **Direct pressure with a hand and a cloth. The single highest-value act in the entry**, and it stops most bleeding. - **A tourniquet, impro-**

**vised from a cloth and a stick, or commercial.** For catastrophic limb haemorrhage it is life-saving and it is improvisable. - **Bystander haemorrhage control training.** Teaching pressure, packing and tourniquet use to lay people is a short course and a small kit. **The evidence is programme evaluation rather than randomised**, and the underlying intervention evidence for tourniquets and pressure is strong. - **Washing the wound with clean running water and soap. Tap water is as good as sterile saline** for most wounds, which removes a supply chain. - **Fifteen minutes of soap and water washing for an animal bite. This single act substantially reduces rabies risk and it is free**. - **Removing visible foreign material.** - **A clean cloth dressing**, boiled and dried where sterility matters. **Clean cotton cloth is adequate for most wounds**, and simple non-adherent dressings are as good as expensive ones. - **Elevation and immobilisation.** - **Honey as a wound dressing.** Cochrane-reviewed evidence supports it for partial-thickness burns and it is used for wounds: cheap, locally available, antibacterial, non-adherent. The evidence quality is moderate and heterogeneous. - **Leaving a contaminated wound open** rather than closing it. **The intervention is not doing something**, and it prevents the infection that closure causes. - **Adhesive strips, or clean cloth tape, for small low-tension wounds** — no needle, no anaesthetic, no removal visit. - **The recovery position and keeping the patient warm** during transport. - **Boiled water cooled, and clean containers.** - **Teaching the warning signs of infection** — spreading redness, increasing pain, pus, fever, and the pain-out-of-proportion that signals necrotising infection. **Free, and it is what brings the patient back in time.** - **Oral rehydration** for the patient with significant blood loss during transport. - **Not applying earth, dung, ash, oil or herbal preparations** — the classic tetanus route and a cause of necrotising infection. **A conversation.**

The minimum chain: **water, soap, a cloth and a hand.** Those four cure the majority of open wounds. Beyond them, tetanus vaccine at cents, lidocaine at cents, antibiotics for the minority that need them, and surgical debridement for the contaminated and the necrotising.

**Gaps.** There is no global incidence figure of any kind for open wounds, one of the commonest lesions in medicine, and GBD's structure means they are counted only through their external causes. No deaths figure attaches to the lesion. Non-neonatal tetanus deaths were not retrievable, so the open-wound tetanus burden is only partially quantified. **Much standard wound-care practice is unsupported or shown to be equivalent to cheaper alternatives** — irrigation fluid, irrigation pressure, the closure time window, routine prophylactic antibiotics, and expensive dressings — which is a case where the evidence favours the simple option and practice has not fully followed. No effect sizes for any preventive measure specific to wounds were located. Bystander haemorrhage control programme evidence is pre-post, though the component interventions are well evidenced. The honey evidence is moderate-quality and heterogeneous. Chronic wounds — diabetic foot, venous ulcer, pressure injury — carry a very large global burden that is not quantified in any source reached and that behaves as a different condition from the acute wound described here. Necrotising infection incidence and mortality by setting are not reported anywhere located, despite being the wound complication with the highest case fatality.

---

## Crush injury

**What it is.** A part of the body is compressed for a prolonged period — under rubble, machinery, or the person's own body weight after a long collapse. Muscle dies while compressed. When the pressure is released the dead muscle's contents flood the circulation, which can stop the heart and destroy the kidneys.

**Measured. No global incidence figure and no deaths figure** for crush injury were located, in the current or the prior round. GBD reports injury burden by external cause: the relevant causes are exposure to forces of nature, for earthquakes, and exposure to mechanical forces, and **no global figure was retrieved for either**.

The burden is **episodic rather than endemic.** It arrives in earthquakes, building collapses, landslides and conflict, and the published case series come from named events: the Marmara earthquake of 1999, Bam in 2003, Kashmir in 2005, Wenchuan in 2008, Haiti in 2010, Nepal in 2015 and Türkiye and Syria in 2023, and building collapses such as Rana Plaza in 2013.

**Earthquake case series consistently report crush syndrome in a substantial minority of hospitalised survivors and acute kidney injury requiring dialysis in a large share of those**, with reported dialysis requirements in the range of roughly 10 to 50 per cent of crush syndrome cases depending on the event and the rescue interval. These are case-series figures from individual disasters and were not verified, so no pooled figure is asserted.

Geography: wherever buildings are not built to seismic standards, and wherever conflict destroys buildings with people inside.

**Where it starts.** The mechanism is well understood. **Prolonged compression of muscle:** skeletal muscle is the vulnerable tissue, compression beyond roughly an hour begins to produce irreversible damage, and the damage scales with duration.

**Earthquakes and building collapse** are the dominant cause, and the reason the burden is episodic. Landslides, mining accidents, industrial machinery, agricultural machinery and vehicle entrapment follow. Conflict and bombardment produce it.

**Prolonged immobility against a hard surface** — the long lie after a fall or a collapse, after a stroke, or after unconsciousness from alcohol, drugs or poisoning — produces the same syndrome without any external crushing force, and is the commonest non-disaster route in high-income settings.

**Non-seismic building standards, unreinforced masonry and informal construction** are the structural determinant of how many people are crushed by a given earthquake. **The rescue interval** determines the outcome, and the intervention that shortens it is organised rescue. No effect sizes were located.

What is not known is the burden. **The condition has no incidence figure, no deaths figure and no GBD series**, and the evidence base is a series of single-event case reports from which no pooled estimate has been constructed in any source reached. Also unresolved in the clinical literature: the optimal fluid regimen and rate, whether bicarbonate and mannitol add anything to volume alone, and the indications and timing for fasciotomy in crushed limbs, where over-aggressive fasciotomy causes infection and amputation.

**Cure status.** Crush syndrome, the systemic illness: CURABLE, with a time-dependence as sharp as any condition in this book and a mortal trap at the moment of rescue. It is survivable and fully recoverable if the patient is given fluid before and during extrication and dialysed where needed. The acute kidney injury of crush syndrome is typically **reversible**: survivors who are dialysed through the acute phase commonly recover renal function completely and come off dialysis. The crushed muscle, limb loss and nerve injury: RELIEF ONLY. That tissue is dead.

**The trap is the central clinical fact: releasing the compression without first establishing fluid resuscitation can kill the patient within minutes.** The potassium and myoglobin held in the crushed limb enter the circulation at the moment of release, producing cardiac arrest and overwhelming the kidneys. **People have been extracted alive from rubble, conscious and talking, and died on release.** This is why the intervention is given **before** the rescue rather than after it, and it is the single most important piece of knowledge in the entry.

**Prevention.** - **Seismic building codes and their enforcement — STRONG, and it is the whole of the prevention.** Earthquakes do not kill people; buildings do. The measured evidence is comparative: earthquakes of similar magnitude produce death tolls differing by orders of magnitude between countries with enforced seismic codes and those without. **No effect size was retrievable**, and the comparison is the standing position in the disaster literature. - **Retrofitting existing unreinforced masonry — STRONG**, and expensive. - **Land-use planning** — not building on landslide-prone slopes or liquefiable ground. - **Enforcement rather than legislation.** The repeated finding after every major earthquake is that codes existed and were not enforced, so **the preventive gap is inspection rather than knowledge.** - **Machine guarding and lock-out procedures in industry and agriculture — MODERATE.** - **Organised search and rescue capacity — STRONG for survival**, because the outcome is determined by the interval. This is preparedness rather than prevention. - **Training first responders and community volunteers in the fluid-before-extrication rule — STRONG** on mechanism; this is the highest-yield piece of preparedness in the entry. - **Preventing the long lie** — personal alarms for older people living alone, and a daily check.

**A visit is the intervention.** - **Earthquake drills and furniture anchoring**, which reduce injury inside surviving buildings.

**Treatment.** The order matters more here than in most entries.

**1. Intravenous fluid, started BEFORE the compression is released, and continued at high volume. This is the treatment, and the sequence is the point.** Isotonic saline, begun while the patient is still trapped if a limb can be reached, at high rates — the published disaster-nephrology guidance recommends starting before extrication and continuing with very large daily volumes under monitoring. Normal saline is EML-listed, off-patent, **a few US dollars a litre**. **A few litres of salt water, given in the right order, is the difference between death on release and full recovery.** Potassium-containing fluids are generally avoided, because hyperkalaemia is the killing mechanism.

**2. Management of hyperkalaemia.** Calcium gluconate or chloride to stabilise the myocardium, insulin-dextrose, salbutamol, and dialysis as the definitive measure. Calcium gluconate, insulin, dextrose and salbutamol are all EML-listed, off-patent and cheap; calcium gluconate was printed at US$10.66 and US$5.01 for the same material number on different pages of the October 2026 indicative catalogue, which is why these are indicative figures and not a price. **Continuous or frequent electrocardiographic monitoring, where available, detects the hyperkalaemia before the arrest.**

**3. Renal replacement therapy — dialysis.** The intervention that determines survival in established crush-related acute kidney injury. **Peritoneal dialysis is the low-resource form and has been used at scale in disaster settings**, requiring a catheter, fluid and no machine and no electricity — which is why it matters here. Dialysis demand after an earthquake arrives all at once in a place whose dialysis capacity has also been destroyed.

**4. Urine output monitoring and alkalinisation — CONTESTED.** Sodium bicarbonate to alkalinise the urine and mannitol to force diuresis are widely used and **their added benefit over adequate volume alone is not established.** Reported as contested.

**5. Fasciotomy — CONTESTED and over-performed.** Indicated for measured compartment syndrome. **Routine or prophylactic fasciotomy in crushed limbs is associated with infection, sepsis and amputation**, and the disaster literature is explicit that restraint improves outcomes. **Measured compartment pressures, not clinical impression.**

**6. Wound care, debridement and antibiotics** for the open and contaminated components, and **tetanus prophylaxis.**

**7. Amputation** where the limb is unsalvageable or the patient is dying from it, sometimes performed at the scene to permit extrication.

**8. Analgesia.** Crush injury is extremely painful and analgesia at the scene is routinely absent. Morphine is EML-listed, off-patent, and works out at about US$0.57 an ampoule on October 2026 indicative prices.

**9. Treatment of hypothermia.** People under rubble become cold, and hypothermia compounds coagulopathy and acidosis.

**10. Rehabilitation** for the surviving limb and for the amputee.

**Simple means.** - **Fluid before release. The highest-value simple means in the entry and one of the highest in the chapter: a bag of salt water and the knowledge of the order in which to do things.** A litre of saline costs about a dollar. **A first responder who starts fluid before lifting the slab saves a life that is otherwise lost at the moment of rescue.** If no intravenous access is possible, **oral fluid, including oral rehydration solution, given to a conscious trapped person is a real and recommended fallback.** - **Teaching the rule.** The whole intervention is a piece of knowledge, transmissible in a sentence, and its absence is the mechanism of death. **This is the clearest case in the chapter where information, not equipment, is the intervention.** - **Not applying a tourniquet to a crushed limb as a routine measure.** The released-toxin logic that motivates it does not hold and the limb is lost. Tourniquets are for haemorrhage. - **Keeping the trapped person warm, hydrated and talking.** Insulation from the ground, covering, and fluid by mouth. Free. - **Marking the time of entrapment.** The rescue interval determines management, and writing it down costs nothing. - **Community search and rescue with hand tools.** The great majority of people rescued alive after earthquakes are pulled out by neighbours

in the first hours, before any organised team arrives. **Hands, levers, jacks and digging tools, used by trained community volunteers, save more lives after an earthquake than any medical intervention.** - **Oral rehydration solution** — sugar, salt and water, for the conscious trapped or just-released patient, at about US$0.048 a sachet on October 2026 indicative prices. - **Peritoneal dialysis** — a catheter and fluid, no machine and no electricity. The low-resource form of the definitive treatment. - **Analgesia, including oral morphine or ketamine where available.** - **Splinting the limb and wound dressing.** - **Anchoring furniture and knowing where to shelter** — household earthquake preparedness, free. - **A daily check on an older person living alone**, which prevents the long lie that produces the same syndrome without an earthquake.

The minimum chain: a bag of saline, or failing that oral rehydration solution, and the knowledge to give it before the weight comes off. For the established kidney injury, dialysis — and peritoneal dialysis is the form that works without a machine.

**Gaps.** There is no incidence figure, no deaths figure and no GBD series for crush injury: the evidence base is single-event case series from named disasters, and no pooled estimate has been constructed in any source reached. The dialysis-requirement figures are from individual event series and were not verified, and no pooled figure is asserted. The seismic building code effect size could not be retrieved, despite being the entire prevention. The optimal fluid regimen, rate and composition are not established by trial; the guidance is expert consensus from disaster nephrology experience. Bicarbonate and mannitol are widely used and their added benefit over volume alone is not established. Fasciotomy indications and timing are contested, and the disaster literature's position that it is over-performed and causes harm conflicts with general trauma practice. The burden is episodic, so it is absent from annual accounting frameworks and reappears as an emergency each time, which is itself a structural reason the data do not exist. Conflict-related crush injury is essentially unmeasured. The long-lie route in older people is recognised clinically and not quantified anywhere located.

---

## Hypothermia and heat illness

**What it is.** Two opposite failures of the body's temperature control. In hypothermia the core cools below about 35 °C and the heart and brain slow until they stop. In heat stroke the core rises above about 40 °C and proteins and cells begin to fail. Both kill, and both are reversible if the temperature is corrected in time.

**Measured. About 489,000 heat-related deaths a year**, as a 2000 to 2019 average. **The source is unnamed in the compilation that carries this figure**, and it is printed with that caveat. **GBD's environmental heat and cold exposure cause series was not retrievable**, in the current or the prior round.

**Neonatal hypothermia has no burden figure at all** — no GBD cause line, no global prevalence estimate, and its mortality counted inside preterm birth complications and sepsis.

**No global incidence figure for either hypothermia or heat illness as a clinical presentation** was located. The available figures are mortality attributions to ambient temperature, which is a different measure: the attributable-burden literature estimates deaths attributable to non-optimal ambient temperature in the millions annually, with **cold-attributable deaths exceeding heat-attributable deaths** in most of that work. Those figures could not be verified and are not asserted; they measure temperature-attributable mortality across all causes, not cases of hypothermia and heat stroke.

Heat exposure is rising with the climate, and the attributable-burden literature reports rising heat-attributable and falling cold-attributable mortality, unverified here.

Cold-water drowning is relevant: in cold-water submersion with rapid deep cooling, survival with intact neurology has been documented after very prolonged submersion, which is why prolonged resuscitation is attempted in cold water and not in warm.

**Where it starts.** For hypothermia: **cold exposure, with wind and wet multiplying it**, and immersion cooling far faster than air. **The age extremes. The newborn is the most vulnerable human**: a large surface area to mass, no shivering, no fat, and no ability to move or dress itself. Older people have reduced shivering, reduced perception of cold and reduced mobility. **Alcohol and drugs** through vasodilatation and impaired judgement, the classic ur-

ban hypothermia death. **Immobility and the long lie** — a fall, a stroke, or unconsciousness on a cold floor. Hypoglycaemia, hypothyroidism, adrenal insufficiency, malnutrition and sepsis, and **in a newborn hypothermia may be the presenting sign of sepsis rather than its cause. Poverty** — inadequate heating, inadequate housing, homelessness, fuel poverty — is the determinant in high-income-country winter mortality. And **trauma**, where hypothermia, acidosis and coagulopathy form a lethal triad, and trauma patients become hypothermic even in warm environments through exposure, fluid and blood loss.

For heat illness: **ambient heat and humidity**, with humidity decisive, because evaporative cooling is the body's only mechanism at high temperature and above a wet-bulb threshold it fails entirely. **Exertional heat stroke** in athletes, soldiers and labourers occurs in moderate ambient conditions with high work rates and affects the young and fit. **Classical heat stroke** in older, chronically ill and isolated people during heatwaves produces the mortality spikes. The age extremes; chronic illness; cardiovascular and renal disease; obesity. **Medications** — anticholinergics, diuretics, beta blockers, antipsychotics — and drugs of abuse. Dehydration, lack of acclimatisation, occlusive clothing. **Urban heat island, living on a top floor, no shade, no fan, no air conditioning, and social isolation** — the 2003 European and 1995 Chicago heatwave analyses identified social isolation as a leading risk factor, which is a finding about society rather than physiology. And **outdoor and indoor manual labour** — agricultural and construction work in heat, which is the largest occupational exposure and is growing. **No effect sizes were located for any risk factor.**

What is not known is the burden, for either. **The 489,000 heat figure has no named source.** And the attributable-burden approach and the clinical-case approach measure different things: a heatwave kills mostly by precipitating cardiovascular and respiratory death in people who are never diagnosed with heat stroke, so the clinical incidence of heat illness and the mortality attributable to heat differ by orders of magnitude and neither is well counted. **The same applies to hypothermia: excess winter mortality is largely cardiovascular and respiratory, not diagnosed hypothermia.**

**Cure status.** Both conditions are CURABLE, with RELIEF ONLY for the organ damage and hypoxic injury established once the threshold is passed. Both have a time-dependent threshold beyond which they are not.

**Hypothermia: CURABLE, and notably so.** Rewarming reverses it and recovery is complete. **The maxim in the resuscitation literature — no one is dead until they are warm and dead — reflects a real finding: patients have survived with intact neurology after profound hypothermia with prolonged cardiac arrest, because the cold protects the brain while it protects nothing else**. Prolonged resuscitation and extracorporeal rewarming are therefore justified in hypothermic arrest in a way they are not in normothermic arrest. **Accidental hypothermia has one of the best outcomes of any cause of cardiac arrest, if the rewarming is achieved.**

**Heat stroke: CURABLE if cooled fast, RELIEF ONLY for what the heat has already destroyed. Cooling rate is the determinant of outcome and the evidence is unusually clear**: in exertional heat stroke, cooling to below about 39 °C within 30 minutes is associated with survival approaching 100 per cent in the military and athletic series, while delay produces multi-organ failure. What is not reversible is the established damage — hepatic failure, rhabdomyolysis with renal failure by the same mechanism as crush injury, disseminated intravascular coagulation, and permanent cerebellar and cognitive injury in a share of survivors.

So both conditions are, at the moment of presentation, temperature problems with temperature solutions, and both become organ-failure problems if the temperature is not corrected.

**Prevention.** For hypothermia: - **The newborn warm chain — STRONG, free, and the highest-yield item**: immediate drying, skin-to-skin, a hat, delayed bathing, a warm room, keeping mother and baby together, warm transport. **Plastic wrapping of very preterm babies at birth is randomised-trial and Cochrane-supported** and costs a plastic bag. - **Adequate home heating and insulation, and addressing fuel poverty — STRONG** for winter mortality, and it is a housing and income intervention rather than a medical one. - **Winter fuel payments, cold weather alerts, and warm-space provision — MODERATE.** - **Shelter for homeless people during cold weather — STRONG.** - **Daily contact with isolated older people — MODERATE**, and it prevents the long lie. - **Clothing, layering,**

**head covering, and staying dry — STRONG** on mechanism. - **Not drinking alcohol in the cold — MODERATE.** - **Active warming of trauma patients and of surgical patients — STRONG.** Perioperative warming reduces wound infection, blood loss and cardiac events in randomised trials, and the measure is a blanket and warmed fluid. - **Flotation and immersion protection for those working on water — STRONG.**

For heat illness: - **Heat-health action plans and early warning systems — STRONG.** Introduced across Europe after the 2003 heatwave, and the evaluations report reduced heat mortality in subsequent comparable events. **No effect size retrievable**. - **Checking on isolated older people during a heatwave — STRONG.** Social isolation was identified as a leading risk factor in the Chicago 1995 and Europe 2003 analyses. **A visit is the intervention.** - **Cooling centres, shade, and access to a fan or air conditioning — STRONG.** - **Urban greening, tree planting, reflective roofing and reducing the urban heat island — MODERATE**, slow-acting. - **Housing design** — ventilation, shutters, insulation — **MODERATE.** - **Acclimatisation protocols, work-rest cycles, hydration and shade for outdoor workers — STRONG** in the occupational literature, and the regulatory instrument is a heat standard with mandatory rest breaks. - **Rescheduling work and sport away from the hottest hours, and cancelling events on high wet-bulb days — STRONG.** - **Medication review before summer** for drugs that impair thermoregulation — **MODERATE**, and free. - **Never leaving a child or an animal in a parked vehicle — STRONG**, and the mechanism is rapid interior heating. - **Education on recognising heat illness — MODERATE.**

**Treatment.** For **hypothermia**: **1. Remove from the cold, remove wet clothing, insulate, and prevent further loss.** First, and free. **2. Passive external rewarming** for mild hypothermia — dry insulation, a warm environment, and the patient's own shivering, which is an effective heat source if fuel is available. **3. Active external rewarming** — forced warm air, heating pads, radiant heat, warm water immersion. **4. Active internal rewarming** — warmed humidified oxygen and warmed intravenous fluids, and in severe cases body-cavity lavage. **5. Extracorporeal rewarming** for hypothermic cardiac arrest. **The best survival of any cardiac arrest aetiology, and it requires a centre. 6. Careful handling and minimal movement** in moderate and severe hypothermia; rough handling can precipitate ventricular fibrillation. **7. Prolonged resuscitation.** Defibrillation and drugs are ineffective below about 30 °C, so **resuscitation is continued while rewarming proceeds**, sometimes for hours. **8. Treating the cause** — glucose for hypoglycaemia, antibiotics for sepsis, thyroid hormone where indicated, and in a newborn treating the sepsis that the hypothermia may signal. **9. Warming all fluids and blood** in the trauma patient.

For **heat stroke**: **1. Cool immediately, and cool fast. Cooling rate determines survival.** - **Cold water immersion is the most effective method** and is the standard for exertional heat stroke — **cool first, transport second**, which inverts the usual order and is the key clinical instruction. - **Evaporative cooling** — spraying or sponging with water and fanning — where immersion is impossible. Effective, and it needs water and a fan or a piece of card. - **Ice packs to the neck, axillae and groin; cold intravenous fluids; iced gastric or rectal lavage** in extremis. - **Antipyretics do not work.** Paracetamol and non-steroidal anti-inflammatory drugs have no role in heat stroke, because the hypothalamic set point is not raised — this is not fever. **Giving them wastes time, and the anti-inflammatories harm the kidneys that are already at risk. 2. Airway, breathing, circulation, and intravenous fluid**, with care for the fluid status, which differs between exertional and classical heat stroke. **3. Treating the complications** — rhabdomyolysis and acute kidney injury, by the same management as crush injury; hepatic failure; coagulopathy; seizures; electrolyte disturbance. **4. Stopping the exertion and removing the clothing. 5. Monitoring core temperature** — rectal or oesophageal. **Axillary and tympanic readings are unreliable in heat stroke** and underestimate the core. **6. Dantrolene does not work in heat stroke** — it is for malignant hyperthermia, a different condition. A negative worth stating because the two are confused.

**Simple means.** For **hypothermia**: - **A dry cloth, a hat, and body contact. For the newborn this is the entire intervention and it carries the kangaroo mother care mortality effect, relative risk 0.75†.** Nothing in this book is cheaper or better evidenced. - **Drying and removing wet clothing.** Evaporation is the largest heat loss. - **Insulation from the ground** — a mat, cardboard, dry vegetation. Conduction to cold ground is a major

loss and the countermeasure is anything dry underneath. - **Shelter from wind; a blanket; a plastic sheet or survival bag.** - **Warm sweet drinks** for a conscious shivering patient — fuel for shivering, which is the body's own rewarming mechanism. - **Skin-to-skin contact between two people in a sleeping bag or blanket.** - **Not rubbing the extremities, not giving alcohol, and handling the patient gently.** - **Prolonged resuscitation in cold-water drowning and hypothermic arrest** — free, and justified by the neuroprotection. - **Closing windows and doors; a single heated room; blankets and layered clothing** for an older person in a cold house. - **A daily visit** to an isolated older person.

For **heat illness**: - **Water, shade, and rest.** The three-word prevention and treatment. - **Cold water immersion in anything that holds water** — a tub, a tarpaulin held by by-standers, a stock trough, a river. **This is the most effective treatment for exertional heat stroke and it needs only water and a container.** - **Wetting the skin and fanning.** Evaporative cooling with a spray bottle or a wet cloth and a piece of card. **Free, and it works.** - **Ice or cold packs to the neck, armpits and groin**, and wet cloths where there is no ice. - **Removing clothing.** - **Oral rehydration solution** — sugar, salt and water. - **Working in the early morning and late afternoon; a work-rest cycle; a shaded rest place; a water container at the work site.** - **A fan.** Where humidity is not extreme, a fan is an effective cooling intervention at very low power and very low cost, and it is the realistic alternative to air conditioning for most of the world's population. - **Wetting clothing and skin, and wet cloths on the head and neck** during a heatwave. - **Opening windows at night and shuttering by day; a wet sheet in a doorway; shading the roof.** - **Checking on neighbours** during a heatwave. **Social isolation was a leading risk factor in the Chicago and European heatwave analyses, so a knock on a door is a medical intervention.** - **Never leaving a child in a vehicle.** - **Teaching that antipyretics do not work and that cooling comes before transport.**

The minimum chain: a dry cloth and body heat for hypothermia; water, shade and a container to sit in for heat stroke. Both conditions are reversible with materials that cost nothing, and both kill when those materials are not applied in time.

**Gaps.** The 489,000 heat-deaths-per-year figure has no named source in the compilation that carries it, and GBD's environmental heat and cold exposure series was not retrievable. There is no global incidence figure for either condition as a clinical entity. **The temperature-attributable mortality literature, reporting millions annually with cold exceeding heat, could not be verified and measures something different from clinical cases** — most heat and cold deaths are cardiovascular and respiratory deaths never diagnosed as heat or cold illness, and the two literatures are not reconciled anywhere located. Neonatal hypothermia has no burden figure at all, despite being prevented by a dry cloth. No effect sizes were retrievable for heat-health action plans, cooling centres, urban greening, home heating interventions or occupational heat standards. The cooling-rate evidence for heat stroke is from military and athletic series, which are young, fit and observed populations, and its applicability to classical heat stroke in isolated older people is an extrapolation. Occupational heat exposure is growing and is poorly measured, particularly in informal agriculture and construction. The wet-bulb threshold beyond which human thermoregulation fails is a physiological inference with limited direct human data. Trend statements about rising heat mortality rest on attributable-burden modelling that could not be verified here.

---

## Foreign body aspiration

**What it is.** An object — a piece of food, a small toy, a button battery — is breathed in instead of swallowed. If it blocks the windpipe the person cannot breathe and dies within minutes. If it lodges lower it causes coughing, wheeze and repeated chest infection, sometimes for months before it is found.

**Measured. No global incidence figure and no deaths figure** for foreign body aspiration were located, in the current or the prior round. GBD reports injury burden by external cause, and the relevant cause is other unintentional injuries, for which no figure was retrievable.

The condition is concentrated in **children under 3**, in whom it is a leading cause of unintentional injury death in the published national series. In the United States, choking causes of the order of **100 to 200 child deaths a year and tens of thousands of emergency**

**department visits** for food and non-food choking in children, with nuts, seeds, hard sweets, grapes, hot dogs and popcorn the most frequently implicated foods and small toy parts, coins, button batteries and balloons the most frequent non-food items. **These are national-series figures reported as the standing literature position and they were not verified**. No figure is asserted.

**Button batteries are a distinct and growing hazard** with a different mechanism — electrical burn of the oesophagus within hours rather than airway obstruction — and national poison-centre series report rising incidence and a small number of deaths and severe injuries annually.

It occurs everywhere, and **the mortality is concentrated where bronchoscopy is unavailable**, because the lodged foreign body that does not fully obstruct requires rigid bronchoscopy to remove.

**Where it starts. Age under 3 years** is the determinant, and the mechanism is developmental: no molars, immature chewing and swallowing coordination, a narrow airway, hand-to-mouth exploration, and a tendency to run, laugh or cry while eating.

**Food characteristics** — round, hard, smooth, compressible or slippery items that match the paediatric airway diameter. **Nuts, seeds, whole grapes, hard sweets, raw carrot, popcorn, hot dogs and sausage pieces, and chewing gum** are the repeatedly implicated classes.

**Small objects within reach** — coins, marbles, small toy parts, pen caps, beads, pins, and deflated or burst balloons, a repeatedly identified cause of fatal obstruction because the latex conforms to the airway.

**Button and coin cell batteries**, where the mechanism is electrochemical burn, not obstruction, and the hazard window is hours.

In older children and adults: intellectual disability, neurological impairment with impaired swallow, dentures, sedation, alcohol, and eating while talking or lying down. **Stroke and neurodegenerative disease with dysphagia** produce the adult aspiration population, who aspirate food and fluid rather than objects, and whose consequence is pneumonia rather than obstruction. Absence of adult supervision at meals, and older siblings feeding younger ones. No effect sizes were located.

What is not known is the incidence and mortality globally. **This is a condition in which death occurs within minutes in front of a witness, and there is no global count.** Also not well characterised: the share of chronic childhood respiratory morbidity — recurrent wheeze, persistent cough, localised bronchiectasis — caused by an unrecognised retained foreign body. The published bronchoscopy series repeatedly report cases found months after the event, having been treated as asthma, which implies a misdiagnosed population of unknown size.

**Cure status.** Complete airway obstruction: CURABLE in seconds by a bystander, with back blows and abdominal thrusts, or chest thrusts in an infant. **Removing the object restores a completely normal child.** Not removing it causes death, or hypoxic brain injury in the resuscitated — RELIEF ONLY for that. Partial or lower airway obstruction: CURABLE by rigid bronchoscopy, with complete recovery in the large majority. **Delayed diagnosis leads to granulation tissue, persistent infection and localised bronchiectasis**, which is CONTROLLABLE and may require lobectomy — so the cure becomes progressively harder and more destructive with time. Button battery ingestion: CURABLE if removed within hours; catastrophic after. The burn perforates the oesophagus and can erode into the aorta. **The time window is the entire clinical issue and it is measured in hours, not days.** Aspiration pneumonia in the adult with dysphagia: CURABLE as an episode, CONTROLLABLE as a tendency.

**Prevention.** This entry is prevention-dominated, and the measures are cheap and specific. - **Not giving high-risk foods to children under about 4 — STRONG** on mechanism, and it is the single highest-yield measure. **No nuts, whole grapes, hard sweets, popcorn, raw carrot sticks, or whole hot dog or sausage pieces. Cutting grapes lengthways into quarters, grating raw vegetables, and chopping sausage lengthways** removes the hazard. **Free.** - **Supervision at meals; sitting still to eat; not eating while running, laughing or lying down — STRONG** on mechanism. - **Small-parts regulation of toys —**

**STRONG.** The small-parts cylinder test — a gauge approximating the throat of a child under 3, against which toy parts for that age group must not fit — is embodied in United States consumer product safety regulations and in the European and international toy safety standards. **A regulatory measure with a physical gauge**, and the surveillance literature attributes substantial reductions in toy-related choking deaths to it. **No effect size was retrievable**. - **Labelling of choking hazards on toys — MODERATE.** - **Balloon warnings and keeping latex balloons away from young children — MODERATE**, because burst balloon fragments are a recognised cause of fatal obstruction. - **Button battery compartment regulation — STRONG where enacted.** Requiring screw-secured battery compartments in consumer products, child-resistant packaging for loose batteries, and warning labelling. Several jurisdictions have introduced mandatory standards following clusters of deaths, and **United States legislation of 2022 requires secured compartments and performance standards**†. **This is the clearest recent example of product regulation responding to a specific injury mechanism.** - **Keeping small objects out of reach, and getting down to child height to survey a room** — free. - **Child-resistant packaging** for small items. - **Training parents and carers in choking first aid — STRONG** on mechanism. Free knowledge with a minutes-long window. - **Dysphagia assessment, and modified diet and fluid consistency** after stroke or in neurodegenerative disease — **STRONG** for aspiration pneumonia, with the caveat that thickened fluids themselves have a contested evidence base. - **Oral hygiene in the dependent patient — MODERATE** for aspiration pneumonia, and it is a toothbrush. - **Dental care and well-fitting dentures.**

**Treatment.** The ordering by setting matters. **1. For complete obstruction with a conscious patient: back blows and abdominal thrusts, or chest thrusts in an infant, immediately.** - **Adult and child over 1: up to 5 back blows between the shoulder blades, then up to 5 abdominal thrusts, alternating.** - **Infant under 1: up to 5 back blows, then up to 5 chest thrusts. Abdominal thrusts are not used in infants**, because of the risk of visceral injury. - **This is the treatment and it is delivered by a bystander with their hands.** The evidence is observational and mechanistic — a randomised trial is impossible — and the effectiveness in reported series is high. - **Encourage coughing if the person can cough, speak or breathe.** An effective cough is better than any intervention and should not be interrupted.

**2. If the patient becomes unconscious: start resuscitation.** Chest compressions generate airway pressure and may expel the object.

**3. Direct laryngoscopy and removal with Magill forceps**, where equipment and a trained operator are present.

**4. Rigid bronchoscopy. The definitive treatment for a lodged airway foreign body**, with success rates above 95 per cent in the published series†. It requires a rigid bronchoscope, general anaesthesia and a trained operator — **and its absence is what makes this condition lethal or chronically disabling in low-resource settings.** Flexible bronchoscopy has a role for diagnosis and for some removals.

**5. Emergency surgical airway — cricothyroidotomy** for complete obstruction above the cricothyroid membrane that cannot be relieved. A scalpel and a tube; rarely indicated, and the obstruction is usually below the level it bypasses.

**6. For button battery ingestion: immediate removal, endoscopic, within hours. Honey or sucralfate given before removal** has been shown in animal and early clinical work to reduce oesophageal injury by neutralising the alkaline burn, and is now recommended as a holding measure in children over 12 months while transport to endoscopy proceeds†. **Honey, in this instance, is an evidenced emergency treatment.**

**7. Antibiotics** for the pneumonia distal to a retained foreign body, and for aspiration pneumonia. EML-listed, off-patent, cheap. **They do not substitute for removing the object.**

**8. Chest physiotherapy and bronchodilators have no role in dislodging an airway foreign body** and may convert a partial obstruction into a complete one. A negative worth stating.

**9. Lobectomy** for established bronchiectasis distal to a long-retained foreign body.

**Simple means.** This entry's treatment is almost entirely simple means, and so is its prevention. - **Back blows and abdominal or chest thrusts. Hands, and nothing else. The**

**highest-value simple means in the entry and among the highest in the chapter**, because the alternative within four minutes is death and the intervention is free. - **Encouraging an effective cough, and not interfering with it.** - **Teaching choking first aid to every parent, carer, teacher and food-service worker.** A twenty-minute demonstration. **The intervention is knowledge with a minutes-long window and no equipment.** - **Cutting food up. Grapes quartered lengthways, sausage split lengthways, raw vegetables grated, nuts ground or withheld.** Free, and it is the single most effective preventive act. - **Not giving nuts, hard sweets, popcorn or whole grapes to a child under four.** A rule. - **Getting down to the floor and looking at what is within reach of a crawling child.** Free. - **Taping or screwing shut battery compartments on household devices**, and keeping loose button batteries out of reach. A roll of tape. - **Honey for a swallowed button battery** in a child over 12 months, while getting to hospital. A spoonful of honey, as an evidenced emergency measure. - **Sitting the child down to eat, and supervising.** - **A toothbrush.** Oral hygiene in the dependent patient reduces aspiration pneumonia. - **Positioning for swallowing** — upright, chin slightly down, small mouthfuls, no talking while eating — taught to a family caring for someone with dysphagia. Free. - **The recovery position** for the unconscious patient. - **Thinking of it.** A child with persistent unilateral wheeze, chronic cough or recurrent pneumonia in one lobe, treated as asthma, may have a retained foreign body. **Asking whether they could have inhaled something costs nothing and is what prevents the lobectomy.**

The minimum chain: **two hands and a piece of knowledge.** For the lodged foreign body, rigid bronchoscopy, and there is no simple means that substitutes for it, which is why the chronic cases exist.

**Gaps.** There is no global incidence figure and no global deaths figure, for a condition that kills small children within minutes in front of witnesses, and the national figures above are reported as the standing literature position and were not verified. GBD has no retrievable series for foreign body effects. No effect size was retrievable for small-parts toy regulation, for food-cutting advice, for button battery compartment standards or for choking first aid training — the entire prevention set is recommended on mechanism. The share of chronic childhood respiratory morbidity caused by unrecognised retained foreign bodies is unknown, and the bronchoscopy series imply it is not negligible. **Back blows and thrusts cannot be randomised**, so the first-aid evidence is observational and mechanistic; that is an acceptable limitation and should be stated rather than glossed. Button battery injury incidence is rising and is counted only in national poison-centre series, with no global figure. The honey recommendation for button battery ingestion rests on animal work and early clinical data, and the age restriction above 12 months matters because of infant botulism risk. Thickened fluids for dysphagia have a contested evidence base, and the trial evidence has not supported the practice as strongly as its adoption implies. Bronchoscopy availability is not quantified anywhere located, despite being the determinant of outcome for the non-obstructing case.

---

## Animal bites

**What it is.** An animal's teeth break the skin. The wound itself is usually minor; what matters is what was in the animal's mouth. A dog bite can transmit rabies, which is invariably fatal once symptoms begin, and is entirely preventable in the hours after the bite.

**Measured. The rabies death figures differ roughly fourfold and both are printed.** GBD 2023 gives **15,800 rabies deaths** for 2023. WHO's own page gives **44,203** for 2021 on its Global Health Estimates, while its key facts say only "tens of thousands" annually. WHO's long-standing published estimate, widely cited, is approximately **59,000** a year†. The difference arises because rabies deaths occur at home in rural areas with no diagnosis and no registration.

**Dogs transmit 99 per cent of human rabies cases** in WHO's key facts, and "up to 99 per cent" in the body of the same page. **Forty per cent of rabies deaths are children under 15** in the key facts, and the body states only that children aged 5 to 14 are frequent victims, with no percentage. Both printed; WHO's own page hedges between its key facts and its body on both figures.

**Fatality once symptoms appear: 100 per cent** in the key facts and "virtually 100 per cent" in the body.

**Wound washing: at least 15 minutes**. **Incubation: typically 2 to 3 months, with a range from one week to one year**; paralytic rabies accounts for about 20 per cent of human cases.

**Over 29 million people receive human rabies vaccine annually**, and **the average cost of post-exposure prophylaxis was US$108 in 2018**, against at-risk people living on US$1 to 2 a day. **Intradermal vaccination cuts the cost by 60 to 80 per cent**, and there were 3 WHO pre-qualified human rabies vaccines as of 2024. The global economic cost of rabies is about **US$8.6 billion a year**.

**Three countries have been validated for eliminating dog-mediated human rabies — Bhutan, Chile and Mexico — as of September 2026, and 17 countries have self-declared rabies-free status, against a 2030 target**.

Snakebite, covered separately, is by far the largest animal-inflicted mortality in this chapter at 5.4 million bites, 1.8 to 2.7 million envenomings and 81,410 to 137,880 deaths annually†.

**No global incidence figure for animal bites as a lesion** was located. The standing estimate is tens of millions of dog bites requiring medical attention annually, with children disproportionately affected and bitten more often to the head and neck.

Rabies deaths are concentrated in Asia and Africa, in rural areas and among the poor, and the disease has been eliminated from domestic dog populations in most of Europe, the Americas and parts of Asia by dog vaccination.

**Where it starts. Dog bites** are the dominant source of both bite injury and rabies. **Free-roaming and unvaccinated dog populations are the determinant**, and rabies elimination tracks dog vaccination coverage rather than human treatment coverage.

**Children** are disproportionately bitten, bitten to the face and neck because of their height, less able to avoid or fend off a dog, and less likely to report a bite. **Cat bites** are a small puncture with a high infection rate, because the tooth inoculates deeply and the wound closes over; cat bites to the hand have a particularly high rate of septic arthritis and tenosynovitis. **Monkey, bat and other wildlife exposure**: **bats are the principal rabies reservoir in the Americas and a recognised source elsewhere**, and bat bites and scratches may be unnoticed, which is why exposure history includes waking with a bat in the room. **Human bites** have a high infection rate, and the clenched-fist injury over a knuckle inoculates a joint. **Livestock** — kicks, crushing and bites in agricultural work. **Occupational exposure** — veterinarians, animal handlers, abattoir workers, wildlife researchers, who are the pre-exposure prophylaxis population. Provoking behaviour, approaching an unfamiliar or feeding dog, and leaving a young child unsupervised with a dog. Poverty and rurality determine both exposure and whether prophylaxis is reached. No effect sizes were located.

What is not known is the incidence of animal bites globally as a lesion, and, more consequentially, **the true rabies mortality**: GBD's 15,800, WHO's 44,203 for 2021, and the widely cited approximately 59,000 span a fourfold range. **Community-based surveys in India and parts of Africa have repeatedly found rabies deaths far above official figures**, the same under-ascertainment pattern as snakebite.

**Cure status.** The bite wound: CURABLE. Cleaning, selective antibiotics, and delayed rather than primary closure. Recovery is complete apart from scarring, and facial bites in children may need reconstruction. Bite-wound infection: CURABLE with antibiotics and drainage. Rabies, before symptoms appear: CURABLE. **Post-exposure prophylaxis given promptly is close to completely effective.** Wound washing, vaccine, and rabies immunoglobulin for severe exposures prevent the disease in essentially all treated cases. Rabies, once symptomatic: RELIEF ONLY, and fatal. **Case fatality is 100 per cent once symptoms appear**. A handful of survivals have been reported in the world literature, most with severe neurological sequelae, and no treatment protocol has proved reproducible — the Milwaukee protocol has failed on repeated attempt and is not recommended. **Treatment is palliative: sedation and analgesia for one of the most distressing deaths in medicine.** Tetanus: RELIEF ONLY, and preventable by vaccine.

**Rabies is the sharpest division in this book. Entirely preventable before symptoms; essentially 100 per cent fatal after.** The incubation period is typically two to three months,

which is the entire opportunity: a bite today can be rendered harmless this week and is untreatable once the symptoms arrive.

**Prevention.** - **Mass dog vaccination — STRONG, and it is the intervention that eliminates the disease.** WHO's position is that **vaccinating 70 per cent of the dog population interrupts transmission**†, and this is the measure that removed canine rabies from Europe, most of the Americas and parts of Asia. **A dog vaccine dose costs of the order of a US dollar or less**, against **US$108 for a human post-exposure course in 2018** for every person that dog would otherwise bite. **The cost-effectiveness case is overwhelming and the intervention is veterinary, not medical** — which is precisely why it is under-funded, because it falls outside health budgets. Three countries have been validated for elimination of dog-mediated human rabies. The 70 per cent figure is WHO's standing position and was not verified against a source fetched in the retrieval round. - **The global target is zero human deaths from dog-mediated rabies by 2030**. - **Post-exposure prophylaxis availability — STRONG** for the individual, and it is treatment of an exposure rather than prevention of the disease in the population. **Expensive relative to dog vaccination, and required for every exposed person indefinitely as long as the dogs are unvaccinated** — over 29 million people receive the vaccine annually. - **Pre-exposure prophylaxis for high-risk occupations and for children in high-burden areas — MODERATE.** - **Dog population management — MODERATE**, and **culling is ineffective and counterproductive**; vaccination is the measure that works. - **Education — STRONG on mechanism**, and specifically: do not approach unfamiliar, feeding or sleeping dogs; do not run from a dog; do not leave a young child alone with any dog; wash every bite immediately; report every bite. **Teaching children bite avoidance is free and the target population is the one WHO's key facts put at 40 per cent of the deaths**. - **Tetanus immunisation — STRONG.** - **Responsible pet ownership, leashing, and breed-independent dangerous-dog regulation — MODERATE. Breed-specific legislation has a weak evidence base**; bite-prevention programmes and owner liability have more. - **Not handling bats, and not keeping wild animals — MODERATE**, and the exposure may be unnoticed. - **Supervision of children around animals — STRONG** on mechanism.

**Treatment.** The first item is the most important and the cheapest.

**1. Immediate thorough wound washing with soap and running water for at least 15 minutes**. **This is the first-line rabies intervention and it is free.** Mechanical removal and the lipid-solvent action of soap on the virus envelope substantially reduce the risk of rabies before any vaccine is given, and the published animal and observational evidence supports it strongly. Povidone-iodine or another virucidal agent after washing, where available. **This single act, performed by the bitten person or their family within minutes, is the highest-value intervention in the entry.**

**2. Rabies post-exposure prophylaxis, started as soon as possible.** - **Rabies vaccine**, by intramuscular or **intradermal** regimen. **The intradermal route uses roughly a fifth of the vaccine volume per dose and is WHO-recommended precisely because it makes a vial serve several patients**, which is the practical answer to cost and supply in high-burden settings: **WHO gives the cost reduction as 60 to 80 per cent**. The vaccine is EML-listed and off-patent, and **the average cost of a post-exposure course was US$108 in 2018**, which is catastrophic expenditure for a rural household living on US$1 to 2 a day. - **Rabies immunoglobulin, or a monoclonal antibody, infiltrated into and around the wound**, for the most severe exposure category — transdermal bites, licks on broken skin, mucous membrane contact, bat exposure. EML-listed under sera and immunoglobulins, off-patent as a plasma-derived product. **Cost: the most expensive component, and the one most often unavailable.** Rabies monoclonal antibodies are now licensed and reduce dependence on plasma supply. - **Category assessment determines the regimen**, and over-treatment of the mildest exposure category wastes scarce vaccine while under-treatment of the most severe kills.

**3. Tetanus prophylaxis** — vaccine and, for high-risk wounds in the inadequately immunised, tetanus immunoglobulin. EML-listed, off-patent, cents for the vaccine.

**4. Antibiotics — for bites, more often indicated than for other wounds.** - **Amoxicillin-clavulanate** is the standard, covering *Pasteurella* from dogs and cats, *Capnocytophaga*, staphylococci, streptococci and oral anaerobes. - **Prophylaxis is indicated for cat bites, hand bites, deep puncture wounds, bites requiring closure, bites in immunocom-**

**promised or diabetic patients, bites over a joint or tendon, and human bites.** Not routinely for superficial dog bites elsewhere. - EML-listed, off-patent, cheap.

**5. Wound management** — irrigation, debridement, and delayed rather than primary closure. **Closing a bite wound primarily causes the infection**, with facial wounds the usual exception where cosmetic need and good blood supply justify careful primary closure with close follow-up.

**6. Surgical exploration** for hand bites, bites over joints and clenched-fist injuries. **Septic arthritis and tenosynovitis from an apparently trivial puncture is the classic missed injury.**

**7. Reconstruction** for facial and other disfiguring bites, particularly in children.

**8. Palliative care for symptomatic rabies** — sedation and analgesia. **Nothing else. The Milwaukee protocol is not recommended.**

**9. Psychological support.** Post-traumatic symptoms after a dog attack, particularly in children, are common and untreated.

**Simple means.** - **Soap, running water, and fifteen minutes. This is the single highest-value simple means in this chapter by ratio of lives saved to cost**, because rabies is otherwise invariably fatal and the washing substantially reduces the risk before any vaccine is involved. **It costs a bar of soap and a quarter of an hour, and it must be done by the family within minutes of the bite, which means the intervention is knowledge.** - **Teaching every household that every animal bite must be washed and reported.** Free, and it is the bottleneck: people do not present, or present late, or wash inadequately. - **Not closing the wound.** Leaving a bite open is both correct treatment and a simple means. - **A clean cloth dressing.** - **Dog vaccination.** Not a household simple means, and **the cheapest life-saving intervention in this entry by a wide margin** — about a dollar a dog, 70 per cent coverage, and the disease stops. The chain is a vaccine vial, a cold box and a volunteer with a syringe. - **Teaching children how to behave around dogs** — do not approach, do not run, do not disturb a feeding or sleeping dog, do not put your face near one. **Free, and the target group carries the largest share of the deaths.** - **Supervision of young children around animals.** - **Confining and observing the biting dog for ten days** where possible: if the dog is alive and well after ten days it was not infectious at the time of the bite, which can spare a course of vaccine. **Free, and it is a diagnostic test performed by watching.** - **Tetanus vaccine** — cents. - **Not handling bats; not keeping wild animals as pets.** - **Elevation and immobilisation of a bitten hand**, which is the limb where the trivial-looking bite causes the disabling infection. - **Recognising the warning signs of wound infection** — spreading redness, pain out of proportion, pus, fever — and returning. Free. - **Knowing which facility holds rabies vaccine and immunoglobulin**, and going there rather than to a nearer one that does not.

The minimum chain: **soap, water and knowledge** for the first and most important step; **vaccine and immunoglobulin** for the cure, with no substitute, and the intradermal regimen is what makes the vaccine reach more people from the same vial.

**Gaps. The rabies death figures span roughly fourfold: GBD 2023's 15,800, WHO's own 44,203 for 2021, and the widely cited approximately 59,000.** All printed. **WHO's own page also hedges between its key facts and its body on the dog-mediated share, at 99 per cent against up to 99 per cent, and on fatality, at 100 per cent against virtually 100 per cent; and its key facts assert that 40 per cent of deaths are children under 15, a figure the body nowhere supports.** Rabies deaths are under-ascertained, with community surveys finding figures far above official ones, the same pattern as snakebite. No global incidence figure for animal bites as a lesion exists, and no GBD series for animal contact beyond the rabies proxy. No effect sizes were retrievable for any preventive measure, including dog vaccination, which is the intervention that eliminates the disease, and the 70 per cent coverage threshold is a standing position that was not verified. Rabies immunoglobulin availability, as opposed to EML listing, is not quantified anywhere located, and it is the component most often absent. Breed-specific dog legislation has a weak evidence base and remains widely used, and bite-prevention programme evidence is thin. **No survivor has been reproducibly treated**, and the Milwaukee protocol's early reported success did not replicate — a reminder that a single reported survival is not a protocol. Dog bite morbidity, facial scarring in children and the psychological sequelae are essentially unmeasured.

# What no longer holds

Six treatments in this chapter were standard practice and are now known not to work, or to harm. They are collected here because a reference work that records only what is currently recommended leaves the reader unable to recognise the older advice when they meet it.

**Syrup of ipecac.** Standard household advice for decades, kept in home medicine cabinets and recommended for suspected childhood poisoning. **Not recommended.** It delays effective treatment, it does not reliably remove what was swallowed, and the vomiting it induces carries its own aspiration risk.

**Routine gastric lavage.** Once the reflex intervention for poisoning on arrival at hospital. Now **considered only for potentially life-threatening ingestion presenting within 60 minutes, and contraindicated for hydrocarbons**. For most poisonings it adds risk and no benefit, and supportive care is what cures.

**Methylprednisolone in spinal cord injury.** Given for roughly twenty years on the basis of the NASCIS trials, and **withdrawn from most guidelines**: the apparent benefit was a post-hoc subgroup finding, and the harms — infection, pneumonia, gastrointestinal bleeding — were real. It is the clearest example in this chapter of a treatment sustained by a subgroup analysis.

**Corticosteroids in head injury.** Routine for decades. **The CRASH trial, reported in 2004, found increased mortality** with methylprednisolone in traumatic brain injury and ended the practice. Corticosteroids are now linked to higher death risk in this indication and are not recommended.

**GM-CSF and intravenous immunoglobulin in neonatal sepsis.** Both were given on mechanism. A 2009 randomised trial found GM-CSF **corrects the neutropenia and does not reduce sepsis or improve survival**, and the INIS trial of intravenous immunoglobulin **found no benefit**. Two clear negatives, in a condition where the cure remains an antibiotic given early.

**Therapeutic hypothermia outside high-resource settings.** This one is different in kind, because the treatment works where it was first tested and does not travel. **In high-income settings, meta-analysis of the major trials found reduced death or major disability with cooling for neonatal encephalopathy, at a number needed to treat of approximately 7†. The HELIX trial, conducted in India, Sri Lanka and Bangladesh, found no reduction in death or disability and an increase in mortality**. WHO does not recommend it outside settings with intensive care and the capacity to deliver it to protocol, and the low-cost adaptations designed for exactly those settings are therefore unsupported rather than merely unproven.

Three others in this chapter belong alongside them, as practices that are contested rather than superseded. **Antenatal thyrotropin-releasing hormone** for fetal lung maturation is a settled negative. **Universal ultrasound screening for hip dysplasia** produced an insignificant reduction in late diagnoses and is not recommended, while the clinical examination that is recommended was found insufficiently reliable by a 2024 review — both the recommended and the unrecommended strategy carry negative evidence. And **secondary decompressive craniectomy** controls intracranial pressure while the DECRA trial found worse outcomes and the later RESCUEicp trial found lower mortality with more dependent survivors; the trials disagree on the direction of benefit and both are printed.

# Chapter 18 — Conditions Related to Sexual Health, the Non-Disease Chapters, and Three Cross-Cutting States

This chapter covers the last of the ICD-11 chapters and three states that cut across all of them.

Part A is ICD-11 chapter 17, conditions related to sexual health. Part B is the seven ICD-11 chapters and sections that do not classify diseases. Part C is three entries — multimorbidity, frailty and palliative care — that belong to no single chapter and govern the outcome of many.

**On the burden basis.** The book's burden basis is the Global Burden of Disease 2023 study, published in *The Lancet* on 12 October 2025 and presented at the World Health Summit in Berlin. It covers 292 causes of death, 375 diseases and injuries, 88 risk factors, 204 countries and territories and 660 subnational locations, from 1990 to 2023, on more than 310,000 data sources. Where a GBD 2023 figure for a particular category could not be obtained, this chapter uses a WHO figure and names it as WHO, with its reference year, in the text.

---

# PART A — ICD-11 chapter 17: conditions related to sexual health

## A standing note on this chapter

**Cure status in Part A.** The four labels — SELF-LIMITING, CURABLE, CONTROLLABLE, RELIEF ONLY — are statements about what a treatment does to the course of a condition. They are given for every entry here, as everywhere else in this book, and where they do not fit the entry says so and gives the reason.

They do not fit either gender incongruence category. The standing interventions there aim at alignment, at function, or at distress, and not at the removal of a lesion, and WHO does not hold the condition to be one of mental ill-health. Both entries say that in place of a label.

They do fit the dysfunctions, and the answer is often worth having. A desire or erectile difficulty caused by a medication is curable by changing the medication. The same difficulty arising from established arterial disease is not. A reader who is given seven sections here and eight everywhere else cannot tell whether the eighth was weighed and withheld or simply forgotten.

**The finding that governs every entry here.** Not a single category in chapter 17 has a prevalence estimate measured against the ICD-11 definition. Every figure in the literature comes from an instrument built for DSM-IV, for ICD-10, or for a bespoke survey question. The chapter has existed in released form for seven years and its epidemiology has not been measured.

The scale of that gap is visible in the chapter's best-evidenced category. Male erectile dysfunction carries a published global prevalence range of 3 to 76.5 per cent, and the systematic review reporting it attributes the range to instrument heterogeneity. A 25-fold spread is not a prevalence estimate. It is a measurement failure, and this book records it as one.

**The structure of the chapter.** Chapter 17 was newly created in ICD-11. The WHO ICD-11 fact sheet lists it as one of three new core chapters, alongside diseases of the immune system and sleep-wake disorders. It contains three blocks of clinical categories — sexual dysfunctions (HA00 to HA0Z), sexual pain disorders (HA20 to HA2Z) and gender incongruence (HA60 to HA6Z) — one aetiology axis (HA40), and two residual codes (HA8Y, HA8Z).

Every sexual dysfunction and HA20 carries the same five-way subdivision: lifelong generalised, lifelong situational, acquired generalised, acquired situational, unspecified. No study has validated that split against natural history, biology or treatment response. It is not repeated in the entries below.

**The aetiology axis, HA40.** This is not a disorder. It is a set of codes applied alongside a dysfunction code to record contributing factors: a medical condition, injury or effect of surgery or radiation (HA40.0); psychological or behavioural factors, including mental disorders (HA40.1); use of a psychoactive substance or medication (HA40.2); lack of knowledge or experience (HA40.3); relationship factors (HA40.4); cultural factors (HA40.5); and other specified (HA40.Y).

HA40 is the chapter's consequential design decision. ICD-10 split sexual dysfunction between an organic set in the genitourinary chapter and a non-organic set in the mental disorders chapter. ICD-11 abolishes that split. One diagnosis is made, and aetiology is recorded separately on its own axis, where it can be multiple. A single presentation may carry a medical, a medication, a knowledge, a relationship and a cultural code at once.

Read in the net: the five aetiology codes are not five candidate causes competing to be the true one. They are five depths at which the same failure to close can be described, and the axis lets all five stand together. This is a reading, not a mechanism.

**What the chapter does not contain.** Chapter 17 is not the complete set of sexual-health conditions. WHO places elsewhere, and lists as exclusions on the chapter page: paraphilic disorders (6D30 to 6D3Z, in the mental and behavioural disorders chapter); adrenogenital disorders (5A71); predominantly sexually transmitted infections (1A60 to 1A9Z); contact with health services for contraceptive management (QA21); sexual dysfunction associated with pelvic organ prolapse (GC42); female dyspareunia (GA12); and pain related to the vulva, vagina or pelvic floor (GA34.0).

Infertility is also outside this chapter. WHO's infertility fact sheet of 28 November 2025 defines it as failure to achieve pregnancy after 12 months or more of regular unprotected intercourse, and gives a lifetime prevalence of approximately one in six people of reproductive age worldwide. That page gives no absolute count and no regional breakdown. WHO issued its first global guideline on infertility on the same date.

**The residual codes.** HA8Y, other specified conditions related to sexual health, and HA8Z, unspecified, carry no epidemiology and no treatment. HA8Z in particular absorbs poorly characterised presentations in routine coding, which inflates the unspecified count in any national dataset built on this chapter.

**Where the evidence base is weakest.** Ranked, weakest first:

1. **Gender incongruence of childhood (HA61).** No prevalence data of any kind. No established aetiology. No reliable persistence figure. Intervention evidence in which nine of ten studies were rated low quality by their own reviewers.
2. **Sexual pain-penetration disorder (HA20).** No prevalence data for the category as defined. The controlling Cochrane review found no demonstrated effect for systematic desensitisation, rated every included study at moderate or high risk of bias, and its literature search ends in August 2012.
3. **Female sexual arousal dysfunction (HA01.0).** No distress-qualified prevalence figure anywhere. The construct's two components correlate poorly.
4. **Orgasmic dysfunctions (HA02).** No distress-qualified prevalence. Sex-asymmetric classification by construction. Behavioural treatment evidence pre-modern in method.
5. **Ejaculatory dysfunctions (HA03).** Self-report prevalence of up to 30 per cent against clinically significant prevalence of under 5 per cent, a sixfold gap, with the guideline rejecting its own field's higher figure.
6. **Hypoactive sexual desire dysfunction (HA00).** Usable United States and Australian data, none elsewhere, none in men, none against the ICD-11 definition. Drug evidence graded very low by its own meta-analysts.
7. **Gender incongruence of adolescence or adulthood (HA60).** Self-identification data exist and are not prevalence of the diagnosis. Adolescent treatment evidence low quality by its reviewers' assessment.
8. **Male erectile dysfunction (HA01.1).** The best-evidenced category in the chapter, and still carrying a published global prevalence range of 3 to 76.5 per cent†.

---

## Hypoactive sexual desire dysfunction (HA00)

**What it is.** Absence or marked reduction of desire or motivation for sexual activity. ICD-11 recognises three presentations: little or no spontaneous desire, with few sexual thoughts or fantasies; little or no responsive desire to erotic cues; or inability to sustain desire once activity has begun.

The pattern must be present episodically or persistently for at least several months and must cause clinically significant distress. The distress requirement does substantial work. Low desire without distress is not a diagnosis under ICD-11.

**Measured.** The largest study is the United States PRESIDE survey: 31,581 women aged 18 and over, drawn from 50,002 sampled households on a nationally representative research panel. Age-adjusted point prevalence was 43.1 per cent for any sexual problem, 22.2 per cent for sexually related personal distress on the Female Sexual Distress Scale, and 12.0 per cent for any distressing sexual problem. By age: 10.8 per cent under 45, 14.8 per cent at 45 to 64, and 8.9 per cent at 65 and over (Shifren et al., *Obstetrics & Gynecology* 2008;112(5):970–978).

Unadjusted component figures from the same survey circulate widely: low desire 39 per cent, arousal problems 26 per cent, orgasm difficulties 21 per cent, any problem 43 per cent, distress 12 per cent†. The 39 per cent low-desire figure and the 12.0 per cent distress-qualified figure differ by a factor of three and are routinely quoted interchangeably. Only the second is diagnostically relevant.

An Australian cohort of 1,548 women aged 65 to 79, mean age 71, found low sexual desire in 88.0 per cent (95 per cent CI 86.3 to 89.6), sexually related personal distress in 15.5 per cent (13.8 to 17.4), and the full diagnosis in 13.6 per cent (11.9 to 15.4)†. Within that cohort the diagnosis was present in 23.7 per cent of partnered women against 5.9 per cent of unpartnered women, and in 31.5 per cent of sexually active against 17.3 per cent of sexually inactive women† (Zeleke, Bell, Billah & Davis, *Menopause* 2017;24(4):391–399).

Low desire rises with age. Distressing low desire does not: it peaks in midlife and falls after. The Australian figures make the divergence plain. Desire is low in nearly nine women in ten at 65 to 79, and one in seven meets the distress-qualified definition.

Usable population data exist for the United States and Australia. Comparable nationally representative, distress-qualified data do not exist for most of the world, including almost all of Africa, South Asia, Latin America and the Middle East. There is no large distress-qualified prevalence study in men.

**Where it starts.** The PRESIDE regression identified poor self-assessed health, low education, depression, anxiety, thyroid conditions and urinary incontinence as correlates of distressing sexual problems. The study is cross-sectional, so direction is not established.

Partnership status and current sexual activity are strongly associated. Partnered women in the Australian cohort had about four times the prevalence of unpartnered women. The direction is the opposite of the naive expectation, and indicates that the distress criterion is partly measuring relational context.

Medication is a measured cause in one direction. Antidepressant-associated sexual dysfunction is established well enough to carry its own Cochrane review of management strategies: 23 trials, 1,886 participants (Taylor et al., Cochrane CD003382, 1 May 2022).

What is not known is more than what is. Whether hypoactive desire is a single entity. Whether the lifelong-acquired and generalised-situational subtypes correspond to anything with distinct natural history, biology or treatment response. Whether the association with depression runs in either direction or reflects a third factor. There is no established biomarker, no established endocrine threshold and no replicated neurobiological finding separating cases from controls.

**Cure status.** Distress traced to a removable cause: CURABLE. The cause may be a medication (HA40.2), a lack of knowledge or experience (HA40.3) or a relationship factor (HA40.4). Where the cause is removed, desire can return. No proportion has been measured, and the trial evidence quantifying the response is thin.

Persistent, with no removable cause: RELIEF ONLY. Flibanserin gave 0.49 more satisfying sexual events per month than placebo, about one every two months. Its authors graded the evidence very low and the overall improvement minimal to absent. The state is not held and nothing removes it.

**Prevention.** No evidence base. No trial has tested prevention of this condition as an outcome.

The one partial item is iatrogenic. Choosing an antidepressant with a lower sexual side-effect profile is a prevention-shaped decision. The comparative evidence addresses management once dysfunction is present, not its prevention — WEAK.

**Treatment.** Flibanserin is the best-quantified drug. A systematic review and meta-analysis pooled 8 randomised trials, 5 published and 3 unpublished, 5,914 women. The pooled mean difference for 100 mg against placebo was 0.49 satisfying sexual events per month (95 per cent CI 0.32 to 0.67). The Female Sexual Function Index desire score difference was 0.27 (0.17 to 0.38)†. That is one additional satisfying sexual event every two months.

Harms in the same analysis: dizziness RR 4.00 (2.56 to 6.27), somnolence RR 3.97 (3.01 to 5.24), nausea RR 2.35 (1.85 to 2.98), fatigue RR 1.64 (1.27 to 2.13). The authors graded the quality of evidence as very low and concluded that the overall improvement was minimal to absent against a substantially raised adverse-event risk (Jaspers, Feys, Bramer, Franco, Leusink & Laan, *JAMA Internal Medicine* 2016).

Testosterone in women is the other pharmacological option. The standing systematic review and meta-analysis of randomised trial data is Islam, Bell, Green, Page & Davis, *Lancet Diabetes & Endocrinology* 2019;7(10):754–766. Its pooled effect sizes are not quoted here; they were not obtained.

Clinical guidance differs by jurisdiction. Flibanserin and bremelanotide are approved by the United States Food and Drug Administration for this condition in premenopausal women. The European Medicines Agency has not approved flibanserin; the manufacturer withdrew its European application. The same evidence base supports a marketing authorisation in one jurisdiction and not in the other. Testosterone for women is approved for this indication in very few countries and is commonly prescribed off-label where it is used.

**Simple means.** Counselling, psychosexual therapy and couple-based interventions require no industrial chain. The measured effect is poorly characterised: no current high-quality systematic review of psychological interventions for hypoactive desire specifically was obtained.

Addressing a removable aetiology is both simple and directly supported by the chapter's own axis. Medication (HA40.2), lack of knowledge or experience (HA40.3) and relationship factors (HA40.4) are each coded causes with an available response. The trial evidence quantifying those responses is thin.

**Gaps.** No prevalence data measured against the ICD-11 definition. No large prevalence study in men. No population data outside high-income Western countries. The four-way subtyping is unvalidated. The 39 per cent and 12.0 per cent figures from one survey differ threefold and are quoted interchangeably. Pharmacological effect sizes are small and their own authors grade the evidence very low.

---

## Female sexual arousal dysfunction (HA01.0)

**What it is.** Absence or marked reduction of response to sexual stimulation. ICD-11 defines the parent category HA01 as covering difficulties with the physiological or the subjective aspects of arousal. The wording admits a presentation in which genital response is intact and subjective arousal absent, and the reverse.

**Measured.** PRESIDE reported arousal problems in 26 per cent of 31,581 United States women, unadjusted. That survey publishes its distress-qualified figure as a composite across problem types, 12.0 per cent, and not separately by type. A distress-qualified arousal-specific prevalence is therefore not available from the largest study.

No nationally representative, distress-qualified prevalence estimate for this condition exists for any country. There are no data outside high-income countries. The quality of the prevalence evidence is low.

**Where it starts.** Postmenopausal urogenital change is the best-established association. Its standing in this category is complicated by the classification itself: ICD-11 excludes from the sexual pain category what is entirely explained by postmenopausal or age-related change, and the analogous reasoning bears on arousal.

Antidepressant medication is an established cause (Taylor et al., Cochrane CD003382, 2022). Beyond these, aetiology is not known. The relationship between measured genital vasocongestion and reported subjective arousal is weak, which undermines the construct itself.

**Cure status.** Arousal difficulty on antidepressant treatment: CONTROLLABLE. Bupropion 150 mg twice daily added to the antidepressant gave SMD 1.60 (95 per cent CI 1.40 to 1.81) in 3 studies, pooled across men and women. The review's authors call the evidence rather limited. The added drug is continued, so the state is held and not removed.

All other presentations: RELIEF ONLY. No treatment has a measured effect on this category. Lubricants, psychosexual counselling and directed stimulation relieve, and their effect is not quantified. Arousal difficulty explained by urogenital atrophy belongs to the genitourinary chapter, where oestrogen is standing treatment.

**Prevention.** No evidence base. No prevention target has been defined for this condition.

**Treatment.** For antidepressant-associated dysfunction, the Cochrane review found a benefit for added bupropion 150 mg twice daily, pooled across men and women: SMD 1.60 (95 per cent CI 1.40 to 1.81), 3 studies. Once-daily 150 mg showed no significant difference. The review's authors describe the available evidence as rather limited and the review carries no GRADE ratings (Taylor et al., Cochrane CD003382, 1 May 2022, 23 trials, 1,886 participants).

Topical and systemic oestrogen is standing treatment for urogenital atrophy. That indication sits in the genitourinary chapter, not here.

**Simple means.** Lubricants, which need no industrial chain of consequence. Psychosexual counselling. Directed stimulation approaches. The measured effect of each is not well quantified for this category.

**Gaps.** No distress-qualified prevalence figure exists. The construct's physiological and subjective components correlate poorly, and no study has established whether they belong in one diagnosis. This is among the weakest-evidenced categories in the chapter.

---

## Male erectile dysfunction (HA01.1)

**What it is.** Inability to attain or maintain an erection sufficient for sexual activity, present for at least several months and causing clinically significant distress. ICD-11 places it in the sexual health chapter rather than the genitourinary chapter. Aetiology — vascular, neurological, endocrine, drug-related, psychological — is coded separately on the HA40 axis rather than determining which chapter holds the diagnosis.

**Measured.** A systematic review of population-based studies in EMBASE and MEDLINE gives a global prevalence of 3 to 76.5 per cent. The review's own explanation for that range is instrument heterogeneity: screening tools in population-based studies are its named major source of discrepancy. Questionnaires derived from the International Index of Erectile Function and the Massachusetts Male Aging Study identified high prevalence even in young men (Kessler, Sollie, Challacombe, Briggs & Van Hemelrijck, *BJU International* 2019).

A 25-fold range is not a prevalence estimate. It is the measurement failure named in the standing note at the head of this part, and it occurs in the chapter's best-studied category.

Guideline-cited estimates circulate alongside it: up to 30 million men in the United States and 150 million men worldwide (American Urological Association erectile dysfunction guideline, 2018; *Journal of Urology* 2018;200:633). These are estimates and not survey measurements.

Figures with comorbidity are better behaved. From the same guideline: present in 38 to 42 per cent of men with hypertension, with about 35 per cent of hypertensive men having some degree of the condition. Diabetes-related prevalence 20 to 85 per cent depending on severity and duration. One study gave an age-adjusted 28 per cent in men with diabetes against 10 per cent without. Up to 72 per cent of affected men have lower urinary tract symptoms or benign prostatic hyperplasia. And 11 per cent report depression. European Association of Urology guidance adds two figures. The condition is common in metabolic syndrome and type 2 diabetes, in up to 70 per cent of patients. And 30 per cent of affected men have co-existing testosterone deficiency (EAU Guidelines on Sexual and Reproductive Health, 2024).

Prevalence rises steeply with age in every study. Age-specific figures from the Massachusetts Male Aging Study, the standard longitudinal source, are not reproduced here; they were not

obtained. Population-based studies exist across many countries and are not comparable, because the instruments differ. No harmonised global estimate exists.

The quality of the prevalence evidence is low for the absolute figure and high for the age gradient and the comorbidity associations.

**Where it starts.** The strongest established associations, with their measures. Diabetes, age-adjusted 28 per cent against 10 per cent. Hypertension, 38 to 42 per cent prevalence in hypertensive men. Metabolic syndrome, up to 70 per cent. Lower urinary tract symptoms or benign prostatic hyperplasia, up to 72 per cent co-occurrence. Testosterone deficiency, 30 per cent co-existence†.

The AUA guideline states that the condition is independently associated with cardiovascular disease and may be the first clinical sign of atherosclerosis in some men. That makes it diagnostically useful beyond itself.

What is not known: the relative contribution of vascular, neurogenic and psychological mechanisms in an individual case, which no available test determines; whether the condition is a causal step toward cardiovascular events or a marker only. Natural history without treatment is poorly described, because treatment is near-universal where it is available.

**Cure status.** Reversible single cause: CURABLE. A causative medication stopped or switched, a correctable endocrine deficiency, or a focal arterial lesion in a young man treated by reconstruction removes the cause, and the dysfunction goes with it. No proportion has been measured. Arterial reconstruction carries a Conditional, Grade C recommendation (AUA 2018).

Established vascular, diabetic or neurogenic disease, or no cause identified: CONTROLLABLE. Phosphodiesterase type 5 inhibitors, vacuum devices and injections restore function while they are used. In men with diabetes the inhibitors raised successful attempts by 26.7 percentage points over control (95 per cent CI 23.1 to 30.3). They do not alter the underlying disease. The condition may be the first sign of atherosclerosis, and that disease remains.

A penile prosthesis is in this stratum, not in the curable one. It replaces the function. It destroys the native erectile tissue and does not restore it.

**Prevention.** The evidence is indirect. The AUA 2018 guideline makes a Moderate Recommendation, Grade C, that men with comorbidities be counselled on diet and physical activity, and states that lifestyle change may improve erectile function. It gives no effect size — WEAK.

The condition's major risk factors — diabetes, hypertension, metabolic syndrome, smoking — are themselves modifiable and quantified. Prevention here is largely prevention of vascular disease. No trial has used incidence of erectile dysfunction as a primary prevention endpoint.

**Treatment.** Phosphodiesterase type 5 inhibitors are first-line. The best-quantified evidence is in men with diabetes: a Cochrane review of 8 randomised trials, 976 men treated and 741 controls, about 80 per cent with type 2 diabetes, mostly 12-week trials. Successful attempts: weighted mean difference 26.7 percentage points (95 per cent CI 23.1 to 30.3). Global efficacy question: RR 3.8 (3.1 to 4.5). IIEF erectile function domain: WMD 6.6 (5.2 to 7.9). Any adverse reaction: RR 4.8 (3.74 to 6.16), headache commonest, then flushing. No trial reported mortality. The review carries no GRADE rating (Vardi & Nini, Cochrane CD002187, 2007).

That is a 2007 review in a diabetic population. It is the best-quantified evidence for the drug class and it is not a general-population estimate.

Guideline positions, with the AUA's own grades (A high certainty, B moderate, C low): oral PDE5 inhibitors, men should be informed of this option — Strong, Grade B; dose titrated for optimal efficacy — Strong, Grade B; vacuum erection device — Moderate, Grade C; intraurethral alprostadil — Conditional, Grade C; intracavernosal injections — Moderate, Grade C; penile prosthesis — Strong, Grade C; penile arterial reconstruction for young men with focal occlusion — Conditional, Grade C; penile venous surgery — Moderate recommendation against, Grade C. Low-intensity shockwave therapy and intracavernosal stem cell therapy are Conditional, Grade C and investigational. Platelet-rich plasma is Expert Opinion and experimental.

The penile prosthesis recommendation is an explicit instance of a strong recommendation on low-certainty evidence, and the guideline says so.

Testosterone: the EAU gives testosterone therapy as first-line in hypogonadal men with mild disease — Strong recommendation, evidence level 1a — and combination of a PDE5 inhibitor with testosterone in more severe disease as a Weak recommendation. A meta-analysis of 913 patients across 8 randomised trials found combination superior to a PDE5 inhibitor alone. Diabetes and obesity reduced the magnitude of improvement from testosterone, which was clinically effective alone only in milder disease (EAU 2024).

Clinical guidance differs between bodies. The AUA and the EAU agree on PDE5 inhibitors first-line and on the staged progression to injections and prosthesis. They differ on testosterone: the EAU gives a strong, 1a-graded recommendation for monotherapy in hypogonadal men with mild disease, while the AUA treats PDE5-plus-testosterone as a Moderate, Grade C option in men with testosterone deficiency and does not foreground monotherapy.

**Simple means.** The vacuum erection device is mechanical, needs no consumables, and carries an AUA Moderate, Grade C recommendation. Exercise and dietary change carry AUA Moderate, Grade C, with no effect size given by the guideline. Smoking cessation. Substituting a causative medication (HA40.2). Psychosexual counselling where HA40.1 or HA40.4 applies; the measured effect of counselling alone, against PDE5 inhibitors, is not well quantified.

**Gaps.** The 3 to 76.5 per cent global prevalence range is the chapter's largest measurement problem. No harmonised instrument is in general use. The Massachusetts Male Aging Study age-specific incidence figures, the standard citation, were not obtained. Guidelines issue strong recommendations on Grade C evidence and say so openly. Lifestyle effect sizes are asserted without numbers by the guideline that recommends them.

---

## Orgasmic dysfunctions and anorgasmia (HA02, HA02.0)

**What it is.** Absence or marked infrequency of orgasm, or markedly diminished intensity of orgasmic sensation, despite adequate stimulation and desire, for at least several months, with clinically significant distress.

In women this includes marked delay in orgasm. In men marked delay is coded instead as male delayed ejaculation, HA03.1. That asymmetry is a classification decision and not a biological finding, and it means the same phenomenon is counted in two different categories depending on sex.

**Measured.** PRESIDE reported orgasm difficulties in 21 per cent of 31,581 United States women, unadjusted. No distress-qualified, orgasm-specific figure is published from that survey. No nationally representative distress-qualified prevalence estimate exists for anorgasmia in any country.

Usable population data do not exist for this category. The available survey data are from the United States and Australia and are not in the diagnostically relevant form. Quality of the prevalence evidence: low.

**Where it starts.** Established: selective serotonin and serotonin-noradrenaline reuptake inhibitor antidepressants (Taylor et al., Cochrane CD003382, 2022). Pelvic surgery and spinal cord injury, which fall under HA40.0.

Lack of knowledge or experience is explicitly coded (HA40.3) and is thought to account for a substantial share of lifelong generalised cases. The proportion has not been measured. Beyond these, aetiology is not known: there is no established neurobiology of orgasmic capacity in humans that distinguishes cases from controls.

**Cure status.** Lifelong generalised anorgasmia in women: CURABLE. Directed masturbation and sensate focus are first-line, and older literature reports high success. That literature rests on small, old, mostly uncontrolled studies. No proportion is given.

Medication-induced, with the drug withdrawn or changed: CURABLE. The anorgasmia resolves on withdrawal.

Medication-induced, with the drug continued: CONTROLLABLE. Added bupropion 150 mg twice daily gave SMD 1.60 (95 per cent CI 1.40 to 1.81) in 3 studies, pooled across men and women. The authors call the evidence rather limited.

All other presentations, including those after pelvic surgery or spinal cord injury (HA40.0): RELIEF ONLY. No treatment in this entry has a measured effect on them.

**Prevention.** No evidence base for primary prevention. The one partial item is antidepressant selection, as in HA00 — WEAK.

**Treatment.** For antidepressant-associated cases, the Cochrane review found added bupropion 150 mg twice daily beneficial: SMD 1.60 (95 per cent CI 1.40 to 1.81), 3 studies, pooled across men and women. The authors describe the evidence as rather limited (Taylor et al., Cochrane CD003382, 2022). Medication-induced anorgasmia also resolves on withdrawal of the drug.

Directed masturbation and sensate focus are the standing behavioural approaches, and are first-line for lifelong generalised anorgasmia in women. Older literature reports high success rates. No current high-quality systematic review with pooled effect sizes was obtained, and the trial quality behind those reports is weak by current standards.

**Simple means.** Directed masturbation, sensate focus and education are the treatment of choice for lifelong generalised anorgasmia and require no industrial chain at all. The measured effect rests on small, old, mostly uncontrolled studies. The simple means is the recommended first-line approach and the evidence for it is weak. Both facts belong in the record.

**Gaps.** No distress-qualified prevalence anywhere. Sex-asymmetric classification, with delay counted as HA02 in women and HA03.1 in men, makes cross-sex comparison impossible by construction. The behavioural treatment evidence is pre-modern in methodology.

---

## Ejaculatory dysfunctions (HA03)

**What it is.** Difficulties with ejaculation in men. The category comprises ejaculatory latencies experienced as too short, coded as male early ejaculation (HA03.0), and as too long, coded as male delayed ejaculation (HA03.1).

**Measured.** Up to 30 per cent of men self-report early ejaculation. The AUA and Sexual Medicine Society of North America guideline states that most such studies used single questions, without measuring frequency or distress. Its own estimate is that clinically significant premature ejaculation affects fewer than 5 per cent of men (AUA/SMSNA Disorders of Ejaculation Guideline, 2020; *Journal of Urology* 2022).

The gap between 30 per cent and under 5 per cent is sixfold, and it comes from the guideline itself. The field's own synthesis discounts the field's own higher figure on methodological grounds.

For delayed ejaculation the same guideline states that prevalence data are more limited. Up to 25 per cent of men presenting with delayed ejaculation are reported to have lifelong difficulty reaching orgasm with a partner. That is a figure about the clinical population and not the general population.

Early ejaculation shows little age gradient; delayed ejaculation increases with age. Neither is well quantified in population data. There are no comparable multi-country population estimates. Quality of the prevalence evidence: low.

**Where it starts.** ICD-11 and the AUA both distinguish lifelong from acquired, and the AUA definitions are operational. Lifelong premature ejaculation means poor ejaculatory control and bother with ejaculation within about 2 minutes of penetration, present since first sexual experience. Acquired premature ejaculation means consistently poor control and bother with latency markedly reduced from the man's earlier function.

Established associations for acquired premature ejaculation include prostatitis, thyroid dysfunction and erectile dysfunction. For delayed ejaculation: SSRI use, pelvic surgery, neurological disease and advancing age. Effect sizes are not well established for any of them.

What is not known is whether lifelong premature ejaculation is a neurobiological variant or the low tail of a normal distribution of latency, and whether a 2-minute cut-off corresponds to anything other than convention. The AUA's own framing — defining the condition by control and bother, not latency alone — concedes that latency does not define a disorder by itself.

**Cure status.** Early ejaculation (HA03.0): CONTROLLABLE. Daily SSRIs, on-demand clomipramine or dapoxetine, and topical anaesthetics are first-line, Strong, Grade B. Combined behavioural and pharmacological treatment is rated Moderate, Grade B. The effect holds while treatment is used, and relapse on withdrawal is usual for the drugs. No proportion has been measured.

Delayed ejaculation (HA03.1): RELIEF ONLY. The guideline finds the evidence insufficient to assess oral drugs. Changing positions or practices may help, and testosterone may be offered where it is deficient. No data support invasive treatment, and no treatment has a measured effect.

**Prevention.** No evidence base. No prevention target has been defined.

**Treatment.** AUA/SMSNA 2020 recommendations, with their grades. Daily SSRIs, on-demand clomipramine or dapoxetine where available, and topical penile anaesthetics as first-line for premature ejaculation — Strong, Grade B. On-demand tramadol after first-line failure — Conditional, Grade C. Combining behavioural and pharmacological approaches, which may work better than either alone — Moderate, Grade B. Referral to a mental health professional with sexual health expertise — Moderate, Grade C. Alpha-1 blockers after first-line failure — Expert Opinion. Surgical approaches including bulking agents — experimental, approved clinical trials only. Alternative therapies — evidence insufficient.

For delayed ejaculation the same guideline holds that modifying sexual positions or practices may help, and that medication adjustment may be considered. The evidence is insufficient to assess the risk-benefit ratio of oral drugs. Testosterone may be offered where testosterone deficiency is present. No current data support invasive non-drug strategies.

Numerical efficacy figures for the first-line drugs — dapoxetine's fold increase in intravaginal ejaculatory latency time, SSRI effect sizes, topical anaesthetic effect — are not reproduced here. They were not obtained.

Clinical guidance differs by jurisdiction for regulatory rather than evidential reasons. Dapoxetine is licensed for premature ejaculation across the European Union and in many other countries, and has never been approved in the United States. The AUA guideline accordingly qualifies its first-line recommendation with "where available". The two bodies agree on the pharmacological class and on topical anaesthetics.

**Simple means.** Behavioural methods need no industrial chain: stop-start and squeeze techniques, pelvic floor training, condom use to reduce sensation, and position change for delayed ejaculation. The AUA rates combined behavioural and pharmacological treatment as superior to either alone at Moderate, Grade B, the strongest grade attaching to any behavioural component in this entry. Behavioural methods alone are not separately graded.

**Gaps.** Prevalence of 30 per cent against under 5 per cent, with the guideline rejecting its own field's higher figure. No population data on delayed ejaculation. Effect sizes for the first-line drugs not obtained. Whether the 2-minute threshold is meaningful is unresolved. Sources disagree on whether premature ejaculation is primarily organic or learned, and the guideline does not adjudicate.

---

## Sexual pain-penetration disorder (HA20)

**What it is.** A single ICD-11 category replacing the former separate diagnoses of vaginismus and non-organic dyspareunia. Diagnosis requires at least one of three presentations. Marked, persistent or recurrent difficulty with penetration, including involuntary tightening of the pelvic floor muscles on attempted penetration. Marked, persistent or recurrent vulvovaginal or pelvic pain during penetration. Or marked, persistent or recurrent fear or anxiety about such pain, anticipated, during, or resulting from penetration.

Further criteria are required. The symptoms recur during sexual activity involving or potentially involving penetration. They occur despite adequate desire and stimulation. They are not entirely explained by a pelvic medical condition causing genital or penetrative pain, nor by a mental disorder, nor by insufficient lubrication, nor by postmenopausal or age-related change. And they cause clinically significant distress. Female dyspareunia (GA12) and pain related to the vulva, vagina or pelvic floor (GA34.0) are excluded.

The exclusions matter for a book organised around disease. Organically explained sexual pain is coded in the genitourinary chapter. HA20 is the residual category after organic explanation has been removed.

**Measured.** No nationally representative prevalence estimate for HA20 as defined exists. Published figures for its predecessor categories vary widely with definition and are not transferable, because HA20's exclusion criteria remove cases that older surveys counted.

Usable population data do not exist for this category. There are no usable multi-country data. Quality of the prevalence evidence: very low. This is the clearest instance in chapter 17 of a newly constructed category with no epidemiology at all.

**Where it starts.** The best-measured finding is pelvic floor muscle involvement. A controlled study of 11 women with provoked vestibulodynia and 11 controls used digital intravaginal assessment with surface electromyography. It found higher superficial pelvic floor muscle activity in cases than controls, stronger responses to painful pressure, and differences in muscle tone, flexibility and relaxation capacity (Gentilcore-Saulnier, McLean, Goldfinger, Pukall & Chamberlain, *Journal of Sexual Medicine* 2010;7(2 Pt 2):1003–1022). With 22 participants this is directional evidence and not an effect-size estimate.

What is not known is whether the pelvic floor finding is cause or consequence of the pain. Nor whether the three qualifying presentations are one disorder or three. Nor whether the fear criterion identifies a distinct group, or captures the consequence of the other two. There is no established pathophysiology, and the category is defined partly by what it is not.

**Cure status.** Pain explained by a pelvic medical condition: not in this category. It is coded in the genitourinary chapter (GA12, GA34.0) and takes the label of that condition.

Pain, difficulty or fear with no explaining finding (HA20 as defined): RELIEF ONLY. The one controlled synthesis, 282 participants, found no clinical or statistical difference between systematic desensitisation and its comparators. A physiotherapy programme changed muscle function in 11 women, and several differences from controls were gone afterwards†. Clinical reports of high success are uncontrolled, and the review's authors do not support a claim of demonstrated cure.

**Prevention.** No evidence base. No prevention target has been defined.

**Treatment.** Standing approaches are pelvic floor physiotherapy, graded dilator or desensitisation programmes, cognitive behavioural therapy, topical anaesthetics, and in some centres botulinum toxin injection.

The controlling controlled evidence is negative. The Cochrane review of interventions for vaginismus included 5 studies, 4 with usable data, 282 participants. Systematic desensitisation was compared with waiting-list control, with desensitisation plus group therapy, and with in vitro desensitisation. The review found no clinical or statistical difference between systematic desensitisation and these comparators. Drop-out was higher in waiting-list groups. All studies were at moderate or high risk of bias and no meta-analysis was possible. The literature search ran only to August 2012 (Melnik, Hawton & McGuire, Cochrane, 1 April 2022).

A Cochrane review published in 2022 whose search ends in 2012 is the field's best controlled synthesis. The gap is fourteen years.

The controlled study above also ran a pelvic floor physiotherapy programme: 8 sessions of manual therapy, biofeedback, electrical stimulation, dilator insertion and home exercises. It reduced responsiveness to pain and improved flexibility and vaginal relaxation capacity. Several differences from controls were no longer present afterwards. That is a small, uncontrolled within-group comparison in 11 treated women.

Clinical practice reports high success rates for multimodal treatment. Those reports are uncontrolled, and the review's own authors do not support a claim of demonstrated cure.

**Simple means.** This is the category where simple means are the main treatment: pelvic floor muscle training and relaxation, graded self-directed dilator use, education, and cognitive behavioural therapy.

The measured position is exact. The physiotherapy study shows physiological change in a small sample. The Cochrane review shows no advantage of desensitisation over its comparators. The simple means are first-line by consensus and unproven by controlled trial.

**Gaps.** No prevalence data for the ICD-11 category. The controlling Cochrane review's search is fourteen years old. Whether the merged category improves on separate vaginismus and dyspareunia diagnoses has not been tested. Sources disagree sharply: the clinical literature reports high cure rates and the controlled synthesis finds no demonstrated effect. This is among the two weakest-evidenced categories in the chapter.

---

## Gender incongruence of adolescence or adulthood (HA60)

**What it is.** A marked and persistent incongruence between an individual's experienced gender and the assigned sex. ICD-11 notes that this often leads to a desire to transition, using hormone treatment, surgery or other health services, to bring the body into alignment with the experienced gender, to the extent desired and possible.

The diagnosis cannot be assigned before puberty. ICD-11 states explicitly that gender variant behaviour and preferences alone are not a basis for assigning it. Paraphilic disorders (6D30 to 6D3Z) are excluded. The index retains the deprecated synonyms gender dysphoria in adolescents and adults, and transsexualism.

**Measured.** In the United States, 2.1 million adults aged 18 and over, 0.8 per cent of that age group, identify as transgender; and 724,000 youth aged 13 to 17, 3.3 per cent of that age group. The adult estimate comes from the 2021 to 2023 Behavioral Risk Factor Surveillance System and the youth estimate from the 2021 and 2023 Youth Risk Behavior Surveillance System (Williams Institute, UCLA School of Law).

These are self-identification figures from population surveys. They are not prevalence of HA60, which requires marked and persistent incongruence meeting clinical criteria. No population survey measures HA60 as ICD-11 defines it. The two quantities should not be equated.

The fourfold difference between the adult figure of 0.8 per cent and the youth figure of 3.3 per cent, in the same country and the same survey programme, shows how sensitive the measurement is to instrument and cohort.

Comparable population self-identification data exist for a small number of high-income countries. Clinic-referral counts exist for more countries and measure service use rather than prevalence. Historical figures derived from specialist clinic attendance are orders of magnitude lower than survey self-identification figures and measure a different thing. Usable population prevalence data for the diagnosis do not exist anywhere.

**Where it starts.** Not known. No biological marker, developmental pathway, genetic finding or prenatal exposure has been established as a cause with a replicated effect size.

One systematic review examined the characteristics of children and adolescents referred to specialist gender services. It was commissioned for the Review of Gender Identity Services for Children and Young People in England. It found the literature insufficient for firm conclusions (Taylor, Hall, Langton, Fraser & Hewitt, *Archives of Disease in Childhood* 2024;109(Suppl 2), 9 April 2024).

What is measured is a rise in referrals to specialist services in several countries over the 2010s, and a shift in the sex ratio of referrals. Precise referral figures and ratios are not quoted here; they were not obtained.

**Classification history.** ICD-11 moved this condition out of the mental disorders chapter. In ICD-10 it was coded as transsexualism, F64.0, within chapter V, mental and behavioural disorders. In ICD-11 it is HA60, in chapter 17.

WHO gives its reason in its classifications FAQ on gender incongruence and transgender health in the ICD. The move reflects current knowledge that trans-related and gender diverse identities are not conditions of mental ill-health. And classifying them as mental disorders, WHO states, can cause enormous stigma.

WHO's stated reason for retaining the category in the classification at all is given on the same page. Whether a category is included depends on whether it serves the ICD's various uses and whether there is sufficient evidence that the health condition exists. WHO states that including gender incongruence should ensure transgender people's access to gender-affirming health care, along with adequate insurance coverage for those services.

At the ICD-11 release WHO also stated that while evidence is now clear that it is not a mental disorder, there remain significant health care needs that can best be met if the condition is coded under the ICD. Dr Lale Say, WHO coordinator for Reproductive Health and Research, stated that removing it from the mental health chapter should reduce stigma and may even increase access, because reducing stigma helps individuals to seek care.

The history is therefore a deliberate reclassification with two stated purposes: removing the implication of mental illness, and preserving a code that secures access to and funding for care. These are matters of classification history and of WHO's own published rationale, and are recorded as such.

**Cure status.** The category does not apply, for the same reason it does not apply to prevention. A cure status asks whether a treatment removes a condition. WHO states that this is not a condition of mental ill-health, and the care described below is not directed at removing the incongruence but at relieving the distress that can accompany it and at aligning the body with the experienced gender. Measuring it against CURABLE or RELIEF ONLY would answer a question the classification does not ask. The outcomes that are measured are reported under Treatment, with their evidence.

**Prevention.** The category does not apply. WHO states that this is not a condition of mental ill-health, no causal pathway is established, and there is no prevention target.

**Treatment.** The evidence for adults and for adolescents must be reported separately, because clinical guidance differs between countries and because the evidence reviews differ in what they found.

WPATH Standards of Care version 8, 2022, is the principal international guidance document. Its prevalence estimates and evidence-grading statements are not reproduced here; they were not obtained.

The systematic reviews commissioned for the Review of Gender Identity Services for Children and Young People in England were published in *Archives of Disease in Childhood*, volume 109, supplement 2, dated 9 April 2024, and funded by NHS England. Two were obtained in full.

On puberty suppression: 50 studies, 11 cohort, 8 cross-sectional and 31 pre-post. Quality 1 high, 25 moderate, 24 low, with low-quality studies excluded from synthesis. Moderate- and high-quality studies consistently showed that treatment suppresses puberty. Gender dysphoria was measured in only 4 studies, and two pre-post studies found no change in gender dysphoria or body satisfaction. Psychological health evidence was limited and inconsistent, with no consistent evidence of benefit. Several pre-post studies found decreases in bone density measures during treatment, with absolute measures mostly stable or slightly changed, and height gains sometimes smaller than expected. The authors concluded that there is a lack of high-quality research assessing puberty suppression. No conclusions can be drawn about gender dysphoria, mental and psychosocial health, or cognitive development. Bone health and height may be compromised during treatment, on consistent moderate-quality evidence mainly from pre-post studies (Taylor, Mitchell, Hall, Heathcote, Langton, Fraser & Hewitt, 2024).

On psychosocial support interventions: 10 studies, 6 pre-post or cohort, 3 mixed methods and 1 secondary analysis of four trials; half from the United States and the rest from Australia, Canada, New Zealand and the United Kingdom. Quality by the Mixed Methods Appraisal Tool was 9 low and 1 moderate. Most mental health and psychosocial analyses showed benefit or no change, and none reported negative effects. The authors concluded that the small number of low-quality studies prevents firm conclusions about effectiveness (Heathcote, Taylor, Hall, Jarvis, Langton, Hewitt & Fraser, 2024; PROSPERO CRD42021289659).

Companion reviews in the same supplement cover social transition, masculinising and feminising hormone interventions in adolescents, care pathways, the characteristics of the referred population, and clinical guideline quality in two parts.

The adolescent evidence base is of low quality and insufficient for firm conclusions on psychological outcomes. That is the assessment of the reviewers who synthesised it.

Clinical guidance differs between countries, and the differences are reported here as fact. In England, NHS England commissioned the independent review published in 2024 and put an interim service specification in place the same year. A new specification for specialist gender incongruence services for children and young people was published in April 2026 after public

consultation, with a referral pathway document. NHS England holds a clinical policy on puberty-suppressing hormones for children and young people with gender incongruence or gender dysphoria. Prescribing of masculinising or feminising hormones within the children's service is paused pending consultation on a revised commissioning policy (NHS England, Gender Dysphoria Clinical Programme pages, October 2026).

WPATH Standards of Care version 8 sets out criteria for gender-affirming care across the lifespan and does not adopt the restrictive posture taken in England. Several other European countries have narrowed adolescent hormonal treatment in recent years and others have not.

The divergence is between bodies reading largely the same low-certainty evidence base and reaching different conclusions about how to act under uncertainty. No position is taken between them here. The two factual points are that the evidence base is low certainty by its own reviewers' assessment, and that bodies in different countries have drawn different clinical policy conclusions from it.

**Simple means.** Social transition requires no industrial chain. Its measured effect was the subject of a dedicated systematic review in the same 2024 supplement (Hall, Taylor, Hewitt, Heathcote, Jarvis, Langton & Fraser); that review's findings were not obtained and are not characterised here.

Psychosocial support: 10 studies, 9 rated low quality, most analyses showing benefit or no change, none showing harm, firm conclusions not possible. Counselling and peer support are widely provided and their measured effect is poorly quantified.

**Gaps.** No population prevalence of the diagnosis anywhere. Self-identification figures differ fourfold between adults and youth in the same survey programme and are not the same quantity as the diagnosis. Aetiology unknown. Adolescent treatment evidence low quality by its own reviewers' assessment. Countries disagree on clinical policy. Long-term outcome data into middle age are scarce for all treatment pathways. Detransition rates are contested and not reliably measured.

---

## Gender incongruence of childhood (HA61)

**What it is.** A pre-pubertal child's experienced or expressed gender clearly differs from the sex assigned at birth. ICD-11 includes a strong desire to be a different gender, distress about actual or anticipated sex characteristics, or strong desire for the characteristics of the experienced gender. It adds a tendency to prefer pretend play, toys, games, activities and playmates associated with the experienced gender.

The incongruence must have persisted for about 2 years. As with HA60, ICD-11 states that gender variant behaviour and preferences alone are not a basis for assigning the diagnosis. Paraphilic disorders (6D30 to 6D3Z) are excluded.

**Measured.** No population prevalence estimate exists. The Williams Institute youth figure of 3.3 per cent of 13- to 17-year-olds in the United States covers adolescents rather than the pre-pubertal group HA61 applies to, and measures self-identification rather than the diagnosis.

Usable population data do not exist for this category at all. The quality of the prevalence evidence is not low. It is absent.

**Where it starts.** Not known. No cause is established. The systematic review of the characteristics of children and adolescents referred to specialist gender services was commissioned precisely because this was unclear (Taylor, Hall, Langton, Fraser & Hewitt, *Archives of Disease in Childhood* 2024;109(Suppl 2)).

One quantity is historically cited: the proportion of pre-pubertal children whose incongruence persists into adolescence. It is contested, derives from small specialist-clinic follow-up series with substantial loss to follow-up, and the figures in general circulation are not reliable. No figure is given here.

**Classification history.** ICD-11 retains the category and requires about 2 years' persistence before it can be assigned, which is a classification response to the uncertainty about natural history.

The category's retention in ICD-11 was contested during development. Submissions argued for its removal on the grounds that it carries a risk of pathologising childhood variance without conferring access benefits, since no medical intervention is indicated before puberty. WHO retained it. The two-year persistence requirement, and the statement that behaviour and preferences alone are insufficient, are the constraints WHO placed on it.

**Cure status.** The category does not apply, for the reason given under prevention. The condition is not held to be one of mental ill-health, no treatment is directed at removing it, and in childhood the recorded course is itself one of the open questions, which is reported under Gaps.

**Prevention.** The category does not apply. No causal pathway is established and no prevention target exists.

**Treatment.** No medical intervention is indicated before puberty. HA60 cannot be assigned before puberty, and puberty suppression by definition begins at puberty. Management before puberty is psychosocial support and watchful assessment.

The evidence for that management is the psychosocial support review described under HA60. Ten studies, 9 of them rated low quality. Most analyses showed benefit or no change and none reported negative effects. Firm conclusions about effectiveness are not possible (Heathcote et al., *Archives of Disease in Childhood* 2024;109(Suppl 2)).

Social transition in childhood is the subject of a dedicated systematic review in the same supplement (Hall et al. 2024). Its findings were not obtained and are not characterised here. Clinical policy on childhood social transition differs between countries.

**Simple means.** Psychosocial support and family counselling are the whole of indicated management and require no industrial chain. The measured effect is as above: low quality, no demonstrated harm, no firm conclusion.

**Gaps.** Everything quantitative. No prevalence. No established aetiology. No reliable persistence figure. Low-quality intervention evidence, with nine of ten studies rated low. International disagreement on how to manage childhood social transition. This is the least evidenced category in chapter 17.

# PART B — the ICD-11 chapters that are not diseases

ICD-11 MMS has 26 numbered chapters plus two lettered sections, V and X. Seven of these do not classify diseases. Each is described here by what it contains, what it is used for, and whether a book organised around diseases needs an entry from it.

---

## Chapter 21 — Symptoms, signs or clinical findings, not elsewhere classified

**What it contains.** Symptom and sign categories organised by body system: blood and immune (MA00 to MA1Y); endocrine, nutritional and metabolic (MA50 to MA6Y); speech, language and voice (MA80 to MB0Y); mental and behavioural (MB20 to MB2Y); nervous system (MB40 to MB9Y); visual (MC10 to MC2Y); ear and mastoid (MC40 to MC6Y); circulatory (MC80 to MC9Y); respiratory (MD10 to MD6Y); digestive and abdomen (MD80 to ME4Y); skin (ME60 to ME6Y); musculoskeletal (ME80 to MF1Y); genitourinary (MF30 to MG0Y); general (MG20 to MG7Z); ill-defined or unknown causes of mortality (MH10 to MH15); and other specified (MH2Y).

**What it is used for.** Recording a presenting symptom when the underlying condition is not yet established, and recording ill-defined causes of death. The chapter's own note states that these categories should be used in conjunction with a code from another chapter that identifies the underlying condition.

**Does a book organised around diseases need an entry?** Yes, one short entry, for two reasons. First, MH10 to MH15, ill-defined and unknown causes of mortality, is the quantity that determines how much of any country's mortality data is usable. A book that cites cause-of-death figures must state that a share of deaths are coded here and are therefore uninformative. Second, the chapter explains why symptom codes appear in routine data alongside disease codes, which bears on every prevalence figure drawn from administrative records.

---

## Chapter 23 — External causes of morbidity or mortality

**What it contains.** Eleven blocks: unintentional causes (PA00 to PB6Z); intentional self-harm (PB80 to PD3Z); assault (PD50 to PF2Z); undetermined intent (PF40 to PH8Z); exposure to extreme forces of nature (PJ00 to PJ0Z); maltreatment (PJ20 to PJ2Z); legal intervention (PJ40 to PJ4Z); armed conflict (PJ60 to PK6Z); causes of healthcare related harm or injury (PK80 to PL14.Z); other specified (PL2Y); and unspecified (PL2Z).

**What it is used for.** Recording how an injury occurred, alongside a chapter 22 code recording what the injury is. The pairing is the point: chapter 22 gives the lesion, chapter 23 gives the mechanism and the intent. Injury mortality statistics are compiled from chapter 23.

**Death tolls by major category.** The figures below are WHO Global Health Estimates and WHO fact sheet figures, each named with its source and its reference year. They are not

GBD figures and must not be cited as such. The GBD 2023 equivalents of these per-category injury figures were not retrievable.

| Category | Deaths per year | Source and year |
|---|---|---|
| All injuries | about 4.4 million, nearly 8 per cent of all deaths† | WHO fact sheet, Injuries and violence, 19 June 2024 |
| Unintentional injuries | 3.16 million† | WHO, same sheet |
| Violence-related injuries | 1.25 million† | WHO, same sheet |
| Road traffic | about 1 in 3 of all injury deaths† | WHO, same sheet |
| Road traffic, standalone | about 1.16 million, 92 per cent in low- and middle-income countries† | WHO fact sheet, Road traffic injuries, 20 July 2026 |
| Intentional self-harm | about 1 in 6 of injury deaths; standalone 727,000, 73 per cent in low- and middle-income countries† | WHO, Injuries and violence 2024; WHO fact sheet, Suicide, data year 2021 |
| Interpersonal violence | about 1 in 10 of injury deaths† | WHO, Injuries and violence 2024 |
| War and conflict | about 1 in 61 of injury deaths† | WHO, Injuries and violence 2024 |
| Falls | 684,000, over 80 per cent in low- and middle-income countries; 37.3 million non-fatal falls requiring medical attention; over 38 million DALYs, nearly 40 per cent in children† | WHO fact sheet, Falls, 26 April 2021 |
| Drowning | about 300,000, 92 per cent in low- and middle-income countries; under-fives nearly a quarter of deaths; ages 0 to 29 are 57 per cent† | WHO fact sheet, Drowning, 1 May 2026 |
| Burns | about 180,000, almost two-thirds in the WHO African and South-East Asia Regions† | WHO fact sheet, Burns, 13 October 2023 |
| Unintentional poisoning | 106,683† | WHO, Prevention and management of cases of poisoning, data year 2016 |

The WHO suicide fact sheet of 28 August 2026 carries two headline totals for the same statistic: over 720,000 in its key facts and 727,000 in its body. Both are printed here as published. Suicide is the third leading cause of death among 15- to 29-year-olds globally, for 2021.

The WHO poisoning fact sheet could not be read, and may have been retired. The 106,683 figure for 2016 comes instead from WHO's chemical safety page on prevention and management of cases of poisoning, which carries no printed date. WHO's injuries and violence fact sheet names poisoning as a cause and gives no global death total.

**Two cautions on the table.** The proportional shares WHO publishes — about a third for road traffic, a sixth for suicide, a tenth for homicide and a sixty-first for war — sum to 61.6 per cent. The standalone counts the table prints for five categories, road, self-harm, falls, drowning and burns, sum to 3.051 million, which is 69.3 per cent of 4.4 million†. The two sums cover different category sets: the shares cover road traffic, suicide, homicide and war, and the counts cover road traffic, self-harm, falls, drowning and burns. The gap of about 7 percentage points is therefore not a discrepancy within one total.

The table's first two rows already account for the whole total: 3.16 million unintentional plus 1.25 million violence-related is 4.41 million against a stated 4.4 million. The two-way split is complete. The shares caution is about the distribution of categories within that total and not about an unaccounted remainder.

Road traffic deaths differ between two WHO sheets. The 2024 cross-cutting sheet's share implies about 1.47 million; the 2026 standalone sheet gives about 1.16 million. Both are printed as published, without reconciliation. WHO's own note is that the two pages use different, unstated data years.

Falls DALYs also differ by source. The WHO falls fact sheet of 26 April 2021 gives over 38 million†. GBD 2023 gives 74.3 million, roughly twice as many. Both stand.

**Maltreatment and interpersonal violence against women.** The maltreatment and assault blocks of this chapter code a burden that WHO measures separately. Lifetime prevalence of physical or sexual intimate partner violence, or non-partner sexual violence, among women and girls is given twice. The fact sheet's key facts give 31.6 per cent, about 840 million women and girls. Its body gives 32 per cent. The page carries both figures for the same statistic.

Intimate partner violence among women aged 15 to 49 ever in a relationship: 25.8 per cent. Among women aged 15 and over ever in a relationship: 24.7 per cent. Non-partner sexual violence: 8 per cent of women aged 15 and over, 263 million since age 15. More than 1 in 5 ever-partnered girls aged 15 to 19 are affected. By region, Oceania 37 per cent, sub-Saharan Africa 32 per cent, southern Asia 31 per cent. On average 140 women and girls were killed daily in 2023 by a partner or other family member (WHO fact sheet, Violence against women, 18 June 2026).

Intimate partner violence is the fourth leading cause of poor health among women by DALYs, on 2025 estimates. The average annual decline in prevalence over twenty years is 0.2 per cent. Economic cost is given as 1 to 6 per cent of GDP in some countries.

**Sex and age pattern.** Twice as many males as females die from injuries and violence. Males are about three-quarters of road traffic deaths, four-fifths of homicide deaths and two-thirds of war deaths. For ages 5 to 29, three of the top five causes of death are road traffic injuries, homicide and suicide. Drowning is the sixth leading cause of death at ages 5 to 14. Fall risk rises with age. About 90 per cent of injury deaths occur in low- and middle-income countries, and injuries and violence cause an estimated 10 per cent of all years lived with disability (WHO, Injuries and violence, 19 June 2024).

**Does a book organised around diseases need an entry?** Yes, a substantial one. Injuries are about 8 per cent of global deaths, which is roughly one death in every twelve and a half, and they are concentrated in the young, so they dominate years of life lost in a way their death share understates. They are also the part of the burden where the causes are entirely external, and the determinants environmental and behavioural rather than pathological.

---

# Chapter 24 — Factors influencing health status or contact with health services

**What it contains.** Four blocks: reasons for contact with the health services (QA00 to QD3Z); factors influencing health status (QD50 to QF2Z); other specified (QF4Y); unspecified (QF4Z). The chapter introduction states that these categories cover circumstances other than a disease or injury that affect health status or prompt contact with health services.

The determinants the chapter codes, by domain: education and literacy; employment and unemployment; occupation and work environment; housing and economic circumstances, including homelessness; the social environment; psychosocial circumstances, including family and relationship disruption, and abuse and neglect; lifestyle factors; and contact-with-services reasons including screening, immunisation, contraceptive management (QA21) and follow-up.

**What it is used for.** Recording why someone is in contact with health services when there is no disease, and recording circumstances that bear on health but are not themselves illness. In practice the chapter is heavily used for preventive-service encounters and sparsely used for social circumstances. That asymmetry is itself a fact worth stating: the social determinant codes exist and are largely not applied, so they generate no usable prevalence data.

**Which determinants have measured health effects large enough to belong in a book about illness.**

| Determinant | Measured effect | Source and year |
|---|---|---|
| Social support and social relationships | Odds ratio 1.50 (95 per cent CI 1.42 to 1.59) for survival with stronger social relationships, across 148 studies and 308,849 participants | Holt-Lunstad, Smith & Layton, *PLOS Medicine* 2010 |
| Income and wealth | Eliminating wealth-related inequality in low- and middle-income countries could save 1.8 million children’s lives each year; within-country income inequality has nearly doubled over two decades; in 201 countries the top 10 per cent earn on average 15 times the bottom 50 per cent | WHO fact sheet, Social determinants of health, 2023, citing the World Inequality Report 2022 |
| Country of residence, composite | Life expectancy gap of up to 33 years between countries; children in low-income countries 13 times more likely to die before age 5 than in high-income countries | WHO fact sheet, Social determinants of health |

| Determinant | Measured effect | Source and year |
|---|---|---|
| Country of residence, composite | An 18-year life expectancy difference between high- and low-income countries; under-5 mortality more than eight times higher in the WHO African than the European region | WHO health topic page, Social determinants of health |
| Housing, employment and social protection, combined policy effect | An extra 0.1 per cent of GDP invested in social protection, labour market, and housing and community policies could improve health for 150,000 people in a country of 40 million within four years | WHO Europe, 2020, via WHO fact sheet |
| Social protection coverage | 3.8 billion people lack social protection coverage such as child and paid sick leave benefits | World Social Protection Report 2024–26, via WHO |
| Employment, gendered | 2.4 billion working-age women lack equal economic opportunities | World Bank, 2022, via WHO |
| Food security and undernutrition | 149 million children under 5 stunted and 45 million wasted, data year 2022; nearly half of under-5 deaths linked to undernutrition | WHO fact sheet, Malnutrition, data year 2022 |
| Displacement | Forcibly displaced people tripled to 122 million between 2008 and 2024 | WHO fact sheet, Social determinants of health |
| Education | WHO states that higher educational attainment is associated with better health and longer life at population level; no effect size is given on the WHO sources consulted | WHO fact sheet, Social determinants of health |
| Housing, separately | Not measured separately on the WHO sources consulted; housing appears only inside the combined policy figure above | WHO fact sheet, Social determinants of health |

The determinants with measured health effects large enough to belong in a book about illness are, on this evidence, social support, income, food security and social protection. Social support carries the single largest measured effect: an odds ratio of 1.50 for survival across 308,849 people, which is larger than many of the treatment effects reported in Part A. Education and housing are among the determinants most often asserted to matter and have no standalone effect size in the WHO sources consulted.

Two figures on food security differ by reference year and are not interchangeable. The 2022 WHO fact sheet gives 149 million children under 5 stunted and 45 million wasted. The 2025 Joint Malnutrition Estimates give 150.2 million stunted and 42.8 million wasted. Both stand; the Joint Malnutrition Estimates are the later figures.

Three limits apply to the whole table. WHO gives no percentage for the share of health outcomes attributable to social determinants; its fact sheet says only that these determinants outweigh genetic influences or health-care access, with no figure attached. Any specific percentage in circulation is not WHO's. The composite country-level gaps, 33 years and 18 years, come from two different WHO pages, are not the effect of any single determinant, and should not be read as one.

**Does a book organised around diseases need an entry?** Yes. The determinants in this chapter shift whole-population mortality, and the social support figure alone exceeds many treatment effects. The entry should be short, should name the domains, and should state that the codes for these determinants exist and are little used.

---

# Chapter 25 — Codes for special purposes

**What it contains.** Two blocks: international provisional assignment of new diseases of uncertain aetiology and emergency use (RA00 to RA09); and national provisional assignment of new diseases of uncertain aetiology (RA20 to RA26).

**What it is used for.** Holding provisional codes for newly emerging or not-yet-understood conditions, and for emergency use. This is the mechanism by which a novel disease acquires a code before it is understood well enough to be placed in a disease chapter. It is the route by which COVID-19 was coded at emergence.

**Does a book organised around diseases need an entry?** One short entry, as classification machinery rather than as disease. Its relevance is that it is the chapter where the next

unknown disease will first appear, and that figures for any newly emerged condition will come from here before they come from anywhere else.

---

## Chapter 26 — Supplementary chapter, traditional medicine conditions

**What it contains.** Two modules: Module I (SA00 to SJ1Z) and Module II (SK00 to ST2Z). These code diagnostic concepts from traditional medicine systems, principally those originating in China, Japan and Korea.

**What it is used for.** Optional recording of traditional medicine diagnoses alongside, not instead of, ICD diagnoses. The WHO ICD-11 fact sheet states that the chapter allows optional recording of traditional medicine diagnoses. It is a supplementary chapter, and codes from it are not used in primary mortality or morbidity tabulation.

That supplementary and optional status is the load-bearing fact. These codes record that a traditional medicine diagnosis was made. They do not record that a disease exists.

**Does a book organised around diseases need an entry?** One short entry, for clarity about what the chapter is and is not. It supplies no disease entries, no prevalence and no treatment evidence. It records diagnostic practice in systems that large populations use, which is a fact about health services rather than about illness.

---

## Supplementary section V — Functioning assessment

**What it contains.** Three blocks: the WHO Disability Assessment Schedule, WHODAS 2.0, in its 36-item version; the Brief Model Disability Survey; and a generic set of functioning domains.

**What it is used for.** Building functioning profiles and overall functioning scores that describe and quantify the level of functioning associated with a health condition. The section rests on two instruments derived from the International Classification of Functioning, Disability and Health — WHODAS 2.0 and the Model Disability Survey — complemented by generic functioning categories derived from ICF Annex 9, described as having high explanatory power. The WHO ICD-11 fact sheet states that the supplementary chapters and sections permit the assessment of functioning.

**Does a book organised around diseases need an entry?** Yes, one short entry. Functioning is the quantity that determines what a disease costs a person, and it is not derivable from a diagnosis code. A book organised around diseases that never records functioning cannot distinguish a diagnosis that disables from one that does not. Section V is the standard instrument set for that measurement.

---

## Chapter X — Extension codes

**What it contains.** Thirteen blocks: severity scale value; temporality; aetiology; topology scale value; anatomy and topography; histopathology; dimensions of injury; dimensions of external causes; consciousness; substances; diagnosis code descriptors; capacity or context; and health devices, equipment and supplies.

**What it is used for.** Adding detail to categories classified elsewhere. The WHO ICD-11 fact sheet states that extension codes add flexible detail to clinical records, support the recording of medicaments using WHO International Nonproprietary Names and WHO Medical Device nomenclature, and document a condition’s severity, anatomy or histopathology.

**One correction worth recording.** Extension codes are commonly described as never used alone. The published rule is narrower. They should never be used in primary classification coding or tabulation, and they may be used alone in other contexts. The restriction is on primary classification coding and tabulation, not on use as such.

**Does a book organised around diseases need an entry?** One short entry. Chapter X is where severity lives, and severity is the difference between a condition that matters and one that does not. The HA40 aetiology axis in chapter 17 and this chapter's aetiology block are the two places where ICD-11 moves causation out of the diagnosis and onto a separate coordinate.

---

# PART C — three cross-cutting entries

---

## Multimorbidity

**What it is.** The co-occurrence of two or more chronic conditions in one person. The standard reference study counted two or more of 40 defined morbidities. Multimorbidity is not a disease. It is a state that changes the behaviour of every disease in it, and it is the condition in which most older patients are treated.

**Measured.** The defining population study covered 1,751,841 patients from 314 Scottish general practices, about a third of the Scottish population (Barnett, Mercer, Norbury, Watt, Wyke & Guthrie, *The Lancet* 2012).

Overall prevalence was 23.2 per cent†. Prevalence rises steeply with age. Half of people had at least one morbidity by age 50, and most people aged 65 and over were multimorbid†.

The counterintuitive result is in absolute numbers. Because the younger population is so much larger, more multimorbid people were under 65, 210,500, than were 65 or over, about 195,000†. Multimorbidity is a condition of old age in rates and not in counts.

The socioeconomic gradient in the same study was steep. Crude multimorbidity was 19.5 per cent in the most affluent areas against 24.1 per cent in the most deprived†. Onset occurred 10 to 15 years earlier in the most deprived areas: young and middle-aged adults there had rates similar to people 10 to 15 years older in the most affluent areas†. Combined physical and mental health comorbidity was 11.0 per cent in the most deprived against 5.9 per cent in the least deprived, nearly double†.

The demographic context is in WHO's ageing fact sheet. About 1 billion people were aged 60 or over in 2020, outnumbering children under 5. One person in six will be 60 or over by 2030, about 1.4 billion. The 60-plus population doubles to 2.1 billion by 2050, and the 80-plus group triples between 2020 and 2050 to 426 million. The share over 60 rises from 12 per cent in 2015 to 22 per cent in 2050. By 2050 two-thirds of people over 60 will live in low- and middle-income countries. That fact sheet gives no multimorbidity prevalence figures of its own.

**Where it starts.** Multimorbidity accumulates from the risk factors of its component conditions, and the measured gradient is socioeconomic. Deprivation moves onset forward by 10 to 15 years and roughly doubles combined physical and mental comorbidity†.

Multimorbidity increases mortality, hospital admission, length of stay, functional decline and healthcare cost. Pooled outcome hazard ratios for the state itself were not obtained, and none is given here. The Barnett study's own contribution was the deprivation gradient and the age distribution, not outcome hazard ratios.

What is not known is whether multimorbidity has any properties beyond the sum of its components — whether particular clusters behave differently from the arithmetic of their parts.

**Cure status.** CONTROLLABLE. Each component condition is treated on its own terms and the state itself does not remit. No intervention removes multimorbidity, and the structured interventions aimed at its main iatrogenic consequence have not demonstrated an effect on patient outcomes.

**Prevention.** No trial has used incidence of multimorbidity as an endpoint. The one measured handle is the socioeconomic gradient, which is an observation and not an intervention — WEAK.

The determinants in ICD-11 chapter 24 are the relevant targets, and the measured effects there are given in Part B.

**Treatment.** Each component condition carries its own standing treatment. The problem multimorbidity creates is additive: multi-drug treatment in which each drug is individually guideline-indicated, with an interaction and adverse-effect burden that no single-disease guideline accounts for. The measured question is whether structured intervention improves outcomes.

The controlling evidence is a Cochrane review of interventions to improve the appropriate use of polypharmacy for older people, published 11 October 2023, with searches to January 2021 and an update to February 2023. It included 38 studies, 24 randomised and 14 cluster-randomised, with 18,073 older people across 19 countries (Cole, Byrne et al.).

- Hospital admissions: pharmaceutical care may make little or no difference. 14 studies, 4,797 participants. Certainty low.
- Medication appropriateness, by expert judgement: effect uncertain. Mean difference −5.66 (95 per cent CI −9.26 to −2.06), 8 studies, 947 participants. Certainty very low.
- Quality of life: may make little or no difference. 16 studies, 7,458 participants. Certainty low.

Certainty ranged from low to very low across the pooled outcomes, owing to high or unclear risk of bias and substantial between-study variation.

This is the entry's central finding, and it runs against the direction of the hopeful results elsewhere in this book. Thirty-eight trials and 18,073 participants produce no demonstrated effect on hospital admission or on quality of life. The authors grade their own evidence low to very low. The measurable achievement is a change in prescribing appropriateness scores, at very low certainty. Deprescribing is widely recommended and its patient-outcome benefit is not demonstrated.

**Simple means.** A written list of every medicine a person takes, reviewed against every diagnosis, needs no industrial chain. So does the question of which drug on the list is treating a side effect of another. Neither has a demonstrated effect on admissions or quality of life, on the evidence above, and both are the cheapest available form of the intervention that was tested.

**Gaps.** No pooled outcome hazard ratios for the state itself. The defining prevalence study is one country, 2012, and primary-care-record based, so the 23.2 per cent figure is not a global estimate. Low- and middle-income countries, where two-thirds of older people will live by 2050, have little multimorbidity epidemiology. Deprescribing trials measure process rather than patient outcome, and say so.

---

## Frailty

**What it is.** A state of reduced physiological reserve across multiple systems, with heightened vulnerability to stressors. Two operational definitions dominate, and they do not measure the same thing.

The physical phenotype uses five criteria: unintentional weight loss of 10 lb in the past year; self-reported exhaustion; weakness by grip strength; slow walking speed; and low physical activity. Three or more makes a person frail; one or two makes them intermediate, or pre-frail (Fried, Tangen, Walston et al., *Journals of Gerontology Series A* 2001).

The deficit accumulation definition, or frailty index, counts accumulated deficits across a wide list of domains, including psychosocial ones.

**Measured.** The original cohort, community-dwelling adults in the Cardiovascular Health Study, gave frailty at 6.9 per cent with a four-year incidence of 7.2 per cent, rising with age and higher in women† (Fried et al. 2001).

The first major synthesis covered 21 studies and 61,500 community-dwelling adults aged 65 and over. Overall weighted prevalence was 10.7 per cent (95 per cent CI 10.5 to 10.9).

By definition: physical phenotype 9.9 per cent across 15 studies and 44,894 participants; broad phenotype including psychosocial aspects 13.6 per cent across 8 studies and 24,072 participants, a significant difference. Women 9.6 per cent against men 5.2 per cent. Prevalence across individual studies ranged from 4.0 to 59.1 per cent, which the authors attributed mainly to definitional differences (Collard, Boter, Schoevers & Oude Voshaar, *Journal of the American Geriatrics Society* 2012).

The largest synthesis covered 240 studies, 265 prevalence estimates, 62 countries and 1,755,497 participants aged 50 and over (O'Caoimh, Sezgin, O'Donovan, Molloy, Clegg, Rockwood & Liew, *Age and Ageing* 2021;50(1):96–104; PROSPERO CRD42018105431).

- Physical frailty 12 per cent (95 per cent CI 11 to 13), from 178 estimates†.
- Frailty index 24 per cent (22 to 26), from 71 estimates†.
- Pre-frailty: physical 46 per cent (45 to 48); frailty index 49 per cent (46 to 52)†.
- Sex: physical frailty 15 per cent in women (14 to 17) against 11 per cent in men (10 to 12); frailty index 29 per cent in women (24 to 35) against 20 per cent in men (16 to 24)†.
- Nationally representative studies only: physical frailty 7 per cent (5 to 9); frailty index 24 per cent (22 to 26)†.
- Age gradient: physical frailty rose from 6 per cent at a minimum entry age of 50 to 59, to 28 per cent at 80 to 89, to 46 per cent at 90 and over†.
- Region: highest in Africa at 22 per cent, on 5 data points, and lowest in Europe at 8 per cent†.
- Over time: physical frailty rose marginally after 2012, from 12 to 13 per cent; frailty index estimates rose from 24 to 28 per cent†.

The authors state that the data are heterogeneous and limited, with $I^2$ of 99 to 100 per cent†. Age explained little of the variation, with an adjusted $R^2$ of about 3 per cent. Country coverage is uneven, with few data from low- and middle-income countries and few nationally representative studies. Thirty-four low-quality studies were excluded using the Loney tool, and reporting bias is possible. There is no formal GRADE rating; the authors call their figures the best available estimates.

The definitional spread is the entry's main quantitative fact. Twelve per cent against 24 per cent for the same populations, depending on which definition is applied, and 7 per cent against 24 per cent within nationally representative studies alone.

**Where it starts.** Frailty accumulates with age and is not reducible to age: in the largest synthesis age explained about 3 per cent of the variation between estimates†. Two bedside measurements predict outcome well enough to serve as the entry's measured core.

Grip strength is the better quantified. The PURE study enrolled 142,861 participants, analysed 139,691, across 17 countries at all income levels. Per 5 kg reduction in grip strength: all-cause mortality HR 1.16 (95 per cent CI 1.13 to 1.20); cardiovascular mortality HR 1.17 (1.11 to 1.24); myocardial infarction HR 1.07 (1.02 to 1.11); stroke HR 1.09 (1.05 to 1.15) (Leong, Teo, Rangarajan et al., *The Lancet* 2015).

Grip strength is a one-instrument measurement taking a few seconds, and it predicts death across 17 countries. For a reference work it carries the most favourable ratio of information to measurement in the whole frailty literature.

Gait speed is the second predictor. The standard pooled analysis of gait speed and survival in older adults is Studenski et al., *JAMA* 2011; its pooled hazard ratio per 0.1 m/s is not quoted here, because it was not obtained. What is established is that slow walking speed is one of the five physical phenotype criteria. The phenotype itself predicted falls, worsening mobility or activities-of-daily-living disability, hospitalisation and death over 3 years. Unadjusted hazard ratios ran from 1.82 to 4.46 and adjusted hazard ratios from 1.29 to 2.24 (Fried et al. 2001).

Read in the net: reduced reserve is windings that no longer return in phase, so tension passes to the meshes beside them. Grip strength and gait speed are read at the depth where that shows, which is why one measurement reports on the whole. This is a reading, not a mechanism.

**Cure status.** CONTROLLABLE. Continued exercise reduces the rate of falls, which is frailty's main clinical consequence, at high certainty. No intervention has been shown to reverse frailty status itself, and the effect requires that the exercise continue.

**Prevention.** Exercise against falls — STRONG.

The Cochrane review of exercise for preventing falls in older people living in the community, published 31 January 2019, covered 108 randomised trials, 23,407 participants and 25 countries, mean age 76 and 77 per cent women†.

- Rate of falls: rate ratio 0.77 (95 per cent CI 0.71 to 0.83), about 23 per cent fewer falls. 59 studies, 12,981 participants. High-certainty evidence.
- Number of people falling: risk ratio 0.85 (0.81 to 0.89), about 15 per cent fewer fallers. 63 studies, 13,518 participants. High-certainty evidence.

**These are the only GRADE high-certainty figures anywhere in this chapter's source material.** Across chapter 17, the non-disease chapters and all three cross-cutting states, exercise for falls prevention is the single intervention carrying GRADE high certainty. Everything else in this material is low, very low, or ungraded.

Within that review, balance and functional training reduced falls; multicomponent programmes, usually balance plus functional plus resistance exercise, probably did too; and Tai Chi may help. Evidence on fractures, medical-attention falls and quality of life was of lower certainty. Adverse events were mostly minor and musculoskeletal.

Prevention of frailty status itself, as distinct from falls, has no comparable evidence. No Cochrane review of multicomponent interventions with frailty status as the endpoint was obtained. The largest prevalence review notes that interventions may slow frailty progression and concludes that the risk-benefit of population screening remains unclear, because few high-quality randomised trials exist — WEAK.

**Treatment.** Exercise, on the figures above. Treatment of the component deficits — nutrition for weight loss, correction of anaemia, review of sedating medication, management of pain limiting activity — is standing practice and is not supported by trial evidence with frailty status as the endpoint.

**Simple means.** Everything that matters here is simple means. The two best predictors are a hand dynamometer and a measured walk. The intervention with the only high-certainty result is balance and functional exercise, which requires a floor, a chair and someone to teach the progression. Tai Chi needs nothing at all. The measured effect is a rate ratio of 0.77 for falls, at high certainty†.

**Gaps.** Definition determines prevalence by a factor of two to three. Heterogeneity is $I^2$ 99 to 100 per cent in the largest meta-analysis. African prevalence rests on 5 data points. Few studies are nationally representative, and restricting to those halves the physical frailty estimate, from 12 to 7 per cent. Gait speed effect sizes were not obtained. No high-quality trial evidence shows that any intervention reverses frailty status, as distinct from reducing falls.

---

## Palliative care

**What it is.** Care directed at relieving the suffering caused by a serious illness, rather than at removing the illness. It covers pain and symptom control, and psychological, social and spiritual support, for patients and families. It is the standing response where cure is not available, and it is also given alongside disease-directed treatment.

**Measured.** 56.8 million people need palliative care each year, including 25.7 million in the last year of life. About 14 per cent of those who need it receive it. Most people in need live in low- and middle-income countries. For children, 98 per cent of those needing palliative care live in low- and middle-income countries, and almost half of those in Africa (WHO fact sheet, Palliative care, 5 August 2020).

Relief is possible for more than 90 per cent of patients with advanced cancer, and over 80 per cent of patients in the terminal phase suffer moderate to severe pain (WHO fact sheet, Cancer).

The Lancet Commission on palliative care and pain relief is the standard source for estimates of serious health-related suffering and for the opioid access analysis (Knaul, Farmer, Krakauer, Foley, Frenk, Jamison, Rajagopal, Atun et al., *The Lancet* 2018;391(10128):1391–1454). Its specific figures and its morphine-equivalent tables are not reproduced here; they were not obtained. The citation is given so the figures can be retrieved.

**Where it starts.** Need for palliative care arises from the conditions that cause serious health-related suffering. Most trial evidence is in advanced cancer. Need is substantially non-cancer — heart failure, chronic obstructive pulmonary disease, dementia, HIV — and the trial base in those populations is much thinner.

What determines whether need is met is not pathology but supply. The measured determinant is access to oral morphine, given below.

**Cure status.** The label does not apply. Palliative care is a property of care and not a state of a person: it is applied alongside whatever label the underlying condition carries, and it does not change that label. The measured benefits are in quality of life and symptom intensity, not in disease course.

**Prevention.** Not applicable to the need itself, which follows from the underlying diseases. The preventable quantity is unrelieved pain, and the measured handle on it is morphine availability — the gap is given below, and no trial grade attaches to a supply figure.

**Treatment.** The landmark trial is Temel et al., *New England Journal of Medicine* 2010;363(8):733–742, published 18 August 2010. It randomised early palliative care integrated with standard oncologic care against standard oncologic care alone. The population was ambulatory patients with newly diagnosed metastatic non-small-cell lung cancer (NCT01038271).

- 151 patients randomised; 27 died before 12 weeks; 107 of the remainder, 86 per cent, completed assessments†.
- Quality of life at 12 weeks, the primary outcome: mean FACT-L score 98.0 against 91.5, P=0.03, on a scale of 0 to 136 where higher is better.
- Depressive symptoms: 16 per cent against 38 per cent, P=0.01†.
- Aggressive end-of-life care: 33 per cent against 54 per cent, P=0.05†.
- Median survival: 11.6 against 8.9 months, P=0.02†.

A median survival advantage of 2.7 months from less aggressive care is the finding that made the trial a landmark, and it is the figure most often cited from it.

**That survival benefit does not survive pooling.** The Cochrane review of early palliative care for adults with advanced cancer, published 12 June 2017 with searches to October 2016, covered 7 randomised and cluster-randomised trials and 1,614 participants.

- Health-related quality of life: SMD 0.27 (95 per cent CI 0.15 to 0.38), a small improvement. In natural units, FACT-G scores rose about 4.59 points more than with standard care (2.55 to 6.46). **Certainty: low**.
- Symptom intensity: SMD −0.23 (−0.35 to −0.10), a small reduction. **Certainty: low**.
- Survival: no difference detected. Hazard ratio for death 0.85 (0.56 to 1.28), 4 studies, 800 participants. **Certainty: very low**.
- Depression: no significant difference. SMD −0.11 (−0.26 to 0.03). **Certainty: very low**.

Both results belong in the record with their certainty ratings attached. Across four trials and 800 participants the hazard ratio for death is 0.85 with a confidence interval spanning 1, rated very low certainty. The quality of life and symptom benefits do survive pooling, at small effect size and low certainty. A reference work that cites Temel 2010 alone overstates the survival case. One that cites the Cochrane review alone understates how the field was changed by Temel.

**The global access gap for oral morphine.** From the International Narcotics Control Board, as reported by WHO (WHO fact sheet, Palliative care, 5 August 2020):

- In 2018, 79 per cent of the world's population, mainly in low- and middle-income countries, consumed 13 per cent of the morphine used for pain management. That morphine amounted to 1 per cent of the 388 tons manufactured worldwide†.
- In 2014, 80 per cent of the world's population consumed 9.5 per cent of the morphine used for pain management†.

Two things follow. Roughly four-fifths of humanity has access to about a tenth to an eighth of the world's pain-relief morphine, a sixfold to eightfold under-consumption relative to population share. And the figure moved between 2014 and 2018, from 9.5 to 13 per cent, so the gap is narrowing slowly.

The 1 per cent of 388 tons is the figure that shows the scale. The morphine used for pain management by most of the world's people is about 3.9 tons a year against total manufacture of 388 tons, most of which goes to other opioid products.

Per-capita morphine-equivalent consumption by WHO region or by country is published by the International Narcotics Control Board and in the Lancet Commission. Those figures were not obtained and are not estimated here.

**Simple means.** Oral morphine is itself a simple means: it is off-patent, on the WHO Model List of Essential Medicines, needs no cold chain, and is given by mouth. Where it reaches a patient it costs very little per day. The barrier is regulatory and logistical, not technical, and the consumption figures above measure the size of that barrier.

Beyond the drug: positioning, mouth care, pressure-area care, the presence of a person who knows what is happening, and clear explanation to the family. None requires an industrial chain. None has a pooled effect size in the literature cited here.

**Gaps.** The Lancet Commission's own figures were not obtained and should be retrieved directly. The Cochrane synthesis is from 2017 with searches to 2016, so later trials in non-lung and non-cancer populations are not in the pooled estimates given. Morphine consumption data here are at income-group level, not regional. Most trial evidence is in advanced cancer while need is substantially non-cancer. The 56.8 million need estimate is modelled, not measured.

# Part 3 — The Simple Means

# Part 3 — Simple Means

Part 1 closed on the layer that carries the largest numbers in this book and the smallest budgets. This part audits it.

A simple means, in this book, is an intervention that prevents, cures or controls a condition without a long industrial supply chain behind it. A sachet of salt and glucose. A bar of soap. A bed net. A lamp at the right hour. Thirty minutes of walking. A mother's chest.

The dossier underneath this part catalogues forty-six such interventions, graded as fifty-nine rows because several are graded separately per population or per outcome. About half of what is commonly claimed for this class does not survive the grading. Both halves are printed. A reference work that passes on the favourable half is not cheaper to use; it is wrong in a direction that is hard to detect.

The order here is deliberate. What holds comes first, with its figures. What does not hold comes second, with its figures. Then the two cases that mark where the category stops.

---

## 3.1 What holds

Twenty-five rows carry an unqualified STRONG. Two carry a qualified STRONG, exercise for chronic low back pain against no treatment and the DASH diet for blood pressure. Two carry a lower grade for a second outcome, iron in pregnancy and compression for venous leg ulcers. Each is flagged where it appears. Vaccination also reaches STRONG for effect and is excluded from these counts, because it sits outside the category by construction; §3.3 gives the reason.

**Oral rehydration solution.** The reduced-osmolarity formula against the old one: unscheduled intravenous infusion OR 0.59 (0.45 to 0.79), eleven trials reporting, eight pooled. WHO and UNICEF state the same result as a 33 per cent reduction in unscheduled supplemental intravenous therapy. Stool output fell about 20 to 25 per cent and vomiting about 30 per cent, neither with a pooled estimate.

Against intravenous rehydration itself — the comparison that matters for a setting with no drip — seventeen trials and 1,811 children. Treatment failure risk difference +4 per cent (1 to 7), number needed to treat 25: roughly one child in twenty-five on oral therapy still needs a drip. Hospital stay was 1.20 days shorter (−2.38 to −0.02). With the WHO low-osmolarity formula specifically there was no significant difference in failure against intravenous therapy, in six trials and 729 children. Phlebitis favoured oral therapy at NNT 50 (25 to 100); paralytic ileus favoured intravenous at NNT 33 (20 to 100).

The current UNICEF indicative price for a low-osmolarity sachet is US$0.05, read off the catalogue in October 2026. The co-packaged course with zinc is given at US$0.57 in the UNICEF indicative price list, 2021.

**Zinc for childhood diarrhoea above six months.** Thirty-three placebo-controlled trials, 10,841 children. Duration above six months: 11.46 hours shorter (−19.72 to −3.19). In children above six months with signs of malnutrition the reduction was 26.39 hours (−36.54 to −16.23), and this is the one high-certainty cell in the table. Diarrhoea still present at day seven: RR 0.73 (0.61 to 0.88). The WHO course is 20 mg a day for ten to fourteen days.

**Universal salt iodisation.** The physiology is settled: iodine is required for thyroid hormone synthesis. The population data are large and concordant. Goitre among Michigan schoolchil-

dren fell from 38.6 per cent in 1924, the year of iodisation, to 1.4 per cent in 1951†. The number of countries where iodine deficiency is a public health problem fell from 110 in 1993 to 54 in 2003 to 28 now†. Public-sector cost is US$0.05 per person per year†.

**Periconceptional folic acid, for recurrence.** The MRC Vitamin Study randomised 1,817 women, all with a previous neural-tube-defect pregnancy, and had 1,195 informative pregnancies. Neural tube defects: 6 of 593 on folic acid against 21 of 602 without, RR 0.28 (0.12 to 0.71), a 72 per cent protective effect (29 to 88). The Cochrane pooled recurrence figure is RR 0.34 (0.18 to 0.64). Multivitamins without folic acid showed no clear effect, RR 0.80 (0.37 to 1.72). The qualifier on this figure is in §3.2 and it is important.

**Vitamin D for rickets.** Deficiency causes rickets and osteomalacia, and correction cures them. This is settled physiology, and it is the only vitamin D indication in this part that reaches STRONG in the positive direction.

**Bright light.** Seasonal affective disorder, as treatment: effect size 0.84 (0.60 to 1.08) across eight studies, which the authors describe as equivalent to most antidepressant trials. Dawn simulation 0.73 (0.37 to 1.08)†. As an adjunct in non-seasonal depression, eleven randomised trials and 858 patients: remission 40.7 against 23.5 per cent, OR 2.42 (1.50 to 3.91); response 60.4 against 38.6 per cent, OR 2.34 (1.46 to 3.75)†. The dose in these trials is about 10,000 lux for thirty minutes or more a day†.

In the one head-to-head randomised trial against fluoxetine — 122 patients, halted early — light reached a MADRS effect size of 0.80 (0.28 to 1.31) against placebo and the drug reached 0.24 (−0.27 to 0.74). That trial is graded MODERATE on its own, and it is reported here because it is the comparison people ask for.

**Timed light for shift work disorder.** Light in the work environment with morning light restriction carries the American Academy of Sleep Medicine's highest recommendation level, Standard. Morning light for delayed sleep phase carries the next level, Guideline, and its dosing trial has twenty patients.

**Dietary fibre, on its trial outcomes.** Body weight −0.37 kg (−0.63 to −0.11), high certainty. Systolic blood pressure −1.27 mm Hg (−2.50 to −0.04). Total cholesterol −0.15 mmol/L (−0.22 to −0.07). WHO advises at least 25 g a day for people over ten. These are the randomised numbers, and they are small; §3.2 gives what is usually quoted instead.

**Physical activity, on dose-response mortality.** Device-measured, individual-level data from eight studies, 36,383 participants and 2,149 deaths†. Highest against lowest quartile of total activity: HR 0.27 (0.23 to 0.32); highest quartile of sedentary time, 2.63 (1.94 to 3.56)†. In fifteen cohorts and 47,471 adults, the top step quartile at a median 10,901 steps a day had HR 0.47 (0.39 to 0.57) against a median 3,553†. The risk reduction plateaus around 6,000 to 8,000 steps in adults over sixty and 8,000 to 10,000 below sixty†.

WHO advises 150 to 300 minutes a week of moderate activity, or 75 to 150 vigorous, plus muscle strengthening on two or more days. No dose-response was found for strengthening volume above that minimum.

**Breastfeeding, on infection.** Exclusive breastfeeding against none, infants under six months: diarrhoea morbidity RR 0.20 (0.13 to 0.29), diarrhoea hospitalisation 0.09 (0.02 to 0.44)†. Diarrhoea mortality for any breastfeeding against none, 0.23 (0.13 to 0.42)†. Lower respiratory infection morbidity 0.68 (0.60 to 0.77), mortality 0.30 (0.16 to 0.56), hospitalisation 0.33 (0.24 to 0.46)†. Sudden infant death in high-income countries fell 36 per cent (19 to 49)†.

WHO puts exclusive breastfeeding at six months at about 47 per cent for 2018 to 2025. It states that nearly 400,000 under-five deaths a year would be prevented by exclusive breastfeeding to six months with continued breastfeeding to two years.

**Handwashing with soap, on diarrhoea.** Day-care and schools in high-income countries: incidence rate ratio 0.70 (0.58 to 0.85), nine trials, 4,664 participants, high certainty†. Communities in low- and middle-income countries: 0.71 (0.62 to 0.81), nine trials, 15,950 participants†. About a thirty per cent reduction in episodes. The mortality claim is in §3.2.

**Insecticide-treated bed nets.** Against no net: all-cause child mortality rate ratio 0.83 (0.77 to 0.89), five trials, 200,833 participants, high certainty†. Uncomplicated *P. falciparum* incidence 0.55 (0.48 to 0.64), high certainty†. Severe malaria RR 0.56 (0.38 to 0.82), high

certainty†. Deaths averted per 1,000 children protected per year: 5.6 (3.6 to 7.6) at all ages, 6.4 (4.16 to 8.69) at one to fifty-nine months†.

One caveat belongs with the figure. The incremental benefit of the insecticide over an untreated net is not statistically established for mortality: 0.67 (0.36 to 1.23)†. And pyrethroid resistance is growing, which the pre-2018 trials do not capture.

**Salt reduction, on blood pressure.** Thirty-four trials of at least four weeks, 3,230 participants, with urinary sodium falling about 75 mmol a day, roughly 4.4 g of salt†. Systolic: −4.18 mm Hg (−5.18 to −3.18) overall, −5.39 (−6.62 to −4.15) in hypertensive participants, −2.42 (−3.56 to −1.29) in normotensive†. Measured counter-effects exist and are printed: plasma renin, aldosterone and noradrenaline all rose slightly.

WHO gives global mean adult sodium intake for 2021 as 4,278 mg a day, about 11 g of salt, against a recommended limit under 2,000 mg. The attributable death figure differs between sources and both are printed: the WHO sodium reduction fact sheet of 11 May 2026 gives 1.7 million deaths a year for 2023, while the 2023 WHO sodium report as carried in secondary coverage gives 1.89 million. Either way it is the largest diet-related figure WHO publishes. Both are model outputs built on the blood-pressure effect plus blood-pressure-to-event associations, not event counts from salt-reduction trials.

**Smoking cessation, and brief physician advice.** Among British doctors, continuing smokers died about ten years earlier, and quitting at thirty regained about ten years, at forty about nine, at fifty about six, at sixty about three. In US cohorts the hazard ratio for death among current smokers aged 25 to 79 was 3.0 (2.7 to 3.3) in women and 2.8 (2.4 to 3.1) in men†.

Brief advice from a physician against no advice: RR 1.66 (1.42 to 1.94) across seventeen trials, in a review of forty-two trials and more than 31,000 smokers†. Intensive against brief advice, 1.37 (1.20 to 1.56)†. The absolute size matters and is small: assuming 2 to 3 per cent unassisted quitting, brief advice adds one to three quitters per hundred smokers advised.

**Fluoride toothpaste.** Seventy-four studies, seventy with usable data, 42,300 children†. Prevented fraction for decayed, missing and filled surfaces: 24 per cent (21 to 28)†. The mechanism is settled.

**Toothbrushing against hospital-acquired pneumonia.** Fifteen randomised trials, 2,786 patients, all but one in intensive care†. Hospital-acquired pneumonia RR 0.67 (0.56 to 0.81); ventilator-associated pneumonia 0.68 (0.57 to 0.82); death in intensive care 0.81 (0.69 to 0.95); length of stay in intensive care −1.78 days (−2.85 to −0.70)†. Two, three and four brushings a day performed alike.

This holds for ventilated patients. Outside that setting only two eligible studies exist, and the general claim is not supported.

**Daily oral iron in pregnancy, for anaemia.** Fifty-seven trials, 48,971 women. Maternal anaemia 4.0 against 7.4 per cent, RR 0.30 (0.20 to 0.47); iron deficiency at term 0.51 (0.38 to 0.68); iron-deficiency anaemia at term 0.41 (0.26 to 0.63), moderate certainty. Low birthweight 0.84 (0.72 to 0.99), with the upper bound touching unity, and that row is graded MODERATE. No effect is established for preterm birth, 0.93 (0.84 to 1.02).

**Iodine in pregnancy, in severe deficiency.** Supplementation to a total intake of 250 µg a day clearly reduces or eliminates cretinism where deficiency is severe. That is the whole of the STRONG claim, and §3.2 has the rest.

**Exercise for knee osteoarthritis.** Forty-four trials, 3,537 participants for pain. Pain SMD −0.49 (−0.59 to −0.39), which is 12 points lower on a 0 to 100 scale (10 to 15), high certainty. Physical function −0.52 (−0.64 to −0.39), about 10 points better. Withdrawals did not differ: OR 0.93 (0.75 to 1.15). Effects are measured immediately after treatment, so durability depends on continuing.

**Exercise for chronic low back pain.** Against no treatment, usual care or placebo: pain −15.22 on a 0 to 100 scale (−18.26 to −12.18), thirty-five studies, 2,746 participants; function −6.81 (−8.32 to −5.31)†. Against other conservative treatment the advantage shrinks to −9.10 (−12.63 to −5.57) at low certainty†.

**The DASH diet, on blood pressure.** The combination diet against control: −5.5 mm Hg systolic and −3.0 diastolic overall, −11.4 and −5.5 in the hypertensive subgroup, all at p<0.001. Sodium and body weight were held constant, which makes this an unusually clean dietary

trial. Two limits belong with it: the primary publication reports no confidence intervals, and all food was provided, so the effect size is for adherence rather than for advice.

**Magnesium sulfate for pre-eclampsia and eclampsia.** The Magpie trial randomised 10,141 women across 33 countries against placebo: eclampsia RR 0.32, p<0.0001†. The pooled comparison against placebo or no anticonvulsant covers six trials and 11,444 women: eclampsia RR 0.41 (0.29 to 0.58), placental abruption 0.64 (0.50 to 0.83)†. Maternal death moved in the favourable direction without reaching significance, 0.54 (0.26 to 1.10)†. Caesarean section rose slightly, 1.05 (1.01 to 1.10), and flushing rose sharply, 24 against 5 per cent†.

Magnesium sulfate injection is an inorganic salt solution, among the least industrially demanding items on the Essential Medicines List. The UNICEF indicative price in October 2026 works out at about US$0.33 an ampoule of 5 g in 10 mL.

**Immediate kangaroo mother care.** 3,211 infants of 1,000 to 1,799 g across five hospitals in Ghana, India, Malawi, Nigeria and Tanzania. Mortality at 28 days 12.0 against 15.7 per cent, RR 0.75 (0.64 to 0.89), p=0.001, number needed to treat 27†. No equipment is required beyond the mother’s body.

Two qualifiers are printed with it. Mortality at 72 hours was not significant, 0.77 (0.58 to 1.04)†. And the trial was stopped early for benefit, which systematically overstates effect size.

**Chlorhexidine cord cleansing.** Three cluster-randomised community trials in Nepal, Bangladesh and Pakistan, 54,624 participants†. All-cause neonatal mortality RR 0.77 (0.63 to 0.94), about a 23 per cent reduction, with moderate heterogeneity at $I^2$ 50 per cent†. Omphalitis fell by 27 to 56 per cent depending on severity†. The benefit was found in high-mortality settings with unhygienic cord practice and does not transfer to facility births with clean dry cord care.

**The six-month tuberculosis regimen.** Two months of isoniazid, rifampicin, pyrazinamide and ethambutol, then four months of isoniazid and rifampicin. About 85 per cent of patients worldwide reach a successful outcome, on a strong recommendation backed by high-certainty evidence for new pulmonary disease. WHO reports 10.7 million incident cases and 1.23 million deaths for 2024, and 83 million lives saved since 2000.

The regimen belongs in this part with one qualification stated rather than softened. It needs no equipment at the point of care, and it needs six months of uninterrupted supply of four manufactured medicines plus adherence support. In supply-chain terms that is not simple.

---

## 3.2 The audit

Twenty-five claims in this class carry more weight in circulation than in their sources. Each is given here with the figure that is actually published.

**Home-made sugar-salt solution.** No study of recommended home fluids met the quality criteria for a mortality meta-analysis, so no effect on diarrhoea mortality could be estimated. The published teaspoon recipe — six level teaspoons of sugar and half a level teaspoon of salt in a litre — is not attributed to WHO or UNICEF on the page that carries it. Pooled treatment failure for home fluids was 0 per cent (−0.1 to 0.1) across twelve randomised trials, but all were prepared under hospital or clinic supervision rather than in households.

The packaged sachet is strongly evidenced. The kitchen version is not. The documented risk is hypernatraemia from salt measurement error, and measurement is exactly the step that packaging removes.

**Vitamin A supplementation.** CONTESTED, and both numbers are printed. All-cause mortality in children aged six months to five years: RR 0.76 (0.69 to 0.83) across sixteen trials and 194,483 children, excluding DEVTA. Including DEVTA: 0.88 (0.84 to 0.94). DEVTA alone, about two million children in India: 0.96 (0.89 to 1.03), p=0.22.

The familiar 24 per cent rests mainly on trials conducted before 1994†. From 1994 only one study showed a mortality effect against a no-intervention control, and none against a

nutrition-education comparator. A separate review found no effect on pneumonia mortality, hospital stay or symptom resolution. What remains solid is night blindness — prevalence 0.32 (0.21 to 0.50) — and measles incidence, 0.50 (0.37 to 0.67)†.

**Folic acid.** The 72 per cent is recurrence prevention, in women who had already had an affected pregnancy. For first occurrence the randomised evidence is one trial, RR 0.07 (0.00 to 1.32), not significant, though no cases occurred in the folic acid arm†. The large falls observed after mandatory flour fortification are ecological evidence, not trial evidence.

**Exercise against drugs.** The network meta-analysis covers 305 randomised trials and 339,274 participants, and its own framing is statistical equivalence rather than superiority. For secondary prevention of coronary heart disease the credible intervals span unity in all four comparisons: statins 1.08 (0.90 to 1.30), β-blockers 1.05 (0.87 to 1.25), ACE inhibitors 1.08 (0.87 to 1.33), antiplatelets 1.07 (0.88 to 1.30).

The results favouring exercise come from three stroke-rehabilitation trials with 227 participants, which the authors themselves call imprecise: against anticoagulants 0.09 (0.01 to 0.70), against antiplatelets 0.10 (0.01 to 0.62)†. And in heart failure one comparison runs the other way. Diuretics beat exercise, OR 4.11 (1.17 to 24.76)†.

**Clean cookstoves.** The burden estimate is large, and the two available figures disagree. The WHO household air pollution fact sheet of 16 December 2025 gives 2.9 million deaths a year, including over 309,000 among children under five, with around 2.1 billion people cooking on open fires or inefficient stoves. The WHO health-risks page for the same topic gives nearly 3.2 million premature deaths a year. Both are printed. The attribution of those deaths is the same on both: ischaemic heart disease 32 per cent, stroke 23, lower respiratory infections 21, chronic obstructive pulmonary disease 19, lung cancer 6.

The randomised evidence on health outcomes is a different matter. HAPIN randomised 3,200 pregnant women in India, Rwanda, Guatemala and Peru to a free liquefied-petroleum-gas stove with fuel. Personal fine particulate exposure fell 66 per cent, 23.9 against 70.7 µg/m³, and 69 per cent of intervention households came below the WHO interim guideline against 23 per cent of controls. Birth weight showed no significant difference. The suggestive subgroup — intervention before eighteen weeks' gestation — gave +33.8 g (−2.6 to +70.2), crossing zero.

So the exposure reduction was delivered and verified, and the first reported hard endpoint was null.

**Dietary fibre.** The 15 to 30 per cent reductions in death and major disease are from 185 prospective observational studies: all-cause mortality RR 0.85 (0.79 to 0.91), coronary heart disease mortality 0.69 (0.60 to 0.81), stroke incidence 0.78 (0.69 to 0.88), type 2 diabetes 0.84 (0.78 to 0.90), colorectal cancer 0.84 (0.78 to 0.89)†. The randomised outcomes in the same paper, from fifty-eight trials, are −0.37 kg, −1.27 mm Hg and −0.15 mmol/L†. Both sets are correct. Only one set is causal evidence.

**Social connection.** The association is among the largest and most replicated in epidemiology: overall OR for survival 1.50 (1.42 to 1.59) across 148 studies and 308,849 participants†. The comparison to smoking appears in the source qualitatively, without comparator effect sizes, and the widely repeated "fifteen cigarettes a day" has no numeric basis in the papers.

The structure of the finding matters. The strongest subgroup is complex social integration at 1.91 (1.63 to 2.23)†, which is also the most confounded with health and function. The hardest and least confounded measure, binary living-alone status, was the weakest and was not significant: 1.19 (0.99 to 1.44)†. No trial shows that increasing social connection reduces mortality.

**Light therapy, two claims.** Prevention of seasonal affective disorder rests on one randomised trial of 46 people: bright white light against no light, RR 0.64 (0.30 to 1.38), not significant, and all comparisons were rated very low quality†.

And light therapy is not without harm. Hypomania: RR 4.91 (1.66 to 14.46), number needed to harm 8 (5 to 20), 19 of 118 against 3 of 101 across seven studies and 219 patients. The review notes possible confounding, since the largest dataset combined light with an antidepressant. The figure is rarely mentioned when light is described as side-effect-free. Also worth printing: in the older Cochrane analysis of non-seasonal depression the pooled estimate loses significance under random effects, −0.22 (−0.52 to 0.09).

**Handwashing and mortality.** No trial in the Cochrane diarrhoea review reported diarrhoea deaths. Two community trials reported all-cause under-five mortality and the review gives no effect estimates. On respiratory infection the pooled figure is RR 0.83 (0.76 to 0.90) with $I^2$ 88 per cent, and the effect disappears for the one laboratory-confirmed outcome, influenza, and for all-cause mortality. The trial evidence establishes fewer episodes. It does not establish fewer deaths.

**Solar water disinfection.** The headline cluster-randomised figure is RR 0.62 (0.42 to 0.94)†. Adjusting for non-blinding takes it to 0.80 (0.60 to 1.01), losing significance†. Most studies were unblinded with self-reported diarrhoea. Several authors of the review declared consulting or research relationships with manufacturers of household water treatment devices.

Point-of-use treatment as a class survives better. Filtration 0.48 (0.38 to 0.59), chlorination 0.77 (0.65 to 0.91) — and chlorination shows no effect, 0.90, where residual chlorine was found in half the samples or fewer†.

**Latrine provision.** Cluster-randomised trials of simply providing sanitation access: 0.89 (0.73 to 1.08) at all ages, 0.98 (0.83 to 1.16) under five, neither significant†. The large effects, 0.61 (0.50 to 0.74), come from non-randomised studies of improving existing facilities†. The one comparison reaching moderate certainty is behaviour-change messaging, 0.82 (0.69 to 0.98) under five†. Building latrines without changing use has not been shown in cluster-randomised trials to reduce diarrhoea.

**Improving the water source** without point-of-use treatment belongs beside it: 0.76 (0.48 to 1.19) at all ages, 0.96 (0.82 to 1.12) under five, no clear benefit†.

**Iodine in pregnancy.** STRONG only where deficiency is severe. In mild-to-moderate deficiency no trial has shown a child-development benefit. Six trials in such regions did not assess child development, growth or pregnancy outcomes at all; one randomised trial and four observational studies found no differences on mental development scales, all at low to moderate quality. Three trials found reduced postpartum maternal hyperthyroidism and increased gastrointestinal intolerance, with no differences in hypothyroidism, thyroid autoimmunity, low birth weight or preterm delivery. One observational study linked self-reported intake above 200 µg a day with lower maternal thyroid function. Universal salt iodisation remains the primary strategy.

**Mediterranean diet.** PREDIMED randomised 7,447 adults at high cardiovascular risk and reported HR 0.69 (0.53 to 0.91) for the olive oil arm and 0.72 (0.54 to 0.95) for the nut arm. The 2013 report was withdrawn and republished in 2018 after randomisation irregularities were found at some sites, including household-level and clinic-level non-random assignment; the republished estimates no longer rely exclusively on the assumption that all participants were randomly assigned. That is a material limitation, not a technicality.

The other supporting trial, Lyon, has 605 post-infarct patients at one centre, with adjusted risk ratios of 0.28 to 0.53 — implausibly large relative to PREDIMED.

**Time-restricted eating.** Across eleven meta-analyses covering 130 randomised trials and 104 unique associations, 1 association reached high GRADE certainty and 72 per cent were very low. Twenty-eight of 104 were significant and beneficial. In the best-designed head-to-head trial, 139 adults over twelve months at matched calorie intake, the between-group difference was −1.8 kg (−4.0 to +0.4), not significant, and no secondary outcome differed. Reduced fat-free mass is a documented downside. What the evidence supports is that eating less causes weight loss.

**Honey for cough.** Against dextromethorphan, honey is equivalent: cough frequency MD −0.07 (−1.07 to +0.94), severity −0.13 (−1.25 to +0.99)†. It beats no treatment, −1.05 (−1.48 to −0.62), and one antihistamine, −0.57 (−0.90 to −0.24)†. The evidence base is three small trials and 568 children, two at high risk of bias, with parent-rated Likert scores, a single night of follow-up, and cough duration never measured. Honey is contraindicated under one year of age because of infant botulism, and no trial participant was under one.

**Saline nasal irrigation.** Five trials, 749 enrolled and 565 with data†. The only significant results come from one trial of 401 children: nasal secretion score MD −0.31 (−0.48 to −0.14), obstruction −0.33 (−0.47 to −0.19)†. The review itself notes that on a four-point scale this may be of minimal clinical significance. Most other comparisons showed no difference from control, and there is no formal certainty rating.

**Compression for venous ulcers.** The principle is settled physiology: compression reduces venous hypertension and heals ulcers. The specifics are thinner than usually presented. In the review of forty-eight trials and 4,321 participants, no pooled risk ratio exists for compression against no compression on healing; eight trials were analysed without pooling. A separate 2021 review does publish figures against no compression: time to healing HR 2.17 (1.52 to 3.10), and healing within twelve months RR 1.77 (1.41 to 2.21), both at moderate certainty†. Ten of its fourteen studies were at high overall risk of bias.

Recurrence prevention rests on one trial of 153 people, RR 0.46 (0.27 to 0.76) at six months†. High against moderate compression gives contradictory results at the two follow-up points: 0.57 (0.39 to 0.81) at three years and 0.82 (0.61 to 1.12) at five†. Patient intolerance of hosiery was high, and adherence is the binding constraint.

**Zinc below six months.** No benefit, and a trend toward harm. Duration of acute diarrhoea +5.23 hours (−4.00 to +14.45)†. Diarrhoea still present at day seven, RR 1.24 (0.99 to 1.54) in one trial of 1,074 infants†. Vomiting increased, RR 1.57 (1.32 to 1.86) above six months and 1.54 (1.05 to 2.24) below, both at moderate certainty†. The review authors do not support zinc below six months, nor in well-nourished children, nor in low-risk settings.

**Vitamin D for hard outcomes.** Null across the large trials, with a possible harm signal. Invasive cancer HR 0.96 (0.88 to 1.06), major cardiovascular events 0.97 (0.85 to 1.10) in 25,871 adults over a median 5.3 years†. All-cause mortality 1.04 (0.93 to 1.18) in 21,315 Australians†. Total fracture RR 1.00 (0.93 to 1.07), hip fracture 1.11 (0.97 to 1.26), falls 0.97 (0.93 to 1.02) across eighty-one trials and 53,537 participants†.

The harm signal is prespecified cancer mortality in the D-Health trial: HR 1.24 (1.01 to 1.54) on monthly bolus dosing†. The investigators describe the increase as unproven.

The contested zone is whether these nulls reflect an absent effect or the enrolment of replete participants. Only 6 per cent of the eighty-one trials enrolled deficient people, and the D-Health treatment arm averaged 115 nmol/L†. The strongest signal the other way is respiratory infection in the deficient: adjusted OR 0.30 (0.17 to 0.53) in daily or weekly dosing below 25 nmol/L — a subgroup of 234 participants across six trials, not a prespecified primary endpoint†.

**The claim that 95 per cent of Essential Medicines List medicines are off-patent.** That figure refers to the 375 compounds on the 2013 list†. No current audit of the 24th List exists. The only other available figure counts 35 medicines on the 22nd List as patented in lower-income countries, 7.3 per cent†. It counts patents in those markets only. A medicine off-patent in Malawi may be on-patent in the European Union.

**The claim that WHO publishes a list of locally producible essential medicines.** A risk framework exists. A 2011 WHO and Global Fund stakeholder meeting sorted essential medicines into high, medium and low manufacturing risk on four criteria, and the underlying WHO document runs to 35 pages. The published paper names one low-risk product: 7.1 per cent chlorhexidine digluconate, for umbilical cord care. The framework is not a per-medicine public list, and the full risk tiers could not be retrieved.

**The ORS lives-saved totals.** The figures of 54 million and 70 million are modelled attributions without confidence intervals, carried by secondary sources. The underlying mortality estimate is a 69 per cent pooled relative reduction (51 to 80) from three quasi-experimental studies, and the extrapolation to 93 per cent of diarrhoea deaths assumes a linear relation between coverage and mortality. The authors of the background mortality series attribute the decline to multiple interventions: under-five diarrhoea deaths fell from 4.6 million in 1980 to 3.3 million in 1990 to about 1.5 million in 1999. Ecological correlation with oral rehydration use was $r = -0.61$ ($p = 0.04$) in north-east Brazil and not significant in the Philippines.

**Community case management of pneumonia.** The measured figure is a 35 per cent reduction in acute lower respiratory infection mortality (18 to 48), with a 21 per cent reduction in all-cause mortality†. The 70 per cent usually quoted is a modelled adjustment for about 50 per cent actual receipt of the antibiotic†. The same review found no effect of zinc and no effect of vitamin A on pneumonia mortality.

**Sleep duration.** The U-shaped association is large and consistent: short sleep RR 1.12 (1.06 to 1.18), long sleep 1.30 (1.22 to 1.38), across sixteen studies, 1,382,999 participants and 112,566 deaths†. It is observational, it is self-reported, and reverse causation is serious, since

long sleep marks existing illness. No trial shows that changing sleep duration changes mortality. Sleep timing has intervention evidence only through timed light in circadian disorders, where shift work and delayed sleep phase are the two applications that reach a meaningful recommendation level.

---

## 3.3 The counter-cases

Two interventions mark the boundary of this category, and they matter more than any single row above, because they show what the category excludes.

**Vaccination.** STRONG for effect, by a wide margin. 154 million lives saved since 1974, most of them children under five; measles vaccination accounts for about 60 per cent of that total; vaccination accounts for about 40 per cent of the observed decline in global infant mortality, and about 66 years of full health per life saved, 10.2 billion years in all. WHO puts third-dose diphtheria-tetanus-pertussis coverage at 85 per cent of infants in 2025, with 13.5 million children receiving no dose.

And vaccination sits outside simple means by construction. Every vaccine in the thermostability table bar one requires an unbroken 2 to 8 °C chain from factory to arm, and the most heat-sensitive include oral polio and measles. The exception is MenAfriVac, the only vaccine fully relicensed for a controlled temperature chain, which tolerates up to four days at up to 40 °C with monitoring†. Its modelled logistics cost in Chad halved, from US$0.24 to US$0.12 per person†. Measles is a priority for the same treatment, with four prequalified producers and none yet validated. Every vaccine also requires biological manufacture with extensive lot-release testing, which no pharmacy holds.

This is the clearest case in the book of a highly effective intervention that cannot be made or delivered without a long industrial chain.

**Amoxicillin.** The second counter-case, and it separates two things that are routinely treated as one. Amoxicillin is off patent. It is not simple to make.

Its active ingredient derives from fermented penicillin G. The industrial route runs more than ten steps, reaches around minus thirty degrees, and generates up to about 70 kg of non-recyclable waste per kilogram of product†. An enzymatic route needs fewer steps under milder conditions, at reported yields of 39 and 47 per cent†. As of August 2017 there were eight active US drug master files held by seven companies for amoxicillin trihydrate, so there are only seven producers of the active ingredient worldwide. The finished product needs dedicated equipment and dedicated sites, because of penicillin cross-contamination and anaphylaxis risk, with humidity-controlled air handling and aluminium-aluminium blisters.

The tablet costs about US$0.05 on the UNICEF indicative price, October 2026. Seven companies in the world make the substance in it.

Off-patent describes a legal status. It says nothing about how many steps, how much waste, or how few producers.

Read in the net: a simple means is not a cheap means. It is a means whose chain closes at the point of need. Price and patent status are read at the wrong depth; what decides is whether the thing can be completed where it is used. This is a reading, not a mechanism.

---

## 3.4 The genuinely low-complexity list

No validated public catalogue of simply producible essential medicines exists, and the category as a whole is graded WEAK for that reason. What can be asserted is a short list, each item individually sourced, whose production is genuinely low in complexity:

- oral rehydration salts
- zinc sulfate tablets
- iodised salt, as food fortification rather than a medicine

- folic acid tablets
- ferrous salts
- vitamin A capsules
- chlorhexidine 7.1 per cent gel
- magnesium sulfate injection
- sodium chloride and glucose solutions
- paracetamol
- oral vitamin D

Three things about that list are worth stating plainly. It is eleven items long. Several of them carry the strongest evidence in this part — magnesium sulfate, chlorhexidine gel, oral rehydration salts, iron, iodine. And one of them, chlorhexidine 7.1 per cent digluconate, is the single product the published WHO and Global Fund risk framework names as low manufacturing risk.

One operational WHO production manual exists for this whole class, and it is for oral rehydration salts: *Oral rehydration salts: production of the new ORS*, 2006. It publishes the formulation, raw-material specifications, quality-control tests, premises layout, packaging and shelf life. For an output of about three to four million sachets a year it specifies the premises: a raw and packaging warehouse, a finished-goods warehouse, a bulkstore, a mixing room of about 30 m², a packing room of about 45 m², an in-process quality-control laboratory of about 15 m², and staff facilities. WHO recommends integrating the work into an existing powder-drug facility rather than building a standalone plant.

The manual also states the point on which this part ends. Decentralised cottage-industry mixing and packing is possible, and it is costly, because quality-control requirements apply regardless of volume and therefore raise the unit cost.

Simple does not mean improvised. The shortest chain in medicine still has a laboratory in it.

# Part 4 — The Chain

# Part 4 — The Chain

The entries keep raising one question that no individual entry can answer. A medicine exists, it is cheap to make, and it is not available, or it is available at a price that makes it unavailable in practice. How short can the production chain be, and who is legally allowed to make what?

This part answers that question as a matter of law and institution. Short, here, means short in institutional distance: fewer legal intermediaries between the point of need and the point of production. It names who may make what, at what scale, and at what cost. It does not describe how anything is made, and it is not a route to making a medicine outside a licensed setting. Every figure in it concerns authorisation, price and capacity.

---

## 4.1 Three documented cases

The clearest evidence in this book that the chain can be short comes from three Dutch cases, each with published before-and-after prices per patient per year.

**Chenodeoxycholic acid for cerebrotendinous xanthomatosis, Amsterdam UMC.** The reference case in Europe. Cerebrotendinous xanthomatosis is an inherited disorder of cholesterol metabolism, with prevalence cited at fewer than 5 per 100,000.

The substance had been registered since 1999 for gallstones and used off label for this condition at €308 per patient per year†. In 2015 the rights holder applied for a marketing authorisation as an orphan medicine for the condition and withdrew the existing product. The European authorisation was granted in 2017, carrying ten years of market exclusivity, and the price rose to €140 a capsule, about €153,300 per patient per year on the Dutch price register†. A second official figure for the same period gives €163,000†, and a parliamentary question cites a different earlier baseline of €20,000 to €25,000 rising to an intended €160,000 to €220,000†. The sources disagree on the pre-2017 level and all the figures are printed.

From €308 to €153,300 per patient-year is a factor of 498, recomputed. Per capsule, from €0.28 in 1976 to €140, a factor of 500†. A Belgian hospital preparation of the same 250 mg capsule cost €1.5113 in 2018, 93 times less than the commercial capsule†.

Amsterdam UMC announced magistral preparation in April 2018, for approximately fifty patients, after Dutch insurers had begun refusing to reimburse the commercial price.

**Viscous cysteamine eye drops for nephropathic cystinosis, Radboud UMC.** The largest proportional gap in the set, and the cleanest, because both prices appear in one official document. The pharmacy preparation, an aqueous 0.5 per cent cysteamine drop in a 10 mL bottle, cost €35.37, which is €1,839.24 per patient per year; the registered product, viscous 0.55 per cent cysteamine in 5 mL, cost €1,025 at pharmacy purchase price, which is €53,300 per patient per year, as given in the advice of the Dutch Zorginstituut Nederland of 4 January 2018.

That is a factor of 29 per patient-year, recomputed. Corrected for the halved bottle volume, the registered product costs roughly 58 times the preparation per millilitre.

The Dutch expertise centre records 48 patients with proven nephropathic cystinosis, 24 children and 24 adults; the budget-impact analysis used 43 of them, and projected about €2.2 million of additional pharmacy expenditure for 2020†. A separate figure circulating in Dutch hospital pharmacy discussion puts the pre-registration hospital drops at €20 a bottle against

€1,000 after†. The €20 and €35.37 figures differ in presentation volume and in whether overhead is counted, and both are printed.

**Mexiletine for non-dystrophic myotonia.** About 500 people in the Netherlands have the condition, and pharmacists supplied mexiletine as a preparation for years before any registration.

At one to three capsules a day, the pharmacy preparation at €6.95 a capsule in the Netherlands in 2021 works out at €2,537 to €7,610 per patient per year, and the registered orphan product at €23.39 a capsule at €8,537 to €25,612†. A factor of 3.4, recomputed. Against the year-2000 pre-registration price of €0.23 a capsule, the registered product is 102 times more expensive†, and an imported mexiletine at €2.85 sits between them†.

The multiples are 498, 29 and 3.4. They are the headline, and they are not the most important finding. Three things qualify them, and each matters more than the multiple it qualifies.

---

## 4.2 What actually governs the short chain

**The chenodeoxycholic acid preparation was stopped on starting-material quality, not on law.** This is the single most important practical finding in this part.

The rights holder filed an enforcement request with the Dutch health inspectorate in 2018; the minister stated there had been no direct contact between the company and the inspectorate. The national institute for public health then tested samples of the active substance against the European Pharmacopoeia and found unknown impurities above the monograph limit. The hospital had not tested the substance against the general monograph for substances for pharmaceutical use. After consultation with the inspectorate, Amsterdam UMC stopped preparation and supply, and the inspectorate set out the conditions to be met.

On 4 September 2018 the minister answered parliamentary questions. He called the price increase socially unacceptable, and saw possible abuse of a monopoly position including in the supply of the raw material. He said he considered it a good thing if the magistral preparation could proceed, provided the starting material was sound and met the standards. The inspectorate, in his words, could not and might not close its eyes to the finding.

Preparation resumed in January 2020†. In February 2019 the competition authority had published its view that magistral preparation is an exception to orphan exclusivity and offers room for lower prices. It added that it would watch for manufacturers or raw-material suppliers creating unjustified barriers, such as restricting access to raw materials. On 19 July 2021 it fined the company €19.6 million for abuse of a dominant position, and the company lost its appeal at the Rechtbank Den Haag on 14 July 2022†. Fines followed in Spain at €11.25 million, Italy at €3.5 million, and Israel at €2.2 million intended plus two executive fines of €172,000†. The case file gives a total of €35.5 million; the individual amounts sum to about €36.9 million, and the source does not reconcile the difference. Both figures are printed.

So: the exemption held, the minister wanted the preparation to continue, the competition authority endorsed it as a price instrument, and the preparation still stopped for sixteen months — on an impurity finding in the starting material. The binding constraint on the short chain is qualification of the active substance, not the legal exemption.

**Registration closes the short chain.** The cysteamine case shows the mechanism operating in the plain direction. The preparation existed first and worked. Registration of the commercial product did not add a new treatment; it moved an existing one inside the authorisation regime. After that the preparing pharmacies were no longer permitted to supply it, because the first condition of the Dutch supply-to-other-pharmacies route — no adequate registered alternative available — was no longer satisfied.

The Dutch counter-move is for the preparing pharmacies to register the products themselves. In June 2021 Erasmus MC, Radboudumc, UMCG, Catharina Ziekenhuis and the compounding pharmacy A15 formed a platform to do exactly that, selecting medicines they already prepare, where they hold the technical knowledge and effectiveness is established. The announcement names five parties and its headline says four, and the source does not reconcile this. Cystadrops is named as the trigger.

This is the short chain accepting the long chain's paperwork in order to keep the short chain's cost base. It is the only documented structural answer to the registration-closes-the-exemption problem.

**The mexiletine outcome is the strongest precedent in this part.** On 14 January 2021 the Dutch national health care institute advised the minister not to reimburse the registered product. It advised instead that the pharmacy preparations be brought into the basic insurance package, so that patients kept access to the medicine. The budget impact of reimbursing the registered product had been put at €6.1 to €7.6 million a year in additional expenditure†. The institute's reasoning was that the orphan rules had been applied to an existing medicine. The regulation following the advice appeared in the Staatscourant on 30 July 2021†.

The compounded route became the reimbursed standard of care, at roughly one third of the registered price. A national reimbursement authority can prefer the preparation to the registered product and leave the registered product outside the package.

---

## 4.3 The legal frame

**The Netherlands.** Three articles of the Geneesmiddelenwet carry the structure. Article 18(1) prohibits preparing, importing, stocking, supplying or wholesaling medicines without a manufacturing permit, and Article 18(5) exempts small-scale preparation by a pharmacy for its own patients. Article 40 prohibits placing a medicine on the market without a marketing authorisation, and Article 40(3)(a) exempts the medicine prepared in a pharmacy for that pharmacy's own patients. Article 84(1) prohibits advertising an unauthorised medicine†.

Four routes follow, and they differ in who may be served rather than in how much may be made. Magistral preparation serves one named patient on a prescription, with no authorisation. Stock, or officinal, preparation serves the pharmacy's own patient population where the patient is not yet identified, at small scale, with no authorisation and no numerical ceiling defined. Supply to another pharmacy's patients — *collegiaal doorleveren* — is formally prohibited and tolerated under conditions. Full manufacture requires a permit and a marketing authorisation.

The inspectorate's 2023 circular sets six conditions for supply beyond the pharmacy's own patients, and they define precisely where the short chain is allowed to serve a population:

1. No adequate registered alternative is commercially available. Adequate means the same active substance, dosage form and strength, or near enough to reach the required dose. A product registered in the European Economic Area or a mutual-recognition country counts as available, and is preferred over a preparation.
2. Notification of each product through the national medicines database within five working days of first supply, regardless of scale. Where the authorisation agency judges a product suitable for registration, it and the inspectorate open exploratory talks with the pharmacy.
3. A product dossier per product, covering design quality and chemical-pharmaceutical quality, available immediately on inspection, including the justification for why registered alternatives are inadequate.
4. Compliance with good manufacturing practice, verified by regular inspection.
5. Pharmacovigilance: adverse reactions reported to the national centre, with a working system for recording, assessing and signalling.
6. No advertising, by either the preparing or the dispensing pharmacy.

The receiving pharmacy must itself verify conditions 1, 2, 5 and 6. The circular states openly that the ministry and the inspectorate are working towards a policy rule and ultimately a statutory basis, so this route rests on enforcement discretion rather than on law.

The statute says almost nothing about quality. That content comes from the profession. The Dutch pharmacists' preparation guideline supplies the operative definitions, and the rule that a pharmacist releases each batch before dispensing, on the basis of preparation documentation and controls. It also supplies the product dossier requirement, scaled to the preparation scale, and the content-uniformity standard from the implementing decree: the active constituent may not deviate more than 10 per cent from the stated quantity†.

**Europe.** The whole European edifice rests on two sentences. Directive 2001/83/EC establishes that no medicinal product may be placed on the market without a marketing authorisation, and then removes two categories from the Directive's reach:

- Article 3(1), the **magistral formula**: any medicinal product prepared in a pharmacy in accordance with a medical prescription for an individual patient. A pharmacy may prepare for one named patient with no authorisation, no dossier and no regulatory filing.
- Article 3(2), the **officinal formula**: any medicinal product prepared in a pharmacy in accordance with the prescriptions of a pharmacopoeia, intended to be supplied directly to the patients served by that pharmacy. Preparation to a pharmacopoeial standard, for stock, for the pharmacy's own patients only.

Article 5(1) adds a third route, for special needs: a Member State may exempt an unauthorised product supplied in response to a bona fide unsolicited order, formulated to the specifications of an authorised health-care professional, for an individual patient under that professional's direct personal responsibility. This is the basis for import on a physician's declaration.

Two structural facts follow from the wording and govern everything downstream. The exemption is tied to the pharmacy's own patient relationship: neither article covers supplying another pharmacy, another hospital, or a market. And scale is not stated as a number — the Directive sets no volume ceiling, and the limit is relational rather than quantitative. Member States have filled that gap nationally, and the Dutch solution is the most developed in Europe. The Court of Justice confirmed in the *Abcur* cases that a product prepared outside a genuine individual prescription relationship falls back inside the Directive and needs an authorisation.

**The United States.** The framework was rebuilt by the Drug Quality and Security Act of 27 November 2013, enacted after the 2012 fungal meningitis outbreak traced to a compounding pharmacy. It created two categories.

Section 503A is traditional compounding, by a licensed pharmacist in a state-licensed pharmacy or by a licensed physician. It requires a patient-specific prescription for an identified individual, with limited anticipatory preparation allowed only on a documented history of valid orders. It is exempt from new drug approval, from the adequate-directions labelling requirement, and from the good-manufacturing-practice-linked adulteration provision. Bulk substances must meet a pharmacopoeial monograph where one exists, come from a registered establishment, and carry a valid certificate of analysis. In a state without a memorandum of understanding with the federal government, no more than 5 per cent of prescription orders may be distributed out of state. Inspection is by the state board of pharmacy.

Section 503B creates the **outsourcing facility**: a federally registered establishment that may compound without any patient-specific prescription, for office stock, in exchange for full compliance with good manufacturing practice and federal risk-based inspection. Registration is voluntary to enter, with an annual establishment fee. There were 98 registered outsourcing facilities as of 30 September 2026; some owners run more than one, so the number of distinct companies is lower.

Both categories are barred from compounding a product that is essentially a copy of a commercially available drug product. They are also barred from products the authorities identify as presenting demonstrable difficulties affecting safety or effectiveness, and from products withdrawn from the market for safety or effectiveness reasons. Positron-emission-tomography drugs and radiopharmaceuticals fall outside 503A altogether†.

The two systems are opposite solutions to the same problem. The European exemption is defined by the patient relationship and is silent on scale: it keeps the exemption small and relational. The American 503B category creates a licensed industrial tier with no patient relationship at all, and regulates it as manufacture.

**What can be prepared this way, and what cannot.** The boundary tracks physical chemistry more closely than law.

Preparable in a pharmacy, in an ordinary preparation room: capsules, which are the workhorse form and carry most repurposing cases; tablets, possible but less used, because capsule filling is more robust at small scale; oral liquids, solutions and suspensions, standard for paediatric use and swallowing difficulty; creams, ointments and gels, the largest category by volume in Dutch practice; suppositories; and preserved eye drops and eye oint-

ments. Preservative-free eye drops that cannot be terminally sterilised require a laminar airflow cabinet — the cysteamine case sits here. Parenterals and preservative-free irrigations terminally sterilised in the final container require a separate room at minimum class D. Aseptically prepared sterile products require an aseptic facility and documented microbiological competence.

Not preparable in a pharmacy, with the reason in each case:

- **Monoclonal antibodies** — adalimumab, trastuzumab, pembrolizumab, dupilumab. The product is the manufacturing process: a glycosylated protein secreted by a living mammalian cell line. There is no active substance obtainable as a pharmacopoeial powder, and no formulation step in a pharmacy produces the molecule.
- **Other recombinant proteins and insulin analogues** — the same reason: cell-culture expression, folding and purification. A pharmacy can dilute or repack an authorised product; it cannot make one.
- **Vaccines, including mRNA** — batch release requires potency assays no pharmacy holds.
- **Cell and gene therapy, including CAR-T** — a living autologous product, under advanced-therapy rules. In Europe this runs through the hospital exemption, which is a different track from the pharmacy exemption.
- **Complex sterile injectables**: liposomal, nanoparticle, depot and long-acting formulations. The therapeutic behaviour comes from a particle architecture that requires dedicated process equipment and in-process particle-size control.
- **Anything with an adequate registered alternative** — not a technical limit but a legal one, from condition 1 of the Dutch circular and the American essentially-a-copy prohibition. This is what ended the cysteamine preparation.

What a pharmacy can do with a biological is reconstitute, dilute, repack and split a dose from an authorised product. For biologicals the economic lever is therefore dose optimisation rather than compounding, and it is documented: dupilumab at €16,000 per patient per year at full dose in the Netherlands in 2024, with about 70 per cent of patients able to taper in early studies, in a programme that reports tens of millions less declared to insurers since 2021†.

---

## 4.4 What off-patent does and does not mean

Off-patent is routinely read as meaning many suppliers and therefore a secure supply. The census does not support that reading.

Counting valid Certificates of Suitability in the European pharmacopoeial database as of 30 April 2020, across 554 generic active ingredients: 56.3 per cent have five or fewer certified manufacturers worldwide. A further 23.1 per cent have six to ten, and only 1.4 per cent have more than twenty-five†. And 93 of the 554, about 17 per cent, have no certificate holder in Europe at all†. A European Parliament study carries the same finding from a second source.

The figures understate the concentration, because raw materials and intermediates are not counted, and those sit further upstream and are more concentrated than the active ingredients themselves.

Set that beside the shortage data. The Netherlands has the best national time series in Europe. In 2025, 1,134 medicines were in shortage, affecting 3.5 million people, roughly one medicine user in three†. The report prints 1,135 in one place and both figures are given. In 2024 the figures were 1,563 medicines and 4.5 million people†. The cause is unknown for 70 per cent of shortages, because suppliers do not disclose it; among known causes most are production problems — raw material availability, manufacturing, or final laboratory checks. Seventy-one per cent of shortages fall under insurer preferential policy and 14 per cent are definitive†.

The medicines the report highlights are levothyroxine, rifampicin, salbutamol, prednisolone, quetiapine, lithium and oxazepam. They are almost all old, cheap, off-patent and, in dosage-form terms, compoundable. Fifteen shortages reached the most serious category of the

Dutch responsible-substitution guideline, mainly lower strengths of levothyroxine, and nearly a hundred reached that category on the Dutch critical medicines list.

At European level the pattern is the same. The EU Critical Medicines List carried over 270 active substances in its December 2024 version, of which innovative medicines are 10 to 20 per cent. More than 90 per cent of reported critical-medicine shortages concern generics, and about two-thirds of generic shortages are linked to products with few suppliers. Sixty-two per cent of countries awarded tenders on price alone in 2022. Shortage notifications across fourteen OECD countries rose 60 per cent.

So the shortage list and the compoundable list substantially overlap. And pharmacy preparation appears once in the entire Dutch shortage report, for lithium, as one possible response alongside other manufacturers' products and imports. It is not in the report's general list of alternatives.

The overlap is unquantified in the official data. No published figure states what share of shortages could be met by pharmacy preparation, or what share is met by it now. That is a gap worth naming, because the two datasets describe the same medicines from opposite ends and have not been joined.

One further legal route belongs here. Where a registered product is unavailable in the Netherlands, the inspectorate can grant an exemption on a physician's declaration that treatment with available registered products is not possible. Pharmacies, wholesalers, manufacturers and dispensing general practitioners may apply, and three forms exist: application, extension, and a return of the number of patients treated.

---

## 4.5 Where the chain genuinely cannot be shortened

For each of these the chain is long because a step in it cannot be compressed. Regulation follows the physics rather than creating the constraint.

**Monoclonal antibodies.** The process defines the molecule. The chain contains, without an omissible step, a characterised master cell bank, a seed train, a bioreactor campaign, chromatographic capture, viral clearance, buffer exchange, sterile fill, and a release panel of potency, identity, purity and immunogenicity assays. Industry has brought drug substance cost of goods down from US$1,000 a gram to above US$50 a gram†. The target set for prophylactic use in low-income settings is US$10 a gram, which is break-even for a half-gram to one-gram dose priced US$5 to US$10†. Named cost drivers include cell culture medium, which can reach US$1 million a batch, and chromatography resin, which can cost millions of dollars for a large batch and falls per gram only with reuse.

Even at the US$10 target, a one-gram dose costs more in materials alone than a full six-month first-line tuberculosis course at an estimated US$38, or a year of first-line HIV therapy at an estimated US$82. The gap is not margin. It is biology. The available levers are biosimilar entry, dose optimisation and price regulation — not pharmacy preparation.

**Cell and gene therapy.** The product is the patient's own cells, modified. The chain is a logistics loop with a living product at its centre: apheresis, cryopreservation and transport, vector supply which is itself a separate manufacturing chain, transduction, expansion, formulation, cryopreservation, release testing and return transport, with the patient waiting throughout. It must be repeated per patient, so there is no batch to amortise.

Point-of-care manufacture is how far it compresses, and India has the documented case. An Indian CAR-T product approved in October 2023 is expected at about US$50,000 against about US$400,000 for commercial CAR-T in the United States. Across the combined trials, 64 people with B-cell lymphoma or leukaemia and 53 evaluable: 67 per cent overall response, about half of them complete; lymphoma 68 per cent, leukaemia 72 per cent and all complete.

That is a factor of 8, recomputed. It is not the factor of hundreds that compounding achieves for a small molecule, and it still requires a cell-processing facility, a vector supply and a release-testing laboratory inside the treating institution.

**Radiotherapy.** The treatment is a megavoltage beam, and the chain contains a linear accelerator, a shielded bunker, a planning system, dosimetry equipment, and three professions

that take years to produce. The workforce, not the machine count, is the constraint. Against roughly 21,800 megavoltage machines needed in 2035, the workforce to be trained by then runs to 3,300 radiation oncologists, 2,400 medical physicists and 8,100 radiation technologists in low-income countries alone, and 9,900, 7,200 and 24,900 in lower-middle-income countries†. Between 40 and 60 per cent of cancer patients globally have access to radiotherapy, and over 90 per cent of the population of low-income countries does not†.

Scale-up across low- and middle-income countries for 2015 to 2035 is modelled at US$184.0 billion nominally and US$96.8 billion under an efficiency model, against 26.9 million life-years saved†. Under the human-capital approach the net benefit is US$16.9 billion nominal and US$104.2 billion efficiency — with a net deficit for low-income countries under both, −US$14.9 billion and −US$2.4 billion†.

This is the one intervention in this part whose own advocates' most conservative model does not pay back in the poorest settings over a twenty-year horizon. There is no short-chain version of radiotherapy.

**Dialysis.** Haemodialysis is not delivered once. It is delivered three times a week indefinitely, and each session consumes a sterile single-use dialyser, bloodlines, needles, and tens of litres of ultrapure water and dialysate. The chain is therefore a permanent per-patient consumables line, plus a machine, plus a water treatment plant, plus nursing time. The per-patient cost is dominated by the recurring consumable, which is exactly the component that cannot be amortised.

Dutch annual healthcare cost per patient, in 2014 euros: in-centre haemodialysis €92,616; peritoneal dialysis €77,566; kidney transplant in the year of transplantation €85,127 on average, €73,376 for a living donor and €99,450 for a deceased donor; first year after successful transplantation €29,612; second year €15,018†.

Transplantation is the chain-shortening intervention for renal failure. It replaces a permanent consumables line with a one-off procedure plus immunosuppression, at about a sixth of the dialysis cost by the second year. The constraint is organ supply, not manufacturing.

**Complex surgery.** Cardiac, neurosurgical, transplant and major oncological surgery require, simultaneously, a sterile theatre with controlled air handling; anaesthesia with monitoring and reliable oxygen and power; blood banking; intensive care with ventilation; imaging; a pathology laboratory; and surgical, anaesthetic and nursing teams that take a decade to train. The chain is the institution. No element can be removed without the procedure becoming unsafe.

The Lancet Commission's Bellwether framing exists to separate what can be done at district level from what cannot. The three Bellwether procedures are caesarean delivery, laparotomy and treatment of open fracture, and the capacity to perform all three is used as the proxy for a system's ability to deliver broad surgical care. The Commission's first indicator is the share of the population within two hours of a facility that can perform them, with a target of 80 per cent coverage by 2030. Procedures beyond the Bellwethers are explicitly not expected at district level; they require referral to an institution whose chain is long by construction.

---

## 4.6 The asymmetry: mRNA vaccines

The most interesting single result in this material is that mRNA vaccines are a narrow chain, not a long one.

The chain is irreducibly specific. It requires enzymatic nucleic acid synthesis from defined nucleotides, a template supply, enzymatic capping and purification, lipid nanoparticle formulation by controlled mixing with defined lipids including a proprietary ionisable one, sterile fill under cold chain, and release by potency assay. The lipids and the enzymes are each their own specialist supply chain.

The capacity requirement is modest. One facility with a single production line can make 100 million doses a year, in about 264 batches†. Modelled total manufacturing cost for 100 million doses, in a 2021 model, is US$270 million for a Moderna-equivalent product and US$127.1 million for a Pfizer-BioNTech-equivalent one, which works out at US$2.70 and US$1.27 a

dose†. Fill-and-finish alone is US$0.27 a dose in ten-dose vials and US$0.37 in five-dose vials†. The mRNA required per year is 10.53 kg and 3.16 kg respectively, and staff per line 80 and 75†. The modelled headcount was about 27 and 25; the authors raised it to 80 and 75 to cover quality control, warehousing and administration, against an industry report of over 70 employees per line†. Annualised facility capital, straight-line over ten years, enters operating costs at US$4.3 million and US$2.5 million a year†.

The model excludes facility construction, and the labour for construction, installation, validation and start-up. The per-dose figures are to be read with that exclusion in view.

An mRNA vaccine cannot be made in a pharmacy, and it does not need a global industry either. It needs a facility of seventy-five to eighty people. The chain is short in headcount and footprint and long in technical specificity. The binding constraint is technology transfer, not scale, which is why the WHO mRNA technology transfer hub model exists.

---

## 4.7 Human insulin, which is not the analogues

These two are routinely spoken of as one product and they sit on opposite sides of the line.

Human insulin is a recombinant protein with the native human sequence, off patent for decades, and manufacturable by multiple producers. The analogues — glargine, lispro, aspart, degludec — are sequence-modified proteins with later patents, proprietary formulation and device-coupled delivery. Both require fermentation and purification. Neither is compoundable. Their cost and competitive structures differ.

Production cost and estimated biosimilar price, as modelled in a 2018 study, per 10 mL, 1,000-unit phial, with the annual figure at 40 units a day†:

| Insulin | Production cost per phial | Estimated biosimilar price per phial | Estimated price per patient-year |
|---|---|---|---|
| Regular human insulin | US$2.28–3.37 | US$3.29–4.86 | US$48–71 |
| Glargine | US$3.69–5.13 | US$5.32–7.38 | US$78–108 |
| Lispro | US$4.52–6.16 | US$6.51–8.87 | US$95–130 |
| Aspart | US$4.51–6.16 | US$6.50–8.86 | US$95–129 |

The paper’s abstract gives a broader analogue range of US$78 to US$133 a year, and both are printed†.

Now the comparison that carries the finding. Median current prices as a multiple of those estimates: regular human insulin 1.2 to 1.8 times; glargine 5.6 to 7.8 times; lispro 2.7 to 3.7; aspart 2.6 to 3.5†. The comparison covers any presentation, phial, pen or cartridge, while the estimates are for phials only.

Human insulin is already priced close to its production cost. Glargine is priced at between five and eight times its own. The economic problem is in the analogues, not in insulin.

A second and lower estimate exists and is printed beside it: one presentation puts the production cost of insulin at US$1 a vial against up to US$240 in the United States†. The two estimates disagree and neither is resolved here.

The market structure is the binding constraint rather than the manufacturing. Three companies hold over 90 per cent of the global insulin market by value, with some sources putting the figure near 99 per cent. Of 108 countries in scope, only 29 have all WHO-listed insulins registered and 24 have none at all.

---

## 4.8 The dead end

One source must be recorded as dead, because four of this book’s research lines named it as the reference that would settle its weakest data.

The MSH International Medical Products Price Guide no longer exists as a live product. Its own publisher's page states that the last edition is the 2017 edition, and that the publisher itself now describes the data as nine years old. The same page states that the website was retired and would no longer be accessible after 30 June 2024. Free PDF editions covered 1996 to 2015 only. A citation to the guide must therefore be dated 2017 at the latest and labelled as such. It cannot retire this book's price debt.

The UNICEF Supply Catalogue is the working substitute, and it was read on 19 October 2026, so the figures it supplies in this book are current as at October 2026. It is the supplier's own catalogue, it gives indicative prices in US dollars per pack, and it carries material numbers so that any row can be rechecked.

It has one property that governs how its figures are printed here. Its pagination returned different indicative prices for the same material number on different pages. Ferrous sulfate oral solution appeared at 0.71 and at 0.61; folic acid at 5.41 and 5.39; iron 60 mg at 1.43 and 1.60; furosemide injection at 2.05 and 1.84; benzathine benzylpenicillin at 29.49 and 29.12; calcium gluconate at 10.66 and 5.01; thiamine at 1.29, 1.42 and 5.55; ibuprofen 400 mg at 2.23 and 1.43; glucose 50 per cent at 62.90 and 56.00. These are indicative prices refreshed against live tenders, so the spread is real movement rather than transcription error. Where two values were seen, both are given in the entries.

A catalogue that quotes two numbers for one material number is still the best available source. It is not a price list. Its figures are printed in this book as indicative and dated, and never as a price.

# Appendices

# Appendix A — The Register of Contradictions

A reference work inherits the disagreements of its sources. This appendix records them rather than smoothing them, for one practical reason: a book that silently picks one of two published figures passes on a choice its reader cannot see, and a reader who later meets the other figure has no way of knowing it was considered.

The register has three parts. First, the places where a single source contradicts itself. Second, the places where two sources of comparable standing disagree. Third, the places where this book's own research lines disagreed with each other, and how each was settled.

---

## A.1 Where one source contradicts itself

All of these were read off the page in October 2026. They are numbered A1 to A31, and the chapters cross-reference them by those numbers. Both numbers are given with their position on the page. None is an error of transcription by this book.

### World Health Organization fact sheets

**A1 — Malaria.** The share of African deaths in children under five appears as 75 per cent in Key Facts, and as 76 per cent and then 75 per cent in consecutive paragraphs of one section of the body.

**A2 — Malaria, date.** Printed 4 December 2025, with a 2026 copyright line and 2026 linked items.

**A3 — Hepatitis B.** Ten million on treatment against 240 million infected gives 4.2 per cent; the page states 4.3 per cent, with no denominator explained.

**A4 — Hepatitis C.** Key Facts gives about 47 million chronic infections. The body's own regional figures sum to 50 million.

**A5 — Dengue.** Key Facts puts half the world at risk, about four billion. The body gives 5.6 billion.

**A6 — Dengue, date.** Printed 21 August 2025, with a 2026 copyright line and an item dated 11 June 2026.

**A7 — Rabies.** Key Facts asserts flatly that 99 per cent of cases are dog-mediated and that the disease is 100 per cent fatal. The body says "up to 99 per cent" and "virtually 100 per cent". Key Facts also states that 40 per cent of deaths are in children under fifteen, which the body does not support anywhere.

**A8 — Neglected tropical diseases.** The metadata says twenty conditions. The page's own footnote lists twenty-one.

**A9 — Soil-transmitted helminths.** The metadata gives 836 million children needing treatment. The body's own figures sum to about 914 million (260 plus 654). The figure 836 million appears neither in Key Facts nor in the body.

**A10 — Lymphatic filariasis.** The country counts do not reconcile: 81 minus 10 leaves 71 treated, while 39 plus 14 plus 21 gives 74. The overlap is unexplained.

**A11 — Trachoma.** Endemic countries appear as 29 in Key Facts and 32 in the page metadata.

**A12 — Sexually transmitted infections.** Syphilis appears as 8 million for 2022 in Key Facts and 7.1 million for 2020 in the body. Two magnitudes, two years, unreconciled.

**A13 — Cardiovascular diseases.** The share in lower- and middle-income countries is “over three quarters” in Key Facts and “approximately 80 per cent” in the body.

**A14 — Hypertension.** 630 million treated is given as 44 per cent of 1.4 billion, which is 45 per cent. And 44 per cent is assigned to both the unaware group of 600 million and the treated group of 630 million.

**A15 — Cancer.** The infection-attributable share is about 30 per cent of cases in lower- and middle-income countries in Key Facts, and about 10 per cent globally in the body.

**A16 — Suicide.** Key Facts gives over 720,000; the Overview gives 727,000. The depression fact sheet also gives 727,000.

**A17 — Tobacco.** The number of Parties to the Framework Convention appears as 182 plus the European Union in one place and 183 in another.

**A18 — Physical activity.** Adolescent inactivity is 80 per cent in Key Facts and 81 per cent in the body, for ages 11 to 17.

**A19 — Deafness and hearing loss.** The same figure of 700 million is attached to two different metrics: “will require hearing rehabilitation” in Key Facts, and “will have disabling hearing loss” in the body.

**A20 — Musculoskeletal health.** The headline is 1.71 billion. The condition-by-condition figures total about 2.5 billion. Comorbidity is never stated.

**A21 — Osteoarthritis.** The share older than 55 is 73 per cent in Key Facts and 70 per cent in the body.

**A22 — Low back pain.** Key Facts says prevalence rises up to 80 years. The body says it is greatest at 80 to 85.

**A23 — Maternal mortality.** The 40 per cent decline in the maternal mortality ratio is global in Key Facts and sub-Saharan Africa only in the body, with no global figure given against which to check it.

**A24 — Maternal mortality, share.** The share in lower- and middle-income countries is “just over 90 per cent” in one place and “approximately 92 per cent” in another.

**A25 — Newborn mortality.** Key Facts states flatly that midwife-led care makes a preterm birth 24 per cent less likely. The body says “by up to 24 per cent” and only where midwifery programmes function well. Key Facts drops both qualifiers.

**A26 — Stillbirth.** The page text projects 15.9 million stillbirths. An infographic on the same page gives more than 19 million.

**A27 — Congenital disorders.** The share in lower- and middle-income countries is nine in ten, about 90 per cent, in Key Facts, and about 94 per cent in the body.

**A28 — Road traffic injuries.** The share in lower- and middle-income countries is 92 per cent in Key Facts and “more than 90 per cent” in the body.

**A29 — Drowning.** The body says the 2024 status report shows a fall while also describing that report as planned for release in 2024; the page is dated 1 May 2026. The page also carries a printing error in a rate.

**A30 — Violence against women.** The headline prevalence appears as 31.6 per cent with “about one in three”, and as 32 per cent with “nearly one in three”.

**A31 — Violence against women, date.** Key Facts says the estimates were published in 2023. The page’s own reference and its linked news item indicate 2025.

## Two pages that are not fact sheets

The expected fact-sheet addresses for neglected tropical diseases and for stillbirth return navigation shells with no Key Facts and no body. Their figures come from health- topic pages instead, and those pages carry no printed date at all. Any work citing a “WHO fact sheet” for either is citing a document that does not exist.

### In the published literature

**EPIC-Oxford, diverticular disease.** The top-against-bottom fibre fifth appears as hazard ratio 0.59 (0.46 to 0.78) in one place and 0.58 (0.46 to 0.73) in the paper's own results section.

**The clubfoot cost range.** The source paper's abstract and results give figures that do not match each other. The arithmetic closes against the printed range, so the inconsistency is the paper's and not a computational error.

**A 2024 review of emollients for eczema prevention** describes a significant benefit that its own printed confidence interval contradicts, and reports one trial's participant number inconsistently.

**A neonatal sepsis source** renders United States early-onset incidence per 100,000, which is inconsistent by two orders of magnitude with the low-birth-weight figures beside it. It is reported here per 1,000.

---

## A.2 Where two sources of comparable standing disagree

These are printed both ways throughout the book, at both ends, with no winner picked.

| Quantity | One figure | The other |
|---|---|---|
| Maternal deaths, 2023 | 260,000, UN interagency group | 239,900, GBD |
| Total deaths, 2023 | 60.04 million, GBD | about 61 million, WHO |
| Neonatal jaundice deaths | 30,300, GBD | more than 100,000, published series |
| Rabies deaths | 15,800, GBD | about 59,000, WHO |
| Fall DALYs | 38 million, WHO | 74.3 million, GBD |
| Road traffic deaths | 1.16 million, WHO 2026 sheet | 1.47 million, WHO 2024 sheet |
| Liver cancer deaths | 732,000, WHO | 507,700, GBD |
| Stomach cancer deaths | 642,000, WHO | 935,900, GBD |
| COVID-19 rank, 2023 | 20th, 797,600, GBD | 14th, about 0.9 million, WHO |
| Hepatitis B chronic infections | 240 million, 2024 | 254 million, 2022 |
| Adult obesity | 940 million | 890 million |
| Multiple sclerosis | 1.8 million, WHO | 2.8 million, MS Atlas |
| Antimicrobial resistance, 2050 | 10 million deaths, O'Neill | 1.91 million attributable and 8.22 million associated, GBD |
| Cervical cancer cases | 662,301, GLOBOCAN 2022 | 604,196, GLOBOCAN 2024 |
| Preterm births | 13.4 million, text | 15 million, metadata |
| Obstructed labour deaths | 23,000 for 2015; 19,000 for 2013; 12,200 for 2023 — non-monotonic across GBD rounds | |

Four of these are not disagreements about the world but about method or vintage. The cervical cancer pair is a methodological revision between GLOBOCAN releases, not a trend. The hepatitis B pair, the obesity pair and the road traffic pair are different reference years. They are listed here because a reader meeting one figure in one chapter and the other elsewhere is entitled to know which kind of difference it is.

---

## A.3 Where this book's own research lines disagreed

Six disagreements arose inside the preparation of this book. Each was settled by going back to the source, and each is recorded because the settlement changed what the book says.

**Whether GBD 2023 exists.** One line reported that no 2023 release existed and substituted WHO estimates throughout. It does exist: published in *The Lancet* on 12 October 2025 and presented at the World Health Summit in Berlin. The substituted WHO figures were kept, labelled and tagged, and the claim was struck.

**Which edition of the Essential Medicines List governs.** One line used the 23rd, another the 24th. The 24th List, 2025, governs. Every status checked against the 23rd was marked for rechecking rather than carried across.

**Whether a bisphosphonate is listed for osteoporosis.** Two lines asserted that one is. A live check of the electronic list shows alendronate returns nothing and zoledronic acid is listed only as a supportive medicine, for bone metastases and for osteogenesis imperfecta. The assertions were wrong and were corrected.

**Whether permethrin is on the list.** One line asserted it; another doubted its own source. Section 13.5 lists both benzyl benzoate and permethrin. The doubt was struck and the claim kept.

**The 53.1 million figure.** It appears both as hearing-loss years lived with disability and as falls years lived with disability, with different intervals, and was flagged as a suspected transcription error. It is not an error: the two are adjacent rows of one table, ranked fourth and fifth, each 5.4 per cent of all-cause years lived with disability. The flag was withdrawn.

**Whether a published number needed to treat exists for aspirin in secondary prevention.** A figure of about 50 over two years circulated in the preparation. The source paper publishes 6.7 against 8.2 per cent a year and no number needed to treat at all. The figure had no origin. Recomputed from the published rates, it is 67 a year and 33 over two years.

That last one is the reason this appendix exists. The figure was plausible, it was in the right range, and nobody had derived it.

---

## A.4 Where the book contradicted itself

The contradictions above are between sources. These were between two places in this book, and they are the more dangerous kind, because no reader can find them. A reader consults one entry. Only someone reading two chapters side by side would see that they disagree, and nobody reads a reference work that way.

They were found by listing every entry heading in the book and comparing them for near matches. Three conditions turned out to have a complete entry in two different chapters, each written by a different hand from a different dossier.

**A32 — Uterine fibroids, in the neoplasms chapter and in the genitourinary chapter.** The only flat contradiction of the three. One entry labelled myomectomy CURABLE; the other labelled it CONTROLLABLE. Their recurrence figures differed — roughly 15 to 30 per cent within five to ten years against about 15 per cent at five years and 25 to 50 per cent at ten — and the two figures carried different provenance tags, one unreachable and one named. Both entries were internally coherent and both were defensible. Resolved to one entry, in the neoplasms chapter, where ICD-11 codes uterine leiomyoma. Myomectomy is CURABLE of the fibroids it removes, which is how this book labels the excision of a localised tumour everywhere else; new fibroids are new clonal growths and not regrowth, and the entry says so and gives the better-sourced figures. Embolisation, which shrinks rather than removes, is CONTROLLABLE.

**A32a — What the fibroid merge actually found.** The cure-status conflict was visible from outside. Merging the two entries found eight more disagreements that were not. The incidence by age fifty in Black women stood at above 80 per cent in one entry and 80 to 90 per cent in the other, with different tags. The hysterectomy share was a third to 40 per cent in the United States against 30 to 40 per cent across many countries — different scopes presented as the same statistic. Tranexamic acid reduced blood loss by roughly a third in one and by 40 to 50 per cent in the other. The levonorgestrel system gave 80 to 90 per cent in one and 70 to 95 per cent in the other. Neither of those last two figures carried a provenance tag in either entry. The risk that a presumed fibroid is in fact a sarcoma ran to one in 1,000 to one in 2,000 in one entry and to one in 10,000 in the other. All are now printed side by side, with both values and both tags, and the entry says the sources disagree.

The lesson is not about fibroids. Two competent writers, working from two dossiers on one condition, produced nine disagreements, and only one of them was a disagreement about the headline answer. The other eight were in the detail, where nobody was looking.

**A32b — The default tag, denied and restored.** When the two fibroid entries were merged, eight figures in the second carried no tag. The reviewer gave them all the dagger tag, on the

rule that a dossier figure with no tag of its own takes one. That is the book's rule, written in its own conventions, and the reviewer was right.

The coordinating session said otherwise. It searched the house style for the word "default", did not find it — the style states the rule in different words — and told two further reviewers that no default existed and that an untagged figure must be struck. One of them struck twenty-five figures in the digestive, genitourinary and musculoskeletal chapters on that instruction: cure proportions for gallstone surgery, appendicitis treated with antibiotics, osteomyelitis, glomerulonephritis, obstetric fistula repair and others. All are restored with daggers.

Six of the original eight fibroid figures do appear in no dossier at all, and those remain struck. That is the real distinction, and it is worth stating plainly because it is the distinction the whole provenance scheme rests on. A figure sitting untagged in a dossier has a research line behind it that did not record where it came from; it is printed with a dagger, which says exactly that. A figure appearing in no dossier has nothing behind it at all. Nobody consulted anything. It is not published.

**A33 — Allergic rhinitis, in the immune chapter and in the respiratory chapter.** Not a flat contradiction. The respiratory entry carried a CURABLE stratum — avoidance, where a single removable allergen is responsible — that the immune entry did not have at all. One question, two answers, in one book.

**A34 — Erectile dysfunction, in the genitourinary chapter and in the sexual health chapter.** The labels agreed once both were written. The genitourinary entry, however, called a penile prosthesis "a mechanical cure", which this book's own definition does not allow: the native erectile tissue is destroyed and its function substituted, so the deviation remains. It also filed treated hypogonadism under CURABLE although the testosterone must be continued. Both were corrected against the book's own rules.

**A35 — Two figures with no origin at all.** The same genitourinary entry gave 60 to 80 per cent success for first-line drug treatment and 80 to 90 per cent satisfaction with a prosthesis. Neither figure carried a provenance tag, and neither appears in any dossier behind this book. They were not taken from a source and then mis-tagged. They were never taken from anything. They are struck, and the text says in words what is known.

The sexual health chapter, meanwhile, had excused itself from the cure status entirely, on the argument that its categories are not diseases in the sense the rest of the book uses. That argument holds for gender incongruence and fails for a dysfunction with a removable cause — and the book had already refuted it against itself, by giving erectile dysfunction a full cure status in another chapter.

**A36 — Trachoma, in the infectious chapter and in the eye chapter.** Found only after a fault in the checking was corrected: chapter 1 headed its entries one level higher than every other chapter, so an automated comparison of entry titles had been skipping all forty-two of them. The two entries disagree on the answer. The infectious entry splits trachoma three ways — active infection CURABLE, trichiasis corrected by surgery CURABLE, established corneal opacity and blindness RELIEF ONLY. The eye entry says CURABLE, without qualification. For a book whose subject is what can and cannot be cured, that omission is the whole of the matter. Merged into the infectious chapter, where ICD-11 codes it.

**A37 — Scabies, in the same two chapters.** No contradiction; both say CURABLE. Merged for the same reason, with the eye chapter's population-scale data carried over.

# Appendix B — What Is Not Known, and What Was Not Checked

This appendix states the limits of the book. It has two parts: gaps in the measured record itself, and gaps in this book's verification of it.

---

## B.1 Where the measured record is silent

These are not failures of this book. They are absences in the data the world has.

### Conditions with no global burden figure

The Global Burden of Disease study carries no global figure for any of the following, although several affect tens or hundreds of millions of people.

Heart failure as a syndrome, which affects about 64 million. Venous thromboembolism. Aortic aneurysm. Infective endocarditis. Pericarditis. Pulmonary hypertension, affecting about one per cent of the world population. Cardiac arrest. Varicose veins, in 20 to 35 per cent of adults. Arrhythmias other than atrial fibrillation. Bronchiectasis. Chronic rhinosinusitis, in about 10 per cent of adults. Allergic rhinitis, affecting about 400 million. Pleural effusion. Pneumothorax. Acute respiratory distress syndrome. Cystic fibrosis.

And the whole of ICD-11 chapter 07, sleep-wake disorders, has no condition that is a level-three cause in the burden study — including obstructive sleep apnoea, which affects about 936 million adults aged 30 to 69. A chapter of the classification exists for which no burden series exists at all.

ICD-11 chapter 17, conditions related to sexual health, is in the same position, and worse: not one of its categories has a prevalence estimate measured against the ICD-11 definition. Every figure in the literature comes from an earlier classification or a bespoke instrument.

### Figures with no data year

Four WHO fact sheets give their headline figure with no year attached: diarrhoeal disease, falls, epilepsy and kidney disease. The injuries and violence overview states no data year for any of its main statistics.

### Quantities that have never been measured

Overdiagnosis is quantified for breast, prostate, thyroid, lung, melanoma and neuroblastoma. It has never been quantified for gastric, liver, kidney or bladder cancer, for cervical intraepithelial neoplasia, for colonic adenoma, for uterine fibroids, for incidental meningioma, for monoclonal gammopathy or for monoclonal B-cell lymphocytosis — several of which have reservoirs as large or larger.

No trial has ever randomised dietary fibre for diverticular disease, which is why the contradiction between the two best observational findings cannot be resolved.

No trial shows that changing sleep duration changes mortality.

The two-hourly repositioning interval for pressure ulcer prevention has never been established by trial.

The lifetime risk that diverticulosis becomes diverticulitis is given as 10 to 25 per cent in textbooks and 1 to 4 per cent in recent estimates. The tenfold gap is unresolved.

Whether diverticulitis is primarily an infective process at all remains open.

The overlap between the medicines that are in short supply and the medicines a pharmacy could prepare itself is not quantified anywhere in the official record. The Dutch shortage report for 2025 names 1,134 medicines short and 3.5 million people affected, with the cause unknown for 70 per cent. The medicines it names are almost all old, cheap, off-patent and preparable. Pharmacy preparation appears once in that entire report. How much of the shortage the short chain could absorb is therefore unknown, and no published source has asked.

This is the only question raised by the material in Part 4 that has no published answer at all.

---

# B.2 Where this book did not verify

Every numeric claim in this book was checked against a named source while it was compiled, as the front matter describes. This section says what that checking added up to, so the reader can weigh a figure by where it sits.

The honest summary is this: a minority of the figures in this book were read off their source during its preparation. The majority name a source and a year that were not re-opened. A substantial block could not be reached at all.

No single percentage is given for the book as a whole, and that is deliberate. The research lines counted different units — some counted a figure, some a sentence — so any corpus-wide rate would be an invented number, which is the thing this book is trying not to produce.

## What could not be reached, and why

Three classes of source resisted retrieval throughout.

**The GBD Results Tool** is a browser application. It does not render as text, so the per-condition burden table — the single largest outstanding item for this book — could not be queried. The GBD 2023 release notes, the headline totals and the published rankings were obtained; the per-cause detail was not.

**PubMed Central** returns a bot-detection challenge. Several landmark trials could therefore be cited only from repository copies or from their own abstracts.

**The Cochrane Library** returned errors. Six effect sizes that are central to their entries — compression for venous ulcers and antibiotics for acute otitis media among them — rest on secondary reporting as a result, and carry daggers.

The published capstone table of causes of death truncates at the same row on every retrieval route attempted. That is a property of the table, not of any one host, and it is why the death counts for cardiovascular, respiratory, digestive, neurological and injury causes in this book come from WHO estimates rather than from the burden study.

## A source that no longer exists

Four of this book’s research lines independently named the MSH International Medical Products Price Guide as the source that would settle its weakest class of figure. It has not been updated since 2017, and its site was retired after 30 June 2024.

The working substitute is the UNICEF Supply Catalogue, which returns different indicative prices for the same material number on different pages. Its figures therefore appear in this book as indicative and dated, never as a price.

### Figures that were removed rather than published

A number of drug prices in the preparation of this book were order-of-magnitude estimates for which no source had ever been consulted. They are not in the published text. Each was either replaced by a sourced figure or struck and written in words.

A reference work may say it does not know a price. It may not print a number it invented and let the reader take it for a measurement.

---

## B.3 The outstanding list

For a later edition, or for anyone who wishes to close these, the following would settle the largest number of figures that carry daggers, in this order.

1. The GBD 2023 Results Tool, for per-condition deaths, DALYs, years lived with disability, prevalence and incidence. It would retire more daggers than any other single source, and it would also settle the injury block and several of the disagreements in Appendix A.2.
2. One reachable international drug price source. Prices are the weakest data class in four of this book’s chapters.
3. The Essential Medicines List statuses in the blood, immune and metabolic chapter, rechecked against the 24th List. They were originally checked against the 23rd.
4. The Cochrane reviews named above, for the six effect sizes that currently rest on secondary reporting.
5. The ICD-11 simple tabulation, for the per-chapter category counts. The counts in this book are of code blocks, which are a coarser unit.

# Appendix C — How This Book Was Checked, and What That Found

A reference work is only as good as its weakest unchecked number. This appendix records what checking was done, what it found, and what it did not reach. It is here so that a reader can weigh the book by its method rather than by its confidence.

---

## C.1 The method

The book was written from research dossiers, and the dossiers were written from sources. Three separate passes then ran over the result, each by a reader who had not produced what it was reading.

The first pass read the dossiers and reported defects without fixing them. The second applied the decisions that pass produced. The third read the finished chapters against both the dossiers and the decisions.

That separation is the whole of the method, and it rests on one observation: a writer checking their own work finds a fraction of what a separate reader finds. Every round of this book confirmed it.

The reviewers were allowed to correct only what has exactly one possible answer — arithmetic, a figure that does not match its own source, a provenance tag set higher than its source supports, a classification contradicting a live check, a word used outside the scheme the book defines. Everything requiring a judgement was referred back rather than resolved, on the principle that a reviewer who resolves a judgement becomes the author of that resolution, and then nobody has checked it.

---

## C.2 What the checking found

The totals, across the nine chapters and the four parts:

| | |
|---|---|
| Corrections recorded, all four rounds | 3,388 |
| of which provenance tags set too high, in the third round | about 1,480 |
| Cure-status labels using a word outside the four | 29 |
| Compound prevention grades, resolved to the lower | 239 |
| Items referred for a decision | over 170 |
| Passages removed or generalised on safety grounds | 10 |

Every one of those corrections is in *The Review Record*, the companion to this book, with the wording it replaced.

The dominant finding is the first one, and it is worth stating plainly: **the book systematically presented itself as better sourced than it was.** Not in one chapter, not by one writer, but

everywhere, by every hand that worked on it, in the same direction. Figures acquired a higher provenance tag than their sources supported, and no individual step in that drift was large.

Correcting it changed the book's shape. In one chapter the share of figures marked as unreachable rose from 74 to 77 per cent; in another the count of figures carrying a named but unread source fell from 566 to 144, with 461 moving down to the lowest tag. Nothing was discovered to be false by this. What was discovered is that the book did not know what it knew.

---

## C.3 Six findings worth their own sentence

**An invented number.** A number needed to treat for aspirin in secondary prevention circulated through the preparation at a plausible value, in the right range, with a correct citation attached. The cited paper publishes two event rates and no number needed to treat at all. The figure had no origin. Recomputed from the published rates it is 67 a year and 33 over two years.

**A ruling that was wrong.** One figure appearing twice with different uncertainty intervals was flagged as a transcription error and ordered corrected. It was not an error: the two are adjacent rows of one table, correctly quoted, each 5.4 per cent of the same denominator. The order was withdrawn.

**A compliance figure measuring the wrong rule.** A review reported that 30 per cent of entries complied with the cure-status format. It had measured against a rule that had already been superseded. Against the rule actually in force, compliance was 84.5 per cent and the defect count was 57 rather than 250.

**Two prices that looked like a contradiction and were not.** Tamoxifen at US$80 to 250 for five years, and the same entry's per-tablet price implying US$785 to 1,241. Both are correct: one is a generic international price, the other high-income retail. The defect was that neither named its market. The book now requires every price to name its market and its year, or to be written in words.

**A source that no longer exists.** Four research lines independently named one international price guide as the source that would settle the book's weakest data. It has not been updated since 2017 and was retired in 2024.

**Entries written to close a gap.** Three entries were written by the coordinating session itself, quickly, after a writer stopped mid-chapter. The review found in them the same defects it found elsewhere: tags above their sources, a grade of STRONG resting on a trial the entry itself said it could not open, a claim that sources disagreed where only one range was ever given, and a procedural instruction written into a section meant for household measures. Writing an entry oneself is no protection at all.

---

## C.4 What the checking did not reach

Three classes of source resisted retrieval throughout, and they are the reason this book carries as many unreachable figures as it does.

The burden-of-disease results tool is a browser application and does not render as text, so the per-condition table — the single largest outstanding item — could not be queried. A major article repository returns a bot-detection challenge. A major review library returned errors, which is why six effect sizes central to their entries rest on secondary reporting.

One block was recorded here as unresolved, and the record was wrong. About ninety figures in the circulatory and respiratory chapter were said to carry the highest provenance tag while appearing in none of the verification files, and to need their sources re-read. They were checked again at the end of the fourth round. Of the 110 figures in that chapter carrying the

highest tag, 24 are indeed absent from the two verification files — but all of them stand in the chapter's own research dossier, and that dossier records a verified read for every one.

The earlier count came from comparing the chapter against the wrong corpus: the two verification files, which hold the retrieval work, rather than the dossier the chapter was written from. Nothing was wrong with the figures. The check was wrong, and it is left described here rather than quietly deleted, because a reader weighing this book should see that its own accounting needed correcting twice.

Appendix B lists what would close these, in the order that would retire the most.

---

## C.5 The fourth round, and what it cost to get right

A fourth pass ran after the three described above. It was not planned. It happened because the third pass left twenty-four questions its readers could not settle, and because settling them turned up errors the earlier passes had introduced.

**An over-correction, reversed.** The book requires every price to name its market and its year, or to be written in words. Applied strictly, that rule converted 1,261 prices from digits into words in a single pass. That was too much. A price whose market and year stand in the same paragraph is properly sourced, even if they are not repeated in the same clause. A source that gives a market but no year gives a usable price. Both cases had been swept up. The rule was rewritten in three parts, and each converted price was read again against the dossier it came from.

What that re-reading found is worth stating plainly, because it is a fact about this book rather than about the rule. Many of those prices could not be restored. In the circulatory and respiratory chapters, 462 of 489 stayed in words, because the dossier behind them gives only order-of-magnitude bands drawn across three different reference classes that differ by factors of three to fifty. There is no single market behind such a figure. Printing digits would have claimed a precision the source never had.

**A mark that was disappearing.** Assembling the book revealed a fault in the assembly itself. The source text is hard-wrapped. Where a provenance mark happened to fall at the start of a new line, the tool that moved those marks could not see the sentence they belonged to, and dropped them. 541 unconfirmed figures would have reached the page looking confirmed. The marks are counted now: 2,361 of them, against 6,352 figures read off a named source.

**A chapter that had excused itself.** The chapter on conditions related to sexual health carried a note explaining that the cure status was not applied to any of its entries, because its categories are not diseases in the sense the rest of the book uses. The argument holds for gender incongruence and does not hold for a dysfunction with a removable cause — and the book proved as much against itself, because erectile dysfunction carries a full cure status in another chapter. Eight entries were written. Two of them say the label does not apply, and say why. The blanket exemption was withdrawn.

**Three conditions entered twice.** Uterine fibroids, allergic rhinitis and erectile dysfunction each had a complete entry in two different chapters, written by different hands from different dossiers. The fibroid entries disagreed: one called myomectomy curable, the other controllable, and their recurrence figures differed and carried different marks. No reader comparing two chapters would have found that, and no reader reading one chapter would have known to look. Each condition now has one entry and one answer.

**Every figure made to carry its provenance.** The book states that each numeric claim carries exactly one provenance mark. At the end of the fourth round that was measured rather than assumed, and 382 figures carried none. Each was looked up in the dossier its chapter was written from and given the mark its source supports. Two hundred and forty-one were marked; the rest proved to be covered already by a mark at the end of their list or table, or were restatements of a figure marked elsewhere in the same entry, or were thresholds and definitions rather than findings. Not one had to be struck: every figure was traceable to a research line.

What this did not reach: figures written out in words — “one in seven”, “a third”, “twentyfold” — were not swept, because the sweep looked for numerals. They are a small minority and they carry no false precision, but the gap is real and is recorded here rather than left for a reader to find.

**A check that was blind, and what it was hiding.** The duplicate entries above were found by listing every entry heading in the book and comparing them. That list was incomplete, and nobody noticed, because chapter 1 headed its forty-two entries one level higher than every other chapter. The comparison looked for one heading level and silently skipped the whole of the infectious diseases — the largest chapter in the book and the one most likely to share conditions with the chapters on the eye and the skin.

The entries themselves were sound: all forty-two carried the eight sections. The fault was in the checking, not the content. But correcting it immediately produced two more duplicate conditions, trachoma and scabies, and trachoma turned out to be one of the disagreements that matters — one entry splitting it three ways and reserving RELIEF ONLY for established blindness, the other saying simply CURABLE.

That is the shape of this whole round. Each time a check was found to be blind in some respect, correcting it turned up something real. A reader has no way to audit the checking, only the result, which is why the blind spots are recorded here alongside what they hid.

**A rule corrected against itself.** One ruling written during this round — that a vague quantifier may never be replaced by a figure — was tested against the whole book before being applied. It would have destroyed thirty-four properly sourced numbers. The rule was wrong as written and was rewritten before it did any damage. The point of testing a rule against the text before enforcing it is exactly this.

---

## C.6 What a reader should do with this

Read the daggers. They are there for exactly this reason.

A figure without a dagger rests on a named source. Some of those sources were opened during the preparation of this book and some were named but not opened again, which is ordinary for a reference work. A figure with a dagger is reported as commonly carried, and its source could not be opened at all. The distinction is not between true and false. It is between checked and taken on report, and a reader is entitled to know which is which.

No figure in this book is published as a bare number that someone invented. Where a value had no source, it was removed and the text says in words what is known without it.

That is the standard this book holds itself to, and this appendix exists so the reader can check whether it was met.
